Handbook of Neurosurgery

Mark S. Greenberg, MD
Associate Professor
Department of Neurosurgery and Brain Repair
University of South Florida
Tampa, Florida

Eighth Edition

179 illustrations
Dedication

The eighth edition of the Handbook of Neurosurgery is dedicated to my wonderful wife, Debbie. She inspires me to be the best I can be.

This book is also dedicated to “Duke” (August Henry Wagner III), beloved uncle of contributor Jayson Sack, who suffered a fatal aneurysmal subarachnoid hemorrhage as this book was going to press. His selfless life was an inspiration to Jayson and his family. He will be missed and never forgotten.
Contributors

Naomi A. Abel, MD
Assistant Professor
Department of Neurosurgery and Brain Repair
University of South Florida Morsani College of Medicine
Tampa, Florida
Failure of carpal tunnel and ulnar nerve surgery
Electrodiagnostics (EDX)

Siviero Agazzi, MD, MBA
Associate Professor
Department of Neurosurgery and Brain Repair
University of South Florida Morsani College of Medicine
Tampa, Florida
Vestibular schwannomas

Amir Ahmadian, MD
Attending physician
Neurosurgery of West Florida
Hudson, Florida
Adult spinal deformity

*Originally contributed to the Handbook of Neurosurgery, seventh edition
Preface

Shortly after finishing my residency training in 1989, in a time long before the internet, I wrote the first edition of the Handbook of Neurosurgery with the intent to make practical, actionable neurological information accessible at the fingertips of the practitioner.

Over the years, I used desktop publishing technology to expand the scope of the book, and to incorporate diagrams and literature references. I always wanted to make the book “academic” by presenting data that backed up the assertions. My goal was to never publish a cookbook.

Without advertising, I relied solely on word-of-mouth to promote the book. I believed in the same thing that Edwin Land must have when he said, “Marketing is what you do when your product is no good.” I had a test run of 600 copies of the book printed at a small vanity press in Ann Arbor, and sold copies to individuals by mail. My big break came when the medical bookstore at the State University of New York in Syracuse purchased 6 copies to put on their shelves. After that, I regularly packaged 5 or 6 books in a box destined for various bookstores and dropped them off at the loading dock on my way to the O.R. in the morning. After a time, the major medical book distributors in the country began ordering cases of books and my garage became a shipping department. (I still have the pallet jack that I used to unload the delivery trucks.) Then, somehow, international orders began to arrive.

I was finally able to get out of the packing and transporting business when I partnered with Thieme Medical Publishers in 2001. At that time the internet was just becoming “a thing,” and while it was a great way to make connections, the information explosion was still to come. The goal of the book regardless was still the same—to make useful information readily available.

By the time the 6th edition was published in 2006, the process I used to produce the book was becoming more difficult. The page layout software that had been my workhorse for over 10 years was no longer supported, and the developers of the reference manager I utilized had changed their focus and the product was now compatible primarily with word processors (which were poorly suited for complex multi-chapter books like this one). As a result, I was forced to use an obsolete PowerPC computer and had to hack the chapter files in order to trick the reference manager to work with them! After the 7th edition was completed, I could see no way forward with this approach. I never imagined that desktop publishing was going to atrophy and fall victim to the same fate that would later come to claim print newspapers. With the availability of the world wide web, the internet was quickly becoming the chief means of accessing information on demand.

The birth of this 8th edition of the handbook that you are now reading was a particularly difficult one. Thanks to the people at Thieme, the material was painstakingly converted from the defunct software platform to a contemporary format that will facilitate continued updates and availability in digital media. This time-consuming and labor-intensive process included porting thousands of cross references, index entries, and literature citations.

Interestingly, the objectives of the handbook have also gone through a transformation. It is challenging to distill what all of those objectives are, but I believe that it is important to present material in a framework that can serve as a foundation for studying the field of neurosurgery. This book is intended to be a place that brings together the important information that is increasingly scattered across the literature and the web (for instance, practice guidelines for disparate subjects like spinal cord injury, stroke, aneurysms…) that might not necessarily be encountered unless one is actively seeking it out.

My goal with the book has always been to present information succinctly and clearly. To that end, this edition is a completely restructured version of the Handbook of Neurosurgery, presenting the entire content in a collection of more than 100 well-ordered chapters of comparable length and format while retaining the wealth of crosslinks and references the book is known for. This new organization was designed to make the content more easily digestible and accessible — for both browsing the print book and navigating any electronic version.

With its new structure and format, as well as revised and updated content, I hope I have provided readers with an even more valuable resource in this 8th edition of the Handbook of Neurosurgery.
Acknowledgments

I would like to thank all of those who participated in the preparation of this edition. Thanks to the many contributors who helped with the material, and the people known and not known to me at Thieme Medical Publishers. To Brian Scanlan, President of Thieme Medical Publishers, for making the resources available to save the book from disappearing entirely. To Sarah Landis and Torsten Scheihagen for their editorial help. And the deepest debt of gratitude to Dr. Michael Wachinger, Thieme’s Director of Clinical Solutions, who personally spent countless hours and a number of transatlantic trips, guiding the restructuring of the information into a more accessible and logical framework, and ensuring that the content was preserved in the software transfer.

Thanks also to my colleagues and the residents in the neurosurgery program at the University of South Florida from whom I learn every day. Special thanks to our chairman, Dr. Harry van Loveren, for his advice, calm leadership and for inspiring excellence in neurosurgery.
### Abbreviations and Symbols

Abbreviations used only locally are defined in that section using boldface type. Numbers following entries below indicate the page number for the relevant section.

**Symbols**

- Prescribing information
- Causes or leads to
- Change
- Check (e.g. lab or exam item to check)
- Increased
- Decreased
- Approximately
- INNERVATES (nerve distribution)
- Vascular supply
- A branch of the preceding nerve
- Crucial point
- Caution; possible danger; negative factor...
- Summary
- Therefore

**Instrumentation:** the following shorthand allows rapid identification of metrics for spinal instrumentation:

- **ENTRY** screw entry site
- **TRAJ** screw trajectory
- **TARGET** object to aim for
- **SCREWS** typical screw specifications
Conventions

Box types. The Handbook of Neurosurgery uses the following seven box types:

- **Drug info**
  - Drug description & dosage.

- **Key concepts**
  - Foundational knowledge in brief.

- **Practice guideline**
  - Evidence-based guidelines. See below (in this section) for definitions. For a listing of evidence-based guidelines contained in this book, see the index under “Practice guideline.”

- **Booking the case**
  - These sections appear under certain specific operations to help when scheduling that surgery. Default information appears below (in this section), for example, a specific type of anesthesia will only be mentioned if something other than general anesthesia is typically used. A list of operations addressed by this means can be found in the index under “Booking the case.”

- **∑**
  - Summarizing or synthesizing information from the associated text.

- **Side information**
  - E.g., Greenberg IMHO.

- **Signs / symptoms**
  - A description of signs and symptoms.

Cross references. Cross references: the terms “see below” and “see above” are normally used when the referenced item is on the same page, or at most on the following (or preceding) page. When further excursions are needed, the page number will usually be included.

Default values. These details are not repeated in each section or “Booking the case” box.

1. position: (depends on the operation)
2. pre-op:
   a) NPO after midnight the night before except meds with sips of water
   b) antithrombotics: discontinue Coumadin® ≥ 3 days prior to surgery, Plavix® 5–7 d pre-op, aspirin 7–10 d pre-op, other NSAIDs 5 d pre-op
3. cardiology/medical clearance as needed
4. anesthesia: default = general anesthesia, unless otherwise specified
5. equipment: special devices such as ultrasonic aspirator, image guidance...
6. instrumentation: standard surgical instrument trays for a specific operation are assumed. Special instrumentation resident in the hospital will be listed
7. implants: this usually requires scheduling with a vendor (manufacturers representative/distributor) to provide
8. neuromonitoring will be listed if typically used
9. post-op: default care is on the ward (ICU is typically needed after craniotomy)
10. blood availability: specified if recommended
11. consent (these items use lay terms for the patient – not all-inclusive):

Disclaimers: informed consent for surgery requires disclosure of risks and benefits that would substantively affect a normal person’s decision to have the operation. It cannot and should not attempt to include every possibility. The items listed in this section are included as memory joggers for some items for various procedures, but are not meant to be all inclusive. The omission of information from this memory aid is not to be construed as implying that the omitted item is not important or should not be mentioned.

a) procedure: the typical operation and some possible common contingencies
b) alternatives: non-surgical (AKA “conservative”) treatment is almost always an option
c) complications:

- risks of general anesthesia include: heart attack, stroke, pneumonia
- infection: a risk with any invasive procedure
- usual craniotomy complications include: bleeding intra-op and postop, seizure, stroke, coma, death, hydrocephalus, meningitis, and neurologic deficit related to the area of surgery including (for applicable locations): paralysis, language or sensory disturbances, coordination impairment...
- usual spine surgery complications include: injury to nerve or spinal cord with possible numbness, weakness or paralysis, failure of the operation to achieve the desired result, dural opening which may cause a CSF leak which occasionally needs to be surgical repair. Hardware complications (when used) include: breakage, pull-out, malposition. Although a rare complication, it is serious enough that it bears mentioning in cases positioned prone with possible significant blood loss (>2 L): blindness (due to PION (p.1056))

Evidence-Based Medicine: Definitions. These definitions are referred to in the “Practice guideline” boxes.

Anatomy and Physiology

1 Gross Anatomy, Cranial and Spine 58
2 Vascular Anatomy 75
3 Neurophysiology and Regional Brain Syndromes 90
1 Gross Anatomy, Cranial and Spine

1.1 Cortical surface anatomy

1.1.1 Lateral cortical surface

Fig. 1.1. For abbreviations, see Table 1.1 and Table 1.2. The middle frontal gyrus (MFG) is usually more sinuous than the IFG or SFG, and it often connects to the pre-central gyrus via a thin isthmus. The central sulcus joins the Sylvian fissure in only 2% of cases (i.e., in 98% of cases there is a “subcentral” gyrus). The intraparietal sulcus (ips) separates the superior and inferior parietal lobules. The IPL is composed primarily of the AG and SMG. The Sylvian fissure terminates in the SMG (Brodmann’s area 40). The superior temporal sulcus terminates in the AG.

1.1.2 Brodmann’s areas

Fig. 1.1 also identifies the clinically significant areas of Brodmann’s (Br.) map of the cytoarchitectonic fields of the human brain. Functional significance of these areas is as follows:

1. Br. areas 3, 1, 2: primary somatosensory cortex
2. Br. areas 41 & 42: primary auditory areas (transverse gyri of Heschl)
3. Br. area 4: precentral gyrus, primary motor cortex (AKA “motor strip”). Large concentration of giant pyramidal cells of Betz
4. Br. area 6: premotor area or supplemental motor area.Immediately anterior to motor strip, it plays a role in contralateral motor programming
5. Br. area 44: (dominant hemisphere) Broca’s area (motor speech)
6. Br. area 17: primary visual cortex

---

Fig. 1.1 Left lateral cerebral cortical surface anatomy.
Br. = Brodmann’s area (shaded). See Table 1.1 and Table 1.2 for abbreviations (lowercase = sulci, UPPERCASE = gyri).

7. Wernicke’s area (language): in the dominant hemisphere, most of Br. area 40 and a portion of Br. area 39 (may also include \(\approx\) posterior third of STG).

8. the striped portion of Br. area 8 in Fig. 1.1 (frontal eye field) initiates voluntary eye movements to the opposite direction.

Brodmann’s area 44, Wernicke’s area: Language function cannot be reliably localized on anatomic grounds due to individual variability in its exact location; in order to perform maximal brain resections with minimal risk of aphasia, techniques such as intra-operative brain mapping\(^2\) or looking for phase reversal on intraoperative cortical SSEP\(^3\) should be employed.

1.1.3 Medial surface

Fig. 1.2. The cingulate sulcus terminates posteriorly in the pars marginalis (pM) (plural: partes marginales). On axial imaging, the pMs are visible on 95\% of CTs and 91\% of MRIs.\(^4\) are usually the most prominent of the paired grooves straddling the midline, and they extend a greater distance into the hemispheres.\(^5\) On axial CT, the pM is located slightly posterior to the widest biparietal diameter;\(^4\) on the typically more horizontally oriented MRI slices the pM assumes a more posterior position.

The pMs curve posteriorly in lower slices and anteriorly in higher slices (here, the paired pMs form the “pars bracket” – a characteristic “handlebar” configuration straddling the midline).

1.2 Central sulcus on axial imaging

See Fig. 1.3. Identification of the central sulcus is important to localize the motor strip (contained in the PreCG). The central sulcus (CS) is visible on 93\% of CTs and 100\% of MRIs.\(^4\) It curves posteriorly as it approaches the interhemispheric fissure (IHF), and often terminates in the paracentral lobule, just anterior to the pars marginalis (pM) within the pars bracket (see above)\(^4\) (i.e. the CS often does not reach the midline).
Pointers:
- parieto-occipital sulcus (pos) (or fissure): more prominent over the medial surface, and on axial imaging is longer, more complex, and more posterior than the pars marginalis.
- post-central sulcus (pocs): usually bifurcates and forms an arc or parenthesis (“lazy-Y”) cupping the pM. The anterior limb does not enter the pM-bracket and the posterior limb curves behind the pM to enter the IHF.

Hand “Knob”: The alpha motor neurons for hand motor function are located in the superior aspect of the prefrontal gyrus. On axial imaging, this appears as a knob-like protrusion (shaped like an inverted greek letter omega Ω) of the precentral gyrus projecting posterolaterally into the central sulcus.

1.3 Surface anatomy of the cranium

1.3.1 Craniometric points

See Fig. 1.4.

- Pterion: region where the following bones are approximated: frontal, parietal, temporal and sphenoid (greater wing). Estimated as 2 finger-breadths above the zygomatic arch, and a thumb’s breadth behind the frontal process of the zygomatic bone (blue circle in Fig. 1.4).
- Asteion: junction of lambdoid, occipitomastoid and parietomastoid sutures. Usually lies within a few millimeters of the posterior-inferior edge of the junction of the posterior and sigmoid sinuses (not always reliable – may overlie either sinus).
- Vertex: the topmost point of the skull.
- Lambda: junction of the lambdoid and sagittal sutures.
- Stephanion: junction of coronal suture and superior temporal line.
- Glabella: the most forward projecting point of the forehead at the level of the supraorbital ridge in the midline.
- Opisthion: the posterior margin of the foramen magnum in the midline.
- Bregma: the junction of the coronal and sagittal sutures.
- Sagittal suture: midline suture from coronal suture to lambdoid suture. Although often assumed to overlie the superior sagittal sinus (SSS), the SSS lies to the right of the sagittal suture in the majority of specimens (but never by >11 mm).

The most anterior mastoid point lies just in front of the sigmoid sinus.

1.3.2 Relation of skull markings to cerebral anatomy – Taylor-Haughton lines

Taylor-Haughton (T-H) lines can be constructed on an angiogram, CT scout film, or skull x-ray, and can then be reconstructed on the patient in the O.R. based on visible external landmarks. T-H lines are shown as dashed lines in Fig. 1.5.
1. Frankfurt plane, AKA baseline: line from inferior margin of orbit through the upper margin of the external auditory meatus (EAM) (as distinguished from Reid’s base line: from inferior orbital margin through the center of the EAM)\(^6\)\(^{12}\)(p 313)

2. the distance from the nasion to the inion is measured across the top of the calvaria and is divided into quarters (can be done simply with a piece of tape which is then folded in half twice)

3. posterior ear line: perpendicular to the baseline through the mastoid process

4. condylar line: perpendicular to the baseline through the mandibular condyle

5. T-H lines can then be used to approximate the sylvian fissure (see below) and the motor cortex (also see below)

**Sylvian fissure** AKA lateral fissure

Approximated by a line connecting the lateral canthus to the point 3/4 of the way posterior along the arc running over convexity from nasion to inion (T-H lines).

**Angular gyrus**

Located just above the pinna, important on the dominant hemisphere as part of Wernicke’s area. Note: there is significant individual variability in the location.\(^2\)
Angular artery
Located 6 cm above the EAM.

Motor cortex
Numerous methods utilize external landmarks to locate the motor strip (pre-central gyrus) or the central sulcus (Rolandic fissure) which separates motor strip anteriorly from primary sensory cortex posteriorly. These are just approximations since individual variability causes the motor strip to lie anywhere from 4 to 5.4 cm behind the coronal suture. The central sulcus cannot even be reliably identified visually at surgery.

1. method 1: the superior aspect of the motor cortex is almost straight up from the EAM near the midline
2. method 2: the central sulcus is approximated by connecting:
   a) the point 2 cm posterior to the midposition of the arc extending from nasion to inion (illustrated in Fig. 1.5), to
   b) the point 5 cm straight up from the EAM
3. method 3: using T-H lines, the central sulcus is approximated by connecting:
   a) the point where the “posterior ear line” intersects the circumference of the skull (Fig. 1.5; usually about 1 cm behind the vertex, and 3–4 cm behind the coronal suture), to
   b) the point where the “condylar line” intersects the line representing the sylvian fissure

4. method 4: a line drawn 45° to Reid’s base line starting at the pterion points in the direction of the motor strip

1.3.3 Relationship of ventricles to skull

Fig. 1.6 shows the relationship of non-hydrocephalic ventricles to the skull in the lateral view. Some dimensions of interest are shown in Table 1.3.17

In the non-hydrocephalic adult, the lateral ventricles lie 4–5 cm below the outer skull surface. The center of the body of the lateral ventricle sits in the midpupillary line, and the frontal horn is intersected by a line passing perpendicular to the calvaria along this line.18 The anterior horns extend 1–2 cm anterior to the coronal suture.

Average length of third ventricle ≈ 2.8 cm.
The midpoint of Twining’s line (in Fig. 1.6) should lie within the 4th ventricle.
1.4 Surface landmarks of spine levels

Estimates of cervical levels for anterior cervical spine surgery may be made using the landmarks shown in Table 1.4. Intra-operative C-spine x-rays are essential to verify these estimates.

The scapular spine is located at about T2–3.

The inferior scapular pole is ≈ T6 posteriorly.

Intercristal line: a line drawn between the highest point of the iliac crests across the back will cross the midline either at the interspace between the L4 and L5 spinous processes, or at the L4 spinous process itself.

1.5.2 Porus acusticus

AKA internal auditory canal (Fig. 1.7)

The filaments of the acoustic portion of VIII penetrate tiny openings of the lamina cribrosa of the cochlear area.\(^2^0\)

Transverse crest: separates superior vestibular area and facial canal (above) from the inferior vestibular area and cochlear area (below).\(^2^0\)

Vertical crest (AKA Bill’s bar – named after Dr. William House): separates the meatus to the facial canal anteriorly (containing VII and nervus intermedius) from the vestibular area posteriorly (containing the superior division of vestibular nerve). Bill’s bar is deeper in the IAC than the transverse crest.

The “5 nerves” of the IAC:

1. facial nerve (VII) (mnemonic: “7-up” as VII is in superior portion)
2. nervus intermedius: the somatic sensory branch of the facial nerve primarily innervating mechanoreceptors of the hair follicles on the inner surface of the pinna and deep mechanoreceptors of nasal and buccal cavities and chemoreceptors in the taste buds on the anterior 2/3 of the tongue
3. acoustic portion of the VIII nerve (mnemonic: “Coke down” for cochlear portion)
4. superior branch of vestibular nerve: passes through the superior vestibular area to terminate in the utricle and in the ampulla of the superior and lateral semicircular canals (mnemonic superior = LSU (Lateral & Superior semicircular canals and the Utricule))
5. inferior branch of vestibular nerve: passes through inferior vestibular area to terminate in the saccule

1.6 Internal capsule

1.6.1 Architectural anatomy

For a schematic diagram, Fig. 1.8; Table 1.6 delineates the thalamic subradiations. Most IC lesions are caused by vascular accidents (thrombosis or hemorrhage).

1.6.2 Vascular supply of the internal capsule (IC)

1. anterior choroidal: all of retrolenticular part (includes optic radiation) and ventral part of posterior limb of IC
2. lateral striate branches (AKA capsular branches) of middle cerebral artery: most of anterior AND posterior limbs of IC
3. genu usually receives some direct branches of the internal carotid artery

1.7 Cerebellopontine angle anatomy

For normal anatomy of right cerebellopontine angle, see Fig. 1.9.
1.8 Occipitoatlantoaxial-complex anatomy

Ligaments of the occipitoatlantoaxial complex. Stability of the occipitoatlantal joint is primarily due to ligaments, with little contribution from bony articulations and joint capsules (see Fig. 1.10, Fig. 1.11, Fig. 1.12):

1. Ligaments that connect the atlas to the occiput:
   a) anterior atlanto-occipital membrane: cephalad extension of the anterior longitudinal ligament. Extends from anterior margin of foramen magnum (FM) to anterior arch of C1

**Fig. 1.12 Normal anatomy of right cerebellopontine angle viewed from behind (as in a suboccipital approach)**
Fig. 1.10 Sagittal view of the ligaments of the craniovertebral junction. (Modified with permission from “In Vitro Cervical Spine Biomechanical Testing” BNI Quarterly, Vol.9, No. 4, 1993)

Fig. 1.11 Dorsal view of the cruciate and alar ligaments. Viewed with tectorial membrane removed. (Modified with permission from “In Vitro Cervical Spine Biomechanical Testing” BNI Quarterly, Vol.9, No. 4, 1993)
b) posterior atlanto-occipital membrane: connects the posterior margin of the FM to posterior arch of C1

c) the ascending band of the cruciate ligament

2. ligaments that connect the axis (viz. the odontoid) to the occiput:
   a) tectorial membrane: some authors distinguish 2 components
      - superficial component: cephalad continuation of the posterior longitudinal ligament. A strong band connecting the dorsal surface of the dens to the ventral surface of the FM above, and dorsal surface of C2 & C3 bodies below
      - accessory (deep) portion: located laterally, connects C2 to occipital condyles
   b) alar (“check”) ligaments
      - occipito-alar portion: connects side of the dens to occipital condyle
      - atlanto-alar portion: connects side of the dens to the lateral mass of C1
   c) apical odontoid ligament: connects tip of dens to the FM. Little mechanical strength

3. ligaments that connect the axis to the atlas:
   a) transverse (atlantoaxial) ligament: the horizontal component of the cruciate ligament. Traps the dens against the anterior atlas via a strap-like mechanism (Fig. 1.12). Provides the majority of the strength (“the strongest ligament of the spine”)
   b) atlanto-alar portion of the alar ligaments (see above)
   c) descending band of the cruciate ligament

The most important structures in maintaining atlanto-occipital stability are the tectorial membrane and the alar ligaments. Without these, the remaining cruciate ligament and apical dentate ligament are insufficient.

1.9 Spinal cord anatomy

1.9.1 Dentate Ligament

The dentate ligament separates dorsal from ventral nerve roots in the spinal nerves. The spinal accessory nerve (Cr. N. XI) is dorsal to the dentate ligament.

1.9.2 Spinal cord tracts

Anatomy

Fig. 1.13 depicts a cross-section of a typical spinal cord segment, combining some elements from different levels (e.g. the intermediolateral grey nucleus is only present from T1 to ≈ L1 or L2 where there are sympathetic (thoracolumbar outflow) nuclei). It is schematically divided into ascending and descending halves, however, in actuality, ascending and descending paths coexist on both sides.

Fig. 1.13 also depicts some of the laminae according to the scheme of Rexed. Lamina II is equivalent to the substantia gelatinosa. Laminae III and IV are the nucleus proprius. Lamina VI is located in the base of the posterior horn.
Fig. 1.13 Schematic cross-section of cervical spinal cord. See Table 1.7, Table 1.8 and Table 1.9 for path names.

*The terminal fibers of this uncrossed tract usually cross in the anterior white commissure to synapse on alpha motor neurons or on internuncial neurons. It is true that some of these fibers do stay on the same side, but it is felt to be a minority. Also, the anterior corticospinal tract is easily identified only in the cervical and upper thoracic regions.
### Sensation

#### Pain and temperature: body
Receptors: free nerve endings (probable).
1st order neuron: small, finely myelinated afferents; soma in dorsal root ganglion (no synapse). Enter cord at dorsolateral tract (zone of Lissauer). Synapse: substantia gelatinosa (Rexed II).
2nd order neuron axon cross obliquely in the anterior white commissure ascending \(\approx 1-3\) segments while crossing to enter the lateral spinothalamic tract.
Synapse: VPL thalamus. 3rd order neurons pass through IC to postcentral gyrus (Brodman’s areas 3, 1, 2).

#### Fine touch, deep pressure and proprioception: body
Fine touch AKA discriminative touch. Receptors: Meissner’s & pacinian corpuscles, Merkel’s disks, free nerve endings.
1st order neuron: heavily myelinated afferents; soma in dorsal root ganglion (no synapse). Short branches synapse in nucleus proprius (Rexed III & IV) of posterior gray; long fibers enter the ipsilateral posterior columns without synapsing (below T6: fasciculus gracilis; above T6: fasciculus cuneatus).
Synapse: nucleus gracilis/cuneatus (respectively), just above pyramidal decussation. 2nd order neuron axons form internal arcuate fibers, decussate in lower medulla as medial lemniscus.
Synapse: VPL thalamus. 3rd order neurons pass through IC primarily to postcentral gyrus.

#### Light (crude) touch: body
Receptors: as fine touch (see above), also peritrichial arborizations.
1st order neuron: large, heavily myelinated afferents (Type II); soma in dorsal root ganglion (no synapse). Some ascend uncrossed in post. columns (with fine touch); most synapse in Rexed VI & VII.
2nd order neuron axons cross in anterior white commissure (a few don’t cross); enter anterior spinothalamic tract.
Synapse: VPL thalamus. 3rd order neurons pass through IC primarily to postcentral gyrus.

### 1.9.3 Dermatomes and sensory nerves
Dermatomes are ares of the body where sensation is subserved by a single nerve root.
Peripheral nerves generally receive contributions from more than one dermatome.

Lesions in peripheral nerves and lesions in nerve roots may sometimes be distinguished in part by the pattern of sensory loss. A classic example is splitting of the ring finger in median nerve or ulnar nerve lesions, which does not occur in C8 nerve root injuries.

Fig. 1.14 shows anterior and posterior view, each schematically separated into sensory dermatomes (segmental) and peripheral sensory nerve distribution.
References

2 Vascular Anatomy

2.1 Cerebral vascular territories

Fig. 2.1 depicts approximate vascular distributions of the major cerebral arteries. There is considerable variability of the major arteries as well as the central distribution. The lenticulostriates may have origins off of different segments of the middle or anterior cerebral artery. Recurrent artery of Heubner (RAH) (AKA medial striate artery) origin: junction of the ACA and a-communicating in 62.3% proximal A2 in 23.3% A1 in 14.3%.

2.2 Cerebral arterial anatomy

2.2.1 General information

The symbol “” is used to denote a region supplied by the indicated artery. See Angiography (cerebral) (p.236) for angiographic diagrams of the following anatomy.

2.2.2 Circle of Willis

See Fig. 2.2. A balanced configuration of the Circle of Willis is present in only 18% of the population. Hypoplasia of 1 or both p-comms occurs in 22–32% absent or hypoplastic A1 segments occurs in 25%

Key point: the anterior cerebral arteries pass over the superior surface of the optic chiasm.

2.2.3 Anatomical segments of intracranial cerebral arteries

1. carotid artery: the traditional numbering system was from rostral to caudal (counter to the direction of flow, and to the numbering scheme of the other arteries). A number of systems have been described to addresses this inconsistency and also to identify anatomically important segments of the ICA that were not originally delineated (e.g. see Table 2.1). Also see below for more detail.

Fig. 2.1 Vascular territories of the cerebral hemispheres. RAH=recurrent artery of Heubner.
2. anterior cerebral:
   a) A1 (precommunicating): ACA from origin to ACoA
   b) A2 (postcommunicating): ACA from ACoA to branch-point of callosomarginal
c) A3 (precallosal): from branch-point of callosomarginal curving around the genu of the corpus
callosum to superior surface of corpus callosum 3 cm posterior to the genu
d) A4: (supracallosal)
e) A5: terminal branch (postcallosal)

3. middle cerebral:
a) M1: MCA from origin to bifurcation (horizontal segment on AP angiogram). A classical
   bifurcation into relatively symmetrical superior and inferior trunks is seen in 50% of
   bifurcation occurs in 2% but 25% have a very proximal branch (middle trunk) arising from the
   superior (15%) or the inferior (10%) trunk creating a “pseudo-trifurcation”, a pseudo-tetra-
   rifurcation occurs in 5%

- lateral fronto-orbital and prefrontal branches arise from M1 or superior M2 trunk
- precentral, central, anterior and posterior parietal arteries arise from a superior (60%) or middle (25%) or inferior (15%) trunk
- the superior M2 trunk does not give any branches to the temporal lobe

b) M2: MCA trunks from bifurcation to emergence from Sylvian fissure
c) M3–4: distal branches
d) M5: terminal branch

4. posterior cerebral (PCA) (several nomenclature schemes exist5,7):
   a) P1: PCA from the origin to posterior communicating artery (AKA mesencephalic, precommunicating, circular, peduncular, basilar...). The long and short circumflex and thalamoperforating arteries arise from P1
   b) P2: PCA from origin of p-comm to the origin of inferior temporal arteries (AKA ambient, postcommunicating, perimesencephalic), P2 traverses the ambient cistern, Hippocampal, anterior temporal, peduncular perforating and medial posterior choroidal arteries arise from P2
   c) P3: PCA from the origin of the inferior temporal branches to the origin of the terminal branches (AKA quadrigeminal segment), P3 traverses the quadrigeminal cistern
d) P4: segment after the origin of the parieto-occipital and calcarine arteries, includes the cortical branches of the PCA

### 2.2.4 Anterior circulation

#### Anatomic variants

Bovine circulation: the common carotids arise from a common trunk off the aorta.

#### External carotid

1. superior thyroid a.: 1st anterior branch
2. ascending pharyngeal a.
   a) neuromeningeal trunk of the ascending pharyngeal a.: supplies IX, X & XI (important when embolizing glomus tumors, 20% of lower cranial nerve palsy if this branch is occluded)
   b) pharyngeal branch: usually the primary feeder for jugular foramen tumors (essentially the only cause of hypertrophy of the ascending pharyngeal a.)
3. lingual a.
4. facial a.: branches anastamose with ophthalmic a.; important in collateral flow with ICA occlusion (p.1265)
5. occipital a.    posterior scalp
6. posterior auricular
7. superficial temporal
   a) frontal branch
   b) parietal branch
8. (internal) maxillary a. – initially within parotid gland
   a) middle meningeal a.
      • anterior branch
      • posterior branch
b) accessory meningeal

c) inferior alveolar

d) infra-orbital

e) others: distal branches of which may anastomose with branches of ophthalmic artery in the orbit

**Internal carotid artery (ICA)**

Lies posterior & medial to the external carotid (ECA).

**Segments of the ICA and its branches**

See Fig. 2.3 for branches, and reference.

1. **C1 (cervical):** begins in neck at carotid bifurcation where the common carotid artery divides into internal and external carotids. Travels in carotid sheath with IJV and vagal nerve, encircled with postganglionic sympathetic nerves (PGSN). C1 ends where the ICA enters carotid canal of petrous bone. No branches

2. **C2 (petrous):** still surrounded by PGSNs. Ends at the posterior edge of the foramen lacerum (f-Lac) (inferomedial to the edge of the Gasserian ganglion in Meckel's cave). Three divisions:

---

**Fig. 2.3** Internal carotid arteriogram (AP view).

ACom: anterior communicating artery

CM: callosomarginal artery

FP: frontopolar artery

LS: lenticulostriate arteries

OF: orbitofrontal artery

PCal: pericallosal artery

PCom: posterior communicating artery

RH: recurrent artery of Heubner (Reprinted courtesy of Eastman Kodak Company)
a) vertical segment: ICA ascends then bends as the...
b) posterior loop: anterior to cochlea, bends antero-medially becoming the...
c) horizontal segment: deep and medial to greater and lesser superficial petrosal nerves, anterior to tympanic membrane (TM)

3. C3 (lacerum): the ICA passes over (but not through) the f-Lac forming the lateral loop. Ascends in the canalicular portion of the f-Lac to juxtasellar position, piercing the dura as it passes the petrolingual ligament to become the cavernous segment. Branches (usually not visible angiographically):
   a) caroticotympanic (inconsistent) tympanic cavity
   b) pterygoid (vidian) branch: passes through foramen lacerum, present in only 30% may continue as artery of pterygoid canal

4. C4 (cavernous): covered by vascular membrane lining sinus, still surrounded by PGSNs. Passes anteriorly then supero-medially, bends posteriorly (medial loop of ICA), travels horizontally, and bends anteriorly (part of anterior loop of ICA) to anterior clinoid process. Ends at the proximal dural ring (incompletely encircles ICA). Many branches, main ones include:
   a) meningo-hypophyseal trunk (MHT) (largest & most proximal). 2 causes of a prominent MHT: 1) tumor (usually petroclival meningioma – see below), 2) dural AVM (p.1251)
      ● a. of tentorium (AKA artery of Bernasconi & Cassinari): the blood supply of petroclival meningiomas
      ● dorsal meningeal a. (AKA dorsal clival a.)
      ● inferior hypophyseal a. (posterior lobe of pituitary): post-partum occlusion causes pituitary infarcts (Sheehan’s necrosis), however, DI is rare because the stalk is spared
   b) anterior meningeal a.
   c) to inferior portion of cavernous sinus (present in 80%)
   d) capsular aa. of McConnell (in 30%): supply the capsule of the pituitary

5. C5 (clinoid): begins at proximal dural ring, ends at distal dural ring (which completely encircles ICA) where the ICA becomes intradural

6. C6 (ophthalmic): begins at distal dural ring, ends just proximal to p-comm. Branches:
   a) ophthalmic a.: the origin from the ICA is distal to the cavernous sinus in 89% (intracavernous in 8% the ophthalmic artery is absent in 3%) and can vary from 5 mm anterior to 7 mm posterior to the anterior clinoid. Passes through the optic canal into the orbit (the intracranial course is very short, usually 1–2 mm). Has a characteristic bayonet-like “kink” on lateral angiogram
   b) superior hypophyseal a. branches anterior lobe of pituitary & stalk (1st branch of supraclino-noid ICA)

7. C7 (communicating): begins just proximal to p-comm origin, travels between Cr. N. II & III, terminates just below anterior perforated substance where it bifurcates into the ACA & MCA
   a) posterior communicating a. (p-comm)
      ● few anterior thalamoperforators (optic tract, chiasm & posterior hypothalamus): below plexal segment: enters supracornual recess of temporal horn, only this portion of choroid plexus
      ● cisternal segment: passes through crural cistern
   b) anterior choroidal artery variability: takeoff 2–4 mm distal to p-comm (variable) portion of optic tract, medial globus pallidus, genu of internal capsule (IC) (in 50%), inferior half of posterior limb of IC, uncus, retrolenticular fibers (optic radiation), lateral geniculate body; for occlusion syndromes (p.1265)

8. “Carotid siphon”: not a segment, but a region incorporating the cavernous, ophthalmic and communicating segments. Begins at the posterior bend of the cavernous ICA, and ends at the ICA bifurcation

Differentiating p-comm from ACh on arteriogram

1. p-comm origin is proximal to that of the anterior choroidal artery (ACh)
2. p-comm is usually larger than ACh
3. p-comm usually goes up or down a little, then straight back & usually bifurcates
4. ACh usually has a superior “hump” (plexal point) where it pass through the choroidal fissure to enter the ventricle
Anterior cerebral artery (ACA)

Passes between Cr. N. II and anterior perforated substance. See Fig. 2.4. Branches:

1. recurrent artery (of Heubner): typically arises from the area of the A1/A2 junction. Various statistics can be found in the literature regarding the percentage that arise from distal A1 vs. proximal A2. It is most important to be mindful that the takeoff is variable, e.g. when treating aneurysms (one of the larger medial lenticulostriates, remainder of lenticulostriates may arise from this artery) head of caudate, putamen, and anterior internal capsule

2. medial orbitofrontal artery
3. frontopolar artery
4. callosomarginal
   a) internal frontal branches
      • anterior
      • middle
      • posterior
   b) paracentral artery
5. pericallosal artery (continuation of ACA)
   a) superior internal parietal (precuneate) artery
   b) inferior internal parietal artery

Anatomic variants
Hypoid: having only one anterior cerebral artery (as in a horse).

Middle cerebral artery (MCA)

See Fig. 2.5 and anatomy (p. 76). Branches vary widely, 10 common ones:

1. medial (3–6 per side) and lateral lenticulostriate arteries
2. anterior temporal
3. posterior temporal
4. lateral orbitofrontal
5. ascending frontal (candelabra)
6. precentral (prerolandic)
7. central (rolandic)
8. anterior parietal (postrolandic)
9. posterior parietal
10. angular

Posterior circulation

Anatomic variants
Fetal circulation: 15–35% of patients supply their posterior cerebral artery on one or both sides primarily from the carotid (via p-comm) instead of via the vertebrobasilar system.

Vertebral artery (VA)

The VA is the first and usually the largest branch of the subclavian artery. Variant: the left VA arises off the aortic arch in ≈4% Diameter ≈ 3 mm. Mean blood flow ≈ 150 ml/min. The left VA is dominant in 60% The right VA will be hypoplastic in 10% and the left will be hypoplastic in 5% The VA is atretic and does not communicate with the BA on the left in 3% and on the right in 2%(the VA may terminate in PICA).

Four segments:

- V1 prevertebral: from subclavian artery, courses superiorly and posteriorly and enters the foramen transversarium, usually of the 6th vertebral body
- V2 ascends vertically within the transverse foramina of the cervical vertebrae surrounded by sympathetic fibers (from the stellate ganglion) and a venous plexus. It is situated anterior to the cervical roots. It turns laterally to enter the foramen within the transverse process of the axis
- V3 exits the foramen of the axis and curves posteriorly and medially in a groove on the upper surface of the atlas and enters the foramen magnum
- V4 pierces the dura (location somewhat variable) and immediately enters the subarachnoid space. Joins the contralateral VA at the vertebral confluens located at the lower pontine border to form the basilar artery (BA)
Fig. 2.4  Anterior cerebral arteriogram (lateral view) (Reprinted courtesy of Eastman Kodak Company)

Fig. 2.5  Middle cerebral arteriogram (lateral view) (Reprinted courtesy of Eastman Kodak Company)
Branches

Anterior meningeal. Arises at body of C2 (axis), may feed chordomas or foramen magnum meningiomas, may also act as collateral in vascular occlusion

Posterior meningeal. May be a source of blood for some dural AVMs (p.1251)

Medullary (bulbar) aa

Posterior spinal

Posterior inferior cerebellar artery (PICA) (largest branch). Usually arises ≈10 mm distal to point where VA becomes intradural, ≈15 mm proximal to the vertebrobasilar junction (Fig. 2.6)

1. anatomic variants:
   a) in 5–8% the PICA has an extradural origin
   b) “AICA-PICA”: origin is off basilar trunk (where AICA would usually originate)

2. 5 segments¹² (some systems some describe only 4). During surgery, the first three must be preserved, but the last 2 may usually be sacrificed with minimal deficit¹³:
   a) anterior medullary: from PICA origin to inferior olivary prominence. 1 or 2 short medullary short circumflex branches ventral medulla
   b) lateral medullary: to origin of nerves IX, X & XI. Up to 5 branches that supply brainstem
   c) tonsillomedullary: to tonsilar midportion (contains caudal loop on angio)

Fig. 2.6 Intradural VA and PICA segments (lateral view) (Modified with permission from: Lewis SB, Chang DI, Peace DA, Lafrentz PJ, Day AL. Distal posterior inferior cerebellar artery aneurysms: clinical features and management. J Neurosurg 2002;97(4):756-66)
d) telovelotonsillar (supratonsillar): ascends in tonsillomedullary fissure (contains cranial loop on angio)
e) cortical segments

3. 3 branches
   a) choroidal a. (BRANCH 1) arises from cranial loop (choroidal point), choroid plexus of 4th ventricle
   b) terminal branches:
      • tonsillohemispheric (BRANCH 2)
      • inferior vermian (BRANCH 3) inferior inflection = copular point on angio
      Anterior spinal

Basilar artery (BA)
Formed by the junction of the 2 vertebral arteries. Branches:
1. anterior inferior cerebellar artery (AICA): from lower part of BA, runs posterolaterally anterior to
   VI, VII & VIII. Often gives off a loop that runs into the IAC and gives off the labyrinthine artery and then emerges to supply the anterolateral inferior cerebellum and then anastomoses with PICA
2. internal auditory (labyrinthine)
3. pontine branches
4. superior cerebellar a. (SCA)
   a) sup. vermian
5. posterior cerebral: joined by p-comms ≈ 1 cm from origin (the p-comm is the major origin of the
   PCA in 15% and is termed “fetal” circulation, bilateral in 2%).
   3 segments (named for surrounding cistern) and their branches:
      a) peduncular segment (P1)
         • mesencephalic perforating aa. (tectum, cerebral peduncles, and these nuclei: Edinger-Westphal, oculomotor and trochlear)
         • interpuduncular thalamoperforators (1st of 2 groups of posterior thalamoperforating aa.)
         • medial post. choroidal (most from P1 or P2)
         • “artery of Percheron”: a rare anatomic variant in which a solitary arterial trunk arising from the proximal segment of one PCA supplies the paramedian thalami and rostral midbrain bilaterally
      b) ambient segment (P2)
         • lateral post. choroidal (most from P2)
         • thalamogeniculate thalamoperforators (2nd of 2 groups of posterior thalamoperforating aa.)
         • anterior temporal (anastomoses with anterior temporal br. of MCA)
         • posterior temporal
         • parieto-occipital
         • calcarine
      c) quadrigeminal segment (P3)
         • quadrigeminal & geniculate branches quadrigeminal plate
         • post. pericallosal (splenial) (anastomoses with pericallosal of ACA)

Posterior cerebral artery (PCA)
See Fig. 2.7.

Carotid-vertebrobasilar anastomoses
P-comm artery: the “normal” (most common) anastomosis.
   Persistent fetal anastomoses result from failure to involute as the VAs and p-comms develop (order of involution: otic, hypoglossal, primitive trigeminal, proatlantal). Most are asymptomatic. However, some may be associated with vascular anomalies such as aneurysms or AVMs, and occasionally cranial nerve symptoms (e.g. trigeminal neuralgia with PPTA) can occur.
   Four types (from cranial to caudal – the 1st 3 are named for the associated cranial nerve):
   1. persistent primitive trigeminal artery (PPTA): seen in ≈ 0.6% of cerebral angiograms. The most common of the persistent fetal anastomoses (83%). May be associated with trigeminal neuralgia (p.479). Connects the cavernous carotid to the basilar artery. Arises from the ICA proximal to the origin of the meningohypophyseal trunk (50% go through sella, 50% exit the cavernous sinus & course with the trigeminal nerve) and connects to the upper basilar artery between AICA & SCA. The VAs may be small. Saltzman type 1 variant: the p-comms are hypoplastic and the PPTA provides significant blood supply to the distributions of the distal BA, PCA and the SCAs (the basilar
artery is often hypoplastic). Saltzman type 2: p-comm supplies PCA. Saltzman type 3: PPTA joins the SCA (instead of the BA). It is critical to recognize a PPTA before doing a Wada test (p.1553) because of the risk anesthetizing the brainstem, and in doing transsphenoidal surgery because of risk of arterial injury. May rarely be an explanation of posterior fossa symptoms in a patient with carotid disease

2. otic: the first to involute, and the rarest to persist (8 cases reported). Passes through IAC to connect petrous carotid to basilar artery

3. hypoglossal: connects petrous or distal cervical ICA (origin usually between C1-C3) to VA. Traverses the hypoglossal canal. Does not cross foramen magnum
4. proatlantal intersegmental: connects cervical ICA to VA. May arise from: bifurcation of common carotid, ECA, or ICA from C2-C4. Anastomosis with VA in suboccipital region. 50% have hypoplastic proximal VA. 40 cases reported.

2.3 Cerebral venous anatomy

2.3.1 Supratentorial venous system

Major veins and tributaries

See Fig. 2.9 for angiogram and branches.

The left and right internal jugular veins (IJVs) are the major source of outflow of blood from the intracranial compartment. The right IJV is usually dominant. Other sources of outflow include orbital veins and the venous plexuses around the vertebral arteries. Diploic and scalp veins may act as collateral pathways, e.g., with superior sagittal sinus obstruction. The following outline traces the venous drainage back from the IJVs.

Inferior petrosal sinus
Terminates (i.e., drains to) ≤ 1 cm of junction of sigmoid and transverse sinuses.

Sigmoid sinus
superior petrosal sinus
Drains to IJV near junction with sigmoid sinus

---

Fig. 2.9 Internal carotid venogram (lateral view) (Reprinted courtesy of Eastman Kodak Company)
Transverse sinus
R>L in 65%
V. of Labbe. (Inferior anastomotic v.)
Confluens of sinuses. (Torcular herophili)
1. occipital sinus
2. superior sagittal sinus
   a) v. of Trolard (superior anastomotic v.): the prominent superficial vein on the non-dominant side (Labbé is more prominent on the dominant side)
   b) cortical veins
3. straight sinus
   a) inferior sagittal sinus
   b) great cerebral v. (of Galen)
      • pre-central cerebellar v.
      • basal vein of Rosenthal
      • internal cerebral v.: joined at the foramen of Monro (venous angle) by:
        anterior septal v.
        thalamostriate v.

Cavernous sinus
Originally named for its superficial resemblance to the corpora cavernosa. Although classical teaching depicts the cavernous sinus as a large venous space with multiple trabeculations, injection studies\(^1\) and surgical experience\(^2\) instead supports the concept of the cavernous sinus as a plexus of veins. It is highly variable between individuals and from side-to-side. Fig. 2.10 is an oversimplified schematic of one section through the right cavernous sinus.
1. inflowing veins:
   a) superior & inferior ophthalmic veins
   b) superficial middle cerebral veins
   c) sphenoparietal sinus
   d) superior & inferior petrosal sinus
2. outflow:
   a) sphenoparietal sinus
   b) superior petrosal sinus
   c) basilar plexus (which drains to the inferior petrosal sinus)
   d) pterygoid plexus
   e) the right and left cavernous sinuses communicate anteriorly and posteriorly via the circular sinus
3. contents\(^3\)
   a) Oculomotor n. (III)
   b) Trochlear n. (IV)
c) Ophthalmic division of trigeminal (V1)

d) Maxillary division of trigeminal (V2): the only nerve of the cavernous sinus that doesn’t exit the skull through the superior orbital fissure (it exits through foramen rotundum)

e) Carotid artery (ICA). 3 segments within the cavernous sinus
   - posterior ascending segment: immediately after ICA enters the sinus
   - horizontal segment: after ICA turns anteriorly (the longest segment of the intracavernous ICA)
   - anterior ascending segment: ICA turns superiorly

f) Abducens n. (VI): the only nerve NOT attached to lateral dural wall, sometimes referred to as the only cranial nerve inside the cavernous sinus

4. triangular space (of Parkinson): superior border formed by Cr. N. III & IV, and the lower margin formed by V1 & VI (a landmark for surgical entrance to the cavernous sinus)

2.3.2 Posterior fossa venous anatomy
See Fig. 2.11.

2.4 Spinal cord vasculature
See Fig. 2.12.

Although a radicular artery from the aorta accompanies the nerve root at many levels, most of these contribute little flow to the spinal cord itself. The anterior spinal artery is formed from the junction of two branches, each from one of the vertebral arteries. Major contributors of blood supply to the anterior spinal cord is from 6–8 radicular arteries at the following levels ("radiculomedullary arteries", the levels listed are fairly consistent, but the side varies):

1. C3 – arises from vertebral artery
2. C6 and C8 (∼10% of population lack an anterior radicular artery in lower cervical spine)
   - a) C6 – usually arises from deep cervical artery
   - b) C8 – usually from costocervical trunk
3. T4 or T5
4. artery of Adamkiewicz AKA arteria radicularis anterior magna
   - a) the main arterial supply for the spinal cord from ∼T8 to the conus
   - b) located on the left in 80% of cases
   - c) situated between T9 & L2 in 85% (between T9 & T12 in 75%); in remaining 15% between T5 & T8 (in these latter cases, there may be a supplemental radicular artery further down)
d) usually fairly large, gives off cephalic and caudal branch (latter is usually larger) giving a characteristic hair-pin appearance on angiography.

The paired posterior spinal arteries are less well defined than the anterior spinal artery, and are fed by 10–23 radicular branches.

The midthoracic region has a tenuous vascular supply ("watershed zone"), possessing only the above noted artery at T4 or T5. It is thus more susceptible to vascular insults.

Anatomic variants. Arcade of Lazorthes: normal variant where the anterior spinal artery joins with the paired posterior spinal arteries at the conus medullaris.

3 Neurophysiology and Regional Brain Syndromes

3.1 Neurophysiology

3.1.1 Blood-brain barrier

General information

The passage of water-soluble substances from the blood to the CNS is limited by tight junctions (zonulae occludentes) which are found between cerebral capillary endothelial cells, limiting penetration of the cerebral parenchyma (blood-brain barrier, BBB), as well as between choroid plexus epithelial cells (blood-CSF barrier).1 A number of specialized mediated transport systems allow transmission of, among other things, glucose and certain amino acids (especially precursors to neurotransmitters).

The efficacy of the BBB is compromised in certain pathological states (e.g. tumor, infection, trauma, stroke, hepatic encephalopathy...), and can also be manipulated pharmacologically (e.g. hypertonic mannitol increases the permeability, whereas steroids reduce the penetration of small hydrophilic molecules).

The BBB is absent in the following areas: choroid plexus, hypophysis, tuber cinereum, area postrema, pineal and preoptic recess.

Means of assessing the integrity of the BBB:
- visible dyes: Evan’s blue, fluorescein
- radioopaque dyes (imaged with CT scan2): iodine (protein-bound contrast agent)
- paramagnetic (imaged on MRI): gadolinium (protein-bound contrast agent)
- microscopic: horseradish peroxidase
- radiolabeled: albumin, sucrose

Cerebral edema and the blood brain barrier

Three basic types of cerebral edema; diffusion-weighted MRI (p.232) may be able to differentiate:
1. cytotoxic: BBB is closed, therefore no protein extravasation, therefore no enhancement on CT or MRI. Cells swell then shrink. Seen e.g. in head injury
2. vasogenic: BBB disrupted. Protein (serum) leaks out of vascular system, and therefore may enhance on imaging. Extracellular space (ECS) expands. Cells are stable. Responds to corticosteroids (e.g. dexamethasone). Seen e.g. surrounding metastatic brain tumor
3. ischemic: a combination of the above. BBB closed initially, but then may open. ECS shrinks then expands. Fluid extravasates late. May cause delayed deterioration following intracerebral hemorrhage (p.1337).

3.1.2 Babinski sign and Hoffmann sign

Introduction

Although the Babinski sign is regarded as the most famous sign in neurology, there is still disagreement over what constitutes a normal response and when abnormal responses should occur.3 The following represents one interpretation.

The plantar reflex (PR) (AKA Babinski sign after Joseph François Félix Babinski (1857–1932) a French neurologist of Polish descent) is a primitive reflex, present in infancy, consisting of extension of the great toe in response to a noxious stimulus applied to the foot. The small toes may fan, but this is not a consistent nor clinically important component. The PR disappears usually at ≈ 10 months age (range: 6 mos to 12 yrs), presumably under inhibitory control as myelination of the CNS occurs, and the normal response then converts to plantarflexion of the great toe. An upper motor neuron (UMN) lesion anywhere along the pyramidal (corticospinal) tract from the motor strip down to ≈ L4 will result in a loss of inhibition, and the PR will be “unmasked” producing extension of the great toe. With such an UMN lesion, there may also be exaggeration of flexor synergy resulting in dorsiflexion of the ankle, and flexion of the knee and hip (AKA triple flexor response) in addition to extension of the great toe.

Neuroanatomy

The afferent limb of the reflex originates in cutaneous receptors restricted to the first sacral dermatome (S1) and travels proximally via the tibial nerve. The spinal cord segments involved in the reflex-arc lie within L4-S2. The efferent limb to the toe extensors travels via the peroneal nerve.
Differential diagnosis

Etiologies
Lesions producing a PR need not be structural, but may be functional and reversible. The roster of possible etiologies is extensive, some are listed in Table 3.1.

Eliciting the PR, and variations
The optimal stimulus consists of stimulation of the lateral plantar surface and transverse arch in a single movement lasting 5–6 seconds. Other means for applying noxious stimuli may also elicit the plantar reflex (even outside the S1 dermatome, although these do not produce toe flexion in normals). Described maneuvers include: Chaddock (scratch the lateral foot; positive in 3% where plantar stimulation was negative), Schaeffer (pinch the Achilles tendon), Oppenheim (slide knuckles down shin), Gordon (momentarily squeeze lower gastrocnemius), Bing (light pinpricks on dorsolateral foot), Gonda or Stronsky (pull the 4th or 5th toe down and out and allow it to snap back).

Hoffman’s (or Hoffmann’s or Hoffmann) sign
Attributed to Johann Hoffman, a German neurologist practicing in the late 1800. May signify a similar UMN interruption to the upper extremities. Elicited by flicking downward on the nail of the middle or ring finger: a positive (pathologic) response consists of involuntary flexion of the adjacent fingers and/or thumb (may be weakly present in normals). Differs from the plantar reflex since it is monosynaptic (synapse in Rexed lamina IX).

Can sometimes be seen as normal in young individual with diffusely brisk reflexes & positive jaw jerk, usually symmetric. When present pathologically, represents disinhibition of a C8 reflex, indicates lesion above C8.

Hoffman sign was observed in 68% of patients operated for cervical spondylotic myelopathy. In 11 patients presenting with lumbar symptoms but no myelopathy, a bilateral Hoffman sign was associated with occult cervical spinal cord compression in 10 (91%). The Hoffman test has a sensitivity of 33-68%, specificity of 59-78%, a positive predictive value of 26-62% and negative predictive value of 67-75%.

3.1.3 Bladder neurophysiology

Central pathways
The primary coordinating center for bladder function resides within the nucleus locus coeruleus of the pons. This center synchronizes bladder contraction with relaxation of the urethral sphincter during voiding.

Voluntary cortical control primarily involves inhibition of the pontine reflex, and originates in the anteromedial portion of the frontal lobes and in the genu of the corpus callosum. In an uninhibited bladder (e.g. infancy) the pontine voiding center functions without cortical inhibition and the detrusor muscle contracts when the bladder reaches a critical capacity. Voluntary suppression from the cortex via the pyramidal tract may contract the external sphincter and may also inhibit detrusor contraction. Cortical lesions in this location → urgency incontinence with inability to suppress the micturition reflex.

Efferents to the bladder travel in the dorsal portion of the lateral columns of the spinal cord (shaded areas in Fig. 3.1).

*in spinal cord injuries, the PR may initially be absent during the period of spinal “shock” (p.931)
Motor
There are two sphincters that prevent the flow of urine from the bladder: internal (autonomic, involuntary control), and external (striated muscle, voluntary control).

Parasympathetics (PSN)
The detrusor muscle of the bladder contracts and the internal sphincter relaxes under PSN stimulation. PSN preganglionic cell bodies reside in the intermediolateral grey of spinal cord segments S2–4. Fibers exit as ventral nerve roots and travel via pelvic splanchnic nerves (nervi erigentes) to terminate on ganglia within the wall of the detrusor muscle in the body and dome of the bladder.

Somatic nerves
Somatic voluntary control descends in the pyramidal tract to synapse on motor nerves in S2–4, and then travels via the pudendal nerve to the external sphincter. This sphincter may be voluntarily contracted, but relaxes reflexly with opening of the internal sphincter at the initiation of micturition. Primarily maintains continence during ↑ vesical pressure (e.g. valsalva).

Sympathetics
Sympathetic cell bodies lie within the intermediolateral gray column of lumbar spinal cord from segments T12 —L2. Preganglionic axons pass through the sympathetic chain (without synapsing) to the inferior mesenteric ganglion. Postganglionic fibers pass through the inferior hypogastric plexus to the bladder wall and internal sphincter. Sympathetics heavily innervate the bladder neck and trigone. Sympathetics have little effect on bladder motor activity, but alpha adrenergic stimulation results in bladder neck closure which is necessary for bladder filling.

Pelvic nerve stimulation → increased sympathetic tone → detrusor relaxation & increased bladder neck tone (allowing larger volume to be accommodated).

Sensory
Less well understood than motor innervation. Bladder wall stretch receptors sense bladder filling and send afferent signals via pelvic, pudendal and hypogastric nerves to spinal cord segments T10-L2 & S2–4. Fibers ascend primarily in the spinothalamic tract.

Urinary bladder dysfunction
The term neurogenic bladder describes bladder dysfunction due to lesions within the central or peripheral nervous systems. Some use the term synonymously with detrusor areflexia.

Dorsal (sensory) roots lesions interrupt the afferent limb, producing an atonic bladder that fills until dribbling and overflow incontinence occur. No sensation of bladder fullness is appreciated. Voluntary voiding is still possible, but is usually incomplete.

Detrusor hyperreflexia
Can result from interruption of efferents anywhere from cortex to sacral cord. When a critical volume is attained, reflex bladder emptying occurs. Clinically associated with frequent, uncontrollable,
precipitous voiding. Cerebral lesions include: stroke, head injury, brain tumors, hydrocephalus, Parkinson’s disease, various dementias, and MS. Cord lesions include anything that causes myelopathy (p.1407).

Detrusor areflexia
Clinically correlates with difficulty initiating micturition, interrupted flow, and significant residual urine. Incontinence may result from over-distention of the bladder (overflow incontinence), or may be associated with absence of sphincter tone. Etiologies include: chronic infection, long-term bladder catheterization, certain drugs (especially phenothiazines), injury or tumor of the cauda equina or conus medullaris, myelomeningocele, and diabetes mellitus (autonomic neuropathy).

Specific injuries affecting the bladder
In general, regarding discrete neurologic lesions affecting the bladder:

1. supraspinal (lesions above the brain stem): loss of centrally mediated inhibition of the pontine voiding reflex. Usually produces involuntary bladder contractions with smooth and striated sphincter synergy, often with preserved sensation and voluntary striated sphincter function. Symptoms: urinary frequency or urgency, urgency incontinence, and nocturia. If sensory pathways are interrupted, unconscious incontinence occurs (incontinence of the unawares type). Since muscles are coordinated, normal bladder pressures are maintained and there is low risk of high-pressure related renal dysfunction. Voluntary bladder emptying is usually maintained, and timed voiding together with anticholinergic medications (see below) are used in management.

2. complete (or near complete) spinal cord lesions:
   a) suprasacral (lesion above the S2 spinal cord level, which is ≈ T12/L1 vertebral body level in an adult): the sacral voiding center is located in the conus medullaris. Etiologies: spinal cord injuries, tumors, transverse myelitis.
      - Initially following spinal cord injury, there may be spinal shock. During spinal shock (p.931), the bladder is acontractile and areflexic (detrusor areflexia); sphincter tone usually persists and urinary retention is the rule (urinary incontinence generally does not occur except with overdistention)
      - After spinal shock subsides, most develop detrusor hyperreflexia → involuntary bladder contractions without sensation (automatic bladder), smooth sphincter synergy, but striated dyssynergy (involuntary contraction of the external sphincter during voiding which produces a functional outlet obstruction with poor emptying and high vesical pressures). Bladder fills and empties spontaneously (or in response to lower extremity cutaneous stimulation). Bladder compliance is often reduced. Managed by intermittent catheterizations + anticholinergics
   b) infrasacral lesions (lesion below the S2 spinal cord level): includes injury to conus medullaris, cauda equina or peripheral nerves (formerly referred to as lower motor neuron lesions). Etiologies: large HLD, trauma with compromise of spinal canal. Usually develop detrusor areflexia, and do not have involuntary bladder contractions. Reduced urinary flow rate or retention results, and voluntary voiding may be lost. Overflow incontinence develops. There may be reduced compliance during filling, and paralysis of the smooth sphincter (the neurologic basis of this has not been settled, and may be due to sympathetic or PNS involvement). Usually associated with loss of bulbocavernosus and anal wink reflex (preserved in suprasacral lesions, except when spinal shock is present (p.931)) and perineal sensory loss

3. interruption of the peripheral reflex arc: may produce disturbances similar to low spinal cord injury with detrusor areflexia, low compliance and inability to relax the striated sphincter
4. herniated lumbar disc (p.1046): most consist initially of difficulty voiding, straining, or urinary retention. Later, irritative symptoms may develop
5. spinal stenosis (lumbar or cervical): urologic symptoms vary, and depend on the spinal level(s) involved and the type of involvement (e.g. in cervical spinal stenosis, detrusor hyperactivity or underactivity may occur depending on whether the involvement of the micturition neural axis is compression of the inhibitory reticulospinal tracts or myelopathy involving the posterior funiculus)
6. cauda equina syndrome (p.1050): usually produces urinary retention, although sometimes incontinence may occur (some cases are overflow incontinence)
7. peripheral neuropathies: such as with diabetes, usually produce impaired detrusor activity
8. neurospinal dysraphism: most myelodysplastic patients have an areflexic bladder with an open bladder neck. The bladder usually fills until the resting residual fixed external sphincter pressure is exceeded and the leakage occurs
9. multiple sclerosis: 50–90% of patients develop voiding symptoms at some time. The demyelination primarily involves the posterior and lateral columns of the cervical spinal cord. Detrusor hyperreflexia is the most common urodynamic abnormality (in 50–99% of cases), with bladder areflexia being less common (5–20%).

**Urinary retention**

Etologies of urinary retention:

1. bladder outlet obstruction (a brief differential diagnosis list is presented here)
   a) urethral stricture: retention tends to be progressive over time
   b) prostatic enlargement in males:
      i. benign prostatic hypertrophy (BPH) & prostate cancer: retention tends to be progressive over time
      ii. acute prostatitis: onset of retention may be sudden
      iii. rare: extruded prostatic stone
   c) women may develop a cystocele which can produce a urethral kink
   d) rare: urethral cancer

2. detrusor areflexia (p. 93) or hypotonia
   a) spinal cord injury
   b) cauda equina syndrome (p. 105)
   c) chronic infection
   d) long-term bladder catheterization
   e) certain drugs (narcotics, phenothiazines)
   f) injury of the cauda equina or conus medullaris, or of the spinal cord at or below the sacrum
      i. trauma
      ii. tumor
      iii. myelomeningoceles
   g) diabetes mellitus (autonomic neuropathy)
   h) herpes zoster at the level of the sacral dorsal root ganglia\(^9\)
   i) incomplete opening of the bladder neck during voiding: occurs almost exclusively in young and middle-aged males with longstanding obstructive and irritative symptoms\(^9\)
   j) initially following severe bladder over distention or with chronic distention and decompression from any of the above

3. postoperative retention: well-recognized but poorly understood. More common after lower urinary tract, perineal, gynecologic and anorectal operations. Anesthesia and analgesia may contribute to a number of factors\(^9\)

4. psychogenic

**Evaluation of bladder function**

Urodynamics

Usually combined with x-ray (cystometrogram (CMG)) or fluoro (videourodynamic). Measures intravesicular pressures during retrograde bladder filling through a urethral catheter, usually combined with sphincter electromyography. Presence or absence (detrusor areflexia, see below) of detrusor reflex is detected. If present, procedure is repeated, asking patient to suppress the urge to void. Inability to suppress is called an uninhibited detrusor reflex (AKA detrusor hyperreflexia, see above).

**Sphincter electromyography (EMG)**

Either via needle electrodes, or with externally mounted surface electrodes. Voluntary sphincter contraction tests intactness of supraspinal innervation. When combined with CMG, detects electrical activity in sphincters during associated phases of detrusor contraction.

**Voiding cystourethrogram and intravenous pyelography (IVP)**

Voiding cystourethrogram (VCUG) detects urethral pathology (diverticula, strictures...), abnormalities of bladder (diverticula, detrusor trabeculations associated with longstanding contractions against high resistance...), and vesical-ureteral reflux.
Pharmacologic Treatment

Goals are to preserve renal function (which usually involves prevention of UTIs, renal calculi, and ureteral reflux due to high intravesicular pressures) and optimization of urinary continence. Patients with inadequate emptying or increased bladder pressure are often managed by intermittent catheterizations and anticholinergics (see below). Anticholinergics and behavioral therapy are used for patients with maintained voluntary bladder emptying with urinary frequency or urgency incontinence.

The majority of the neurologic involvement in bladder contraction is ACh-mediated stimulation of postganglionic parasympathetic muscarinic cholinergic receptors on bladder smooth muscle.

Detrusor hyperreflexia

The following are all synthetic anticholinergics that block postganglionic synapses (muscarinic action) without blocking skeletal neuromuscular or autonomic ganglia (nicotinic junctions). This increases the volume at which automatic (reflex) contraction occurs in the neurogenic (uninhibited) bladder, effectively increasing bladder capacity. These agents increase the threshold at which involuntary bladder contraction occurs, but they do not increase the warning time and they do not increase the ability to suppress contraction, therefore, urgency and incontinence will still occur unless treatment is combined with a regimen of timed voiding.\(^9\)\(^{(p\ 972)}\)

All are contraindicated in glaucoma as the anticholinergic effects include mydriasis. Overdosage results in the classic anticholinergic symptoms ("red as a beet, hot as a stove, dry as a rock, mad as a hatter"). Use is often limited by side effects such as dry mouth.

**Drug info: Oxybutynin (Ditropan®)**

Probably the most widely prescribed agent. Combines anticholinergic activity with independent musculotropic relaxant effect and local anesthetic activity.

- **Adults**: usual dose is 5 mg BID-TID (maximum 4 times daily). **Peds**: not recommended for age <5 years; usual dose is 5 mg BID (maximum 5 mg TID). Supplied: 5 mg tablets, 5 mg/5 ml syrup.

**Drug info: Tolerodine (Detrol®)**

Milder side effects than oxybutynin, but may also be less effective.\(^10\)

- 2 mg PO BID. Can be lowered to 1 mg PO BID in some patients. Supplied: 1 & 2 mg tablets. Detrol® LA 2 & 4 mg capsule

**Drug info: Flavoxate HCl (Urispas®)**

Weak anticholinergic. Direct smooth muscle inhibitor. Few reported side effects. Some studies have shown no benefit in the elderly population.\(^9\)\(^{(p\ 974)}\)

- **Adult**: 100–200 mg PO TID-QID.

**Drug info: Imipramine HCl (Tofranil®)**

A tricyclic antidepressant. Mechanism of beneficial effect is controversial. Does possess some anticholinergic activity as well as other properties.\(^9\)\(^{(p\ 977)}\) Appears to decrease bladder contractility and increase outlet resistance.
Detrusor areflexia

**Drug info: Bethanechol (Urecholine®)**

A parasympathomimetic agent, primarily muscarinic with little nicotinic activity; related to acetylcholine but not destroyed by cholinesterase. Increases the tone of the detrusor muscle, aiding bladder emptying. Also increases gastric motility. Sub-Q administration produces a more intense effect on the bladder than PO. Always have atropine available when giving by sub-Q route. Effects occur within 30–90 minutes after PO dose, and within 15 minutes of sub-Q dose.

- Indicated for acute post-op non-obstructive urinary retention and for neurogenic atony due to spinal cord injury or dysfunction.

- **Side effects:** Sweating and diarrhea are not uncommon but of little danger. Can precipitate severe bronchospasm in asthmatics. Nausea may be reduced by giving with an empty stomach. Atropine is a specific antidote for overdosage (atropine sub-Q: 0.6 mg in adults, or 0.01 mg/kg in children <12 yrs).

  - Start with 5–10 mg PO, and increase hourly until desired effect obtained or 50 mg given. Then, continue minimum effective dosage TID-QID (usual: 10–50 mg PO TID-QID). Sub-Q (have atropine available): 0.5–1 ml, repeat q 15 mins until desired response or 4 doses given; continue minimal effective dose TID-QID. Supplied: 5, 10, 25 & 50 mg tabs. Injection: 5.15 mg/ml (for sub-Q use only).

Bladder management after cauda equina compression

In situations where there is urinary retention with some prospect of return of function (e.g. following surgery for acute cauda equina compression) the following bladder management regimen may be employed:

- Teach the patient or a family member to perform clean intermittent catheterizations (CIC), if CICs can be done:
  - Have them monitor post-void residuals (PVR)
  - Start tamsulosin (Flomax®) 0.4 mg PO q d (see below)
  - If PVRs ever fall to <75 cc, discontinue CICs
- If CICs cannot be performed, manage with an indwelling Foley catheter for a week, and check the PVR after that time.
- If after 1 week the PVR is ≥75 cc, D/C tamsulosin if used, and refer the patient to a urologist for urodynamics (urodynamics earlier than this time will usually not result in a change in management).

**Drug info: Tamsulosin (Flomax®)**

A prostate alpha₁ adrenoceptor antagonist. Used to treat voiding difficulties resulting from outlet obstruction due to benign prostatic hypertrophy (BPH). Has been shown to have some effectiveness in women via other mechanisms. Similar to terazosin (Hytrin®) and doxazosin (Cardura®), but has an advantage for acute relief because the dose of tamsulosin does not need to be gradually ramped up (it can be started at the therapeutic dose). It takes at least 5–7 days to work.

- **Side effects:** Very few. Rhinitis, retrograde or diminished ejaculation, or postural hypotension may occur.11
  - 0.4 mg PO q d (usually given 30 minutes after the same meal each day). If there is no response by 2–4 weeks, a dose of 0.8 mg PO q d can be tried.11

3.2 Regional brain syndromes

This section serves to briefly describe typical syndrome associated with lesions in various areas of the brain. Unless otherwise noted, lesions considered are destructive.

3.2.1 Overview

1. Frontal lobe
   a) Unilateral injury:
      - May produce few clinical findings except with very large lesions
      - Bilateral or large unilateral lesions: apathy, abulia
- the frontal eye field (for contralateral gaze) is located in the posterior frontal lobe (Broca's area 8, shown as the striped area in Fig. 1.1). Destructive lesions impair gaze to the contralateral side (patient looks towards the side of the lesion), whereas irritative lesions (i.e. seizures) cause the center to activate, producing contralateral gaze (patient looks away from the side of the lesion). See also Extraocular muscle (EOM) system (p. 565) for more details.

b) bilateral injury: may produce apathy, abulia
c) olfactory groove region: may produce Foster Kennedy syndrome (see below)
d) prefrontal lobes control “executive function”: planning, prioritizing, organizing thoughts, suppressing impulses, understanding the consequences of decisions

2. parietal lobe: major features (see below for details)
a) either side: cortical sensory syndrome, sensory extinction, contralateral homonymous hemianopia, contralateral neglect
b) dominant parietal lobe lesion (left in most): language disorders (aphasias), Gerstmann’s syndrome (p.98), bilateral astereognosis
c) non-dominant parietal lobe lesions: topographic memory loss, anosognosia and dressing apraxia

3. occipital lobe: homonymous hemianopsia

4. cerebellum
   a) lesions of the cerebellar hemisphere cause ataxia in the ipsilateral limbs
   b) lesions of the cerebellar vermis cause truncal ataxia

5. brainstem: usually produces a mixture of cranial nerve deficits and long tract findings (see below for some specific brainstem syndromes)

6. pineal region
   a) Parinaud’s syndrome (p.99)

3.2.2 Parietal lobe syndromes

See reference. 12 (p. 308–12)

Parietal lobe anatomy

The parietal lobe is located behind the central sulcus, above the Sylvian fissure, merging posteriorly into the occipital lobe (the border on the medial surface of brain is defined by a line connecting the parieto-occipital sulcus to the pre-occipital notch).

Parietal lobe neurophysiology

- either side: anterior parietal cortex organizes tactile precepts (probably contralateral) and integrates with visual and auditory sensation to build awareness of body and its spatial relations
- dominant side (on left in 97% of adults): understanding language, includes “cross-modal matching” (auditory-visual, visual-tactile, etc.). Dysphasia present with dominant lobe lesions often impedes assessment
- non-dominant side (right in most): integrates visual and proprioceptive sensation to allow manipulation of body and objects, and for certain constructional activities

Clinical syndromes of parietal lobe disease

Overview

1. unilateral parietal lobe disease (dominant or non-dominant):
   a) cortical sensory syndrome (see below) and sensory extinction (neglecting 1 of 2 simultaneously presented stimuli). Large lesion → hemianesthesia
   b) congenital injury → mild hemiparesis & contralateral muscle atrophy
   c) homonymous hemianopia or visual inattentiveness
   d) occasionally: anosognosia
   e) neglect of contralateral half of body and visual space (more common with right side lesions)
   f) abolition of optokinetic nystagmus to one side

2. additional effects of dominant parietal lobe lesion (left in most):
   a) language disorders (aphasias)
   b) speech-related or verbally mediated functions, e.g. cross-modal matching (e.g. patient understands spoken words and can read, but cannot understand sentences with elements of relationships)
c) Gerstmann’s syndrome, classically:
   -agraphia without alexia (patients can read but cannot write)
   -left-right confusion
   -digit agnosia: inability to identify finger by name
   -acalculia

d) tactile agnosia (bilateral astereognosis)
e) bilateral ideomotor apraxia (inability to carry out verbal commands for activities that can otherwise be performed spontaneously with ease)

3. additional effects of non-dominant parietal lobe lesions (usually right):
   a) topographic memory loss
   b) anosognosia and dressing apraxia

**Cortical sensory syndrome**

Lesion of postcentral gyrus, especially area that maps to hand.
- sensory deficits:
  a) loss of position sense and of passive movement sense
  b) inability to localize tactile, thermal, and noxious stimuli
  c) astereognosis (inability to judge object size, shape, and identity by feel)
  d) agraphesthesia (cannot interpret numbers written on hand)
  e) loss of two point discrimination
- preserved sensations: pain, touch, pressure, vibration, temperature
- other features
  a) easy fatigability of sensory perceptions
  b) difficulty distinguishing simultaneous stimulations
  c) prolongation of superficial pain with hyperpathia
  d) touch hallucinations

**Anton-Babinski syndrome**

A unilateral asomatagnosia. May seem more common with non-dominant (usually right) parietal lesions because it may be obscured by the aphasia that occurs with dominant (left) sided lesions.
1. anosognosia (indifference or unawareness of deficits, patient may deny that paralyzed extremity is theirs)
2. apathy (indifference to failure)
3. allocheiria (one-sided stimuli perceived contralaterally)
4. dressing apraxia: neglect of one side of body in dressing and grooming
5. extinction: patient is unaware of contralateral stimulus when presented with double-sided simultaneous stimulation
6. inattention to an entire visual field (with or without homonymous hemianopia), with deviation of head, eyes, and torsion of body to unaffected side

**Parietal lobe aphasias**

1. Wernicke’s aphasia: lesion of auditory association areas or their separation from angular gyrus and primary auditory cortex. A fluent aphasia (normal sentence length & intonation, devoid of meaning). May include paraphasias. Lesion in region of Wernicke’s area (Brodmann areas 40 & 39, Fig. 1.1)
2. Broca’s (motor) aphasia: in reality, “apraxia” of motor sequencing for speech (speech and phonation muscles aren’t paralyzed, and function for other activities), producing faltering, dysarthric speech. Lesion in region of Broca’s area (Brodmann area 44, Fig. 1.1)
3. global aphasia: usually due to lesion that destroys large portion of language center; all aspects of speech and language affected
   a) unable to speak except for some clichés, habitual phrases, or expletives
   b) anomia (inability to name objects or parts of objects)
   c) verbal and motor perseveration
   d) unable to understand all except for a few words
   e) inability to read or write
4. conduction aphasia: due to disruption of connections between frontal and temporal speech areas, usually involving supramarginal gyrus. Similar to Wernicke’s (fluent spontaneous speech and paraphasias), but patients understand spoken or written words, and are aware of their deficit. Repetition is severely affected
5. pure word blindness: AKA alexia without agraphia (rare) due to lesion in parieto-occipital lobe that interrupts connections between left angular gyrus and both occipital lobes. Patients can write, but are unable to read what they’ve written, and frequently seem unconcerned about this. Often accompanied by loss of ability to name colors. Reading and naming numbers usually preserved.

3.2.3 Foster Kennedy syndrome

Named after neurologist Robert Foster Kennedy. Usually from olfactory groove or medial third sphenoid wing tumor (usually meningioma). Now rare due to early detection by CT or MRI. Classic triad:
1. ipsilateral anosmia
2. ipsilateral central scotoma (with optic atrophy due pressure on optic nerve)
3. contralateral papilledema (from elevated ICP)

Occasionally ipsilateral proptosis will also occur due to orbital invasion by tumor.

3.2.4 Brain stem and related syndromes

Weber’s syndrome
Cr. N. III palsy with contralateral hemiparesis; also see Lacunar strokes (p. 1267). Third nerve palsies from parenchymal lesions may be relatively pupil sparing.

Benedikt’s syndrome
Similar to Weber’s, plus red nucleus lesion. Cr. N. III palsy with contralateral hemiparesis except arm which has hyperkinesia, ataxia, and a coarse intention tremor. Lesion: midbrain tegmentum involving red nucleus, brachium conjunctivum, and fascicles of III.

Millard-Gubler syndrome
Facial (VII) & abducent (VI) palsy + contralateral hemiplegia (corticospinal tract) from lesion in base of pons (usually ischemic infarct, occasionally tumor).

3.2.5 Parinaud’s syndrome

Definition
AKA dorsal midbrain syndrome, AKA prepectal syndrome. As originally described, a supranuclear paralysis of vertical gaze resulting from damage to the mesencephalon. There are a number of somewhat varying descriptions, however most include:
- supranuclear upward gaze palsy (i.e. upgaze palsy affecting both voluntary saccadic and pursuit movements, with preservation of vestibulo-ocular or oculocephalic (doll’s eyes) reflexes in most cases). Horizontal eye movements are spared.
- lid retraction (Collier’s sign): NB: upgaze palsy + lid retraction produces the “setting sun sign”
- convergence palsy
- accommodation palsy
- less common associations: pseudoabducens palsy (AKA thalamic esotropia), see-saw nystagmus, fixed pupils, dissociated light-near response (pseudo-Argyll Robertson), convergence spasm, nystagmus retractorius, internuclear ophthalmoplegia (INO)

Skew deviation may be a unilateral variant of Parinaud’s syndrome.
Syndrome of the Sylvian aqueduct: Parinaud’s syndrome (PS) combined with downgaze palsy.

Differential diagnosis

Etiologies
1. masses pressing directly on quadrigeminal plate (e.g. pineal region tumors)
2. elevated ICP; secondary to compression of mesencephalic tectum by dilated suprapineal recess, e.g. in hydrocephalus
3. stroke or hemorrhage in upper brainstem
4. multiple sclerosis (MS)
5. occasionally seen with toxoplasmosis

Conditions affecting ocular motility that could mimic the upgaze palsy of PS:
1. Guillain-Barré syndrome
2. myasthenia gravis
3. botulism
4. hypothyroidism
5. there may be a gradual benign loss of upgaze with senescence

### 3.3 Jugular foramen syndromes

#### 3.3.1 Applied anatomy

The jugular foramen (JF) is one of a pair of openings between the lateral part of the occipital bone and the petrous part of the temporal bone. The foramen is usually divided in 2 by a bony spine from the petrous temporal bone that attaches via a fibrous bridge (which is bony in 26%) to the jugular process of the occipital bone.14 The right JF is usually larger than the left.14,15 The carotid ridge separates the JF from the nearby carotid canal. Contents of jugular foramen (JF): Cn. N. IX, X, XI, petrosal sinus, sigmoid sinus, some meningeal branches from the ascending pharyngeal and occipital arteries.16

Nearby: Cr. N. XII passes through the hypoglossal canal just above the occipital condyle. The carotid artery with the sympathetic plexus enters the carotid canal.

Compartmentalization of the jugular foramen remains controversial. As many as 4 foramina have been described over the years. Although it had been recognized previously, an early 2-compartment description was published in 1967 by Hovelacque.17 In this, the bony spine (+ its fibrous septum) divide the foramen into:

- **pars vascularis**: the larger posterolateral compartment containing the vagal nerve (and branching Arnold’s nerve), spinal accessory nerve and the internal jugular vein
- **pars nervosa**: the smaller anteromedial compartment containing the glossopharyngeal nerve (and branching Jacobson’s nerve), inferior petrosal sinus and meningeal branch of the ascending pharyngeal artery

A publication in 1997 described these 3 compartments18:

- Sigmoid: large posterolateral compartment containing sigmoid sinus
- Petrosal: smaller anteromedial compartment containing petrosal sinus
- Intrajugular or neural: CN 9, 10 and 11

#### 3.3.2 Clinical syndromes

**General information**

A number of eponymous syndromes with some conflicting findings in the literature have been described. See Table 3.2 for a summary and Fig. 3.2 for a schematic diagram of deficits in various JF syndromes.

**Vernet’s syndrome**: CN IX, X & XI palsy

AKA syndrome of the jugular foramen. Usually due to intracranial lesion.

Etiologies include: jugular foramen tumors, ICA dissections, myotic aneurysms of the external carotid, thrombosis of the jugular vein, following carotid endarterectomy.

Symptoms: unilateral paralysis of the palate, vocal cords, sternocleidomastoid, trapezius, with loss of taste in the posterior 1/3 tongue, anesthesia of the soft palate, larynx and pharynx.

**Collet-Sicard syndrome**

Palsies of CN IX, X, XI & XII without sympathetic involvement. More likely with lesion outside skull. If caused by an intracranial lesion, it would have to be of such a large size that it would usually produce brain stem compression — long tract findings.
Etiologies include: condylar and Jefferson’s fractures, internal carotid dissection, primary and metastatic tumors, Lyme disease and fibromuscular dysplasia.

Symptoms: unilateral paralysis of the palate, vocal cords, sternocleidomastoid, trapezius, tongue, loss of taste in posterior 1/3 tongue, anesthesia of soft palate, larynx and pharynx.
Villaret’s syndrome: CN IX, X, XI & XII palsy + sympathetic dysfunction

AKA posterior retropharyngeal syndrome, AKA the nervous syndrome of the posterior retropharyngeal space. Collet-Sicard syndrome with sympathetic involvement. Usually due to retropharyngeal lesions.

Etiologies include: parotid tumors, metastases, external carotid aneurysm and osteomyelitis of the skull base.

Symptoms: as with Collet-Sicard + Horner’s syndrome.

Tapia syndrome: CN X & XII palsy (± XI)

AKA Matador’s disease (first described in a bullfighter by Antonio Garcia Tapia). Some authors describe an intracranial and extracranial form. Etiologies include: oral intubation (majority of cases prior to 2013), metastases, rarely associated with carotid or vertebral artery dissections.

Symptoms: hoarseness of voice, dysphagia secondary to incoordination of tongue and food bolus propulsion, unilateral atrophy and paralysis of the tongue, ± paralysis of sternocleidomastoid & trapezius, sparing the soft palate.

(Hughlings) Jackson’s syndrome: CN X, XI & XII palsy

First described in 1864 with unilateral paralysis of the soft palate, larynx, sternocleidomastoid, trapezius and tongue.

Schmidt syndrome: CN X & XI

AKA vago-spinal syndrome. Schmidt first described this in 1892. Unilateral vocal cord and paralysis of sternocleidomastoid, soft palate, larynx and trapezius.

4 Neuroanesthesia

4.1 General information

Table 4.1 shows the American Society of Anesthesiologists (ASA) grading system to estimate anesthetic risk for various conditions.

For issues related to intracranial pressure (ICP), cerebral perfusion pressure (CPP), intracranial constituents, etc., see ICP principles (p. 856). For cerebral blood flow (CBF) and cerebral metabolic rate of oxygen consumption (CMRO₂), see CBF and oxygen utilization (p. 1264).

Parameters of primary relevance to neurological surgery that can be modulated by the anesthesiologist:

1. blood pressure: one of the factors that determines CPP as well as spinal cord perfusion. MAY need to be manipulated (e.g. reduced when working on an aneurysm, or increased to enhance collateral circulation during cross clamping). Measurement by arterial line is most accurate and depending on the patient’s presentation and the planned procedure, often should be placed prior to induction of anesthesia. For intracranial procedures, the arterial line should be calibrated at the external auditory meatus to most closely reflect intracranial blood pressure.

2. jugular venous pressure: one of the factors that influences ICP.

3. arterial CO₂ tension (PaCO₂): CO₂ is the most potent cerebral vasodilator. Hyperventilation reduces PaCO₂ (hypocapnea) which decreases CBV but also CBF. Goal is generally end tidal CO₂ (ETCO₂) of 25–30 mm Hg with a correlating PaCO₂ of 30–35. Use with care for stereotactic procedures to minimize shift of intracranial contents when using this method to control ICP.

4. arterial O₂ tension

5. hematocrit: in neurosurgery it is critical to balance oxygen carrying capacity (decreased by anemia) against improved blood rheology (impaired by elevated Hct).

6. patient temperature: mild hypothermia provides some protection against ischemia by reducing the cerebral metabolic rate of oxygen (CMRO₂) by ≈ 7% for each 1°C drop.

7. blood glucose level: hyperglycemia exacerbates ischemic deficits.

8. CMRO₂: reduced with certain neuro-protective agents and by hypothermia which helps protect against ischemic injury.

9. in cases where a lumbar drain or a ventricular drain has been placed: CSF output.

10. elevation of the head of the patient: lowering the head increases arterial blood flow, but also increases ICP by impairing venous outflow.

11. intravascular volume: hypovolemia can impair blood flow in neurovascular cases. In surgery in the prone position, excessive fluids may contribute to facial edema which is one of the risk factors for PION (p. 1056).

12. positioning injuries: during the procedure, the patient’s position may change and be unnoticed due to draping. Careful and frequent examination of the patient’s position may prevent injuries associated with prolonged malpositioning.

13. post operative nausea and vomiting (PONV): may adversely affect ICP and may negatively impact recent cervical surgical procedures. Avoidance of anesthetic agents known to cause PONV or pretreatment to prevent PONV may be prudent.

4.2 Drugs used in neuroanesthesia

4.2.1 Inhalational agents

General information

Most reduce cerebral metabolism (except nitrous oxide) by suppressing neuronal activity. These agents disturb cerebral autoregulation and cause cerebral vasodilatation which increases cerebral blood volume (CBV) and can increase ICP. With administration >2 hrs they increase CSF volume which can also potentially contribute to increased ICP. Most agents increase the CO₂ reactivity of cerebral blood vessels. These agents affect intra-operative EP monitoring (p. 107).
### Drug info: Nitrous oxide

A potent vasodilator that markedly increases CBF and minimally increases cerebral metabolism. Contributes to post-op N/V.

Nitrous oxide, pneumocephalus and air embolism: The solubility of nitrous oxide (N\textsubscript{2}O) is ≈ 34 times that of nitrogen.\textsuperscript{6} When N\textsubscript{2}O comes out of solution in an airtight space it can increase the pressure which may convert pneumocephalus to “tension pneumocephalus.” It may also aggravate air embolism. Thus caution must be used especially in the sitting position where significant post-op pneumocephalus and air embolism are common. The risk of tension pneumocephalus may be reduced by filling the cavity with fluid in conjunction with turning off N\textsubscript{2}O about 10 minutes prior to completion of dural closure. See Pneumocephalus (p. 887).

### Halogenated agents

Agents in primary usage today are shown below. All suppress EEG activity and may provide some degree of cerebral protection.

### Drug info: Isoflurane (Forane®)

Can produce isoelectric EEG without metabolic toxicity. Improves neurologic outcome in cases of incomplete global ischemia (although in experimental studies on rats, the amount of tissue injury was greater than with thiopental\textsuperscript{6}).

### Drug info: Desflurane (Suprane®)

A cerebral vasodilator, increases CBF and ICP. Decreases CMRO\textsubscript{2} which tends to cause a compensatory vasoconstriction.

### Drug info: Sevoflurane (Ultane®)

Mildly increases CBP and ICP, and reduces CMRO\textsubscript{2}. Mild negative inotrope, cardiac output not as well maintained as with isoflurane or desflurane.

### 4.2.2 Intravenous anesthetic agents

Agents generally used for induction

1. propofol: exact mechanism of action unknown. Short half-life with no active metabolites. May be used for induction and as a continuous infusion during total intravenous anesthesia (TIVA). Causes dose dependent decrease in mean arterial blood pressure (MAP) and ICP. See also information other than use in induction (p.106). Is more rapidly cleared than, and has largely replaced, thiopental
2. barbiturates: produce significant reduction in CMRO\textsubscript{2} and scavenge free radicals among other effects (p. 1202). Produce dose-dependent EEG suppression which can be taken all the way to isoelectric. Minimally affect EPs. Most are anticonvulsant, but methohexital (Brevital®) (p. 132) can lower the seizure threshold. Myocardial suppression and peripheral vasodilatation from barbiturates may cause hypotension and compromise CPP, especially in hypovolemic patients
   - sodium thiopental (Pentothal®): the most common agent. Rapid onset, short acting. Minimal effect on ICP, CBF and CMRO\textsubscript{2}
3. etomidate (Amidate®): a carboxylated imidazole derivative. Anesthetic and amnestic, but no analgesic properties. Sometimes produces myoclonic activity which may be confused with seizures. Impairs renal function and should be avoided in patients with known renal disease. May
produce adrenal insufficiency. See Miscellaneous drugs in neuroanesthesia (p. 106) for information other than use in induction.

4. **Ketamine**: NMDA receptor antagonist. Produces a dissociative anesthesia. Maintains cardiac output. May slightly increase both heart rate and blood pressure. ICP increases in parallel with increased cardiac output.

## Narcotics in anesthesia

### Nonsynthetic narcotics

Narcotics increase CSF absorption and minimally reduce cerebral metabolism. They slow the EEG but will not produce an isoelectric tracing. All narcotics cause dose-dependent respiratory depression which can result in hypercarbia and concomitant increased ICP in non-ventilated patients. Often also contribute to post-op N/V.

- **Morphine**: does not significantly cross the BBB.
- **Disadvantages in neuro patients**:
  1. Causes histamine release which
     a) May produce hypotension
     b) May cause cerebrovascular vasodilation → increased ICP\(^{(p. 153)}\)
     c) The above together may compromise CPP
  2. In renal or hepatic insufficiency, the metabolite morphine-6-glucuronide can accumulate which may cause confusion

### Synthetic narcotics

These do not cause histamine release, unlike morphine and meperidine.

- **Remifentanil** (Ultiva®); see also detailed information (p. 133): reduces CMRO\(_2\), CBV, and ICP. Large doses may be neurotoxic to limbic system and associated areas. May be used for awake craniotomy (p. 1432).
- **Fentanyl**: crosses the BBB. Reduces CMRO\(_2\), CBV, and ICP. May be given as bolus and/or as a continuous infusion.
- **Sufentanil**: more potent than fentanyl. Does not increase CBF. Raises ICP (may be due to hyperventilation – which can occur with any narcotic) and is thus often not appropriate for neurosurgical cases. Expensive.

## 4.2.3 Miscellaneous drugs in neuroanesthesia

**Benzodiazepines.** These drugs are GABA agonists and decrease CMRO\(_2\). They also provide anticonvulsant action and produce amnesia. See also agents and reversal (p. 205).

- **Etomidate** (p. 105). Used primarily for induction (p. 105).
  - A cerebrovasoconstrictor which therefore: reduces CBF and ICP; reduces CMRO\(_2\) but no longer promoted as a cerebral protectant based on experimental studies\(^5\) and a drop in p\(\text{EtO}_2\) with temporary MCA clipping\(^{10}\)
  - Does not suppress brainstem activity
  - Suppresses adrenocortical function cortisol production. This usually occurs with prolonged administration, but can occur even after single dose for induction and may persist up to 8 hrs (no adverse outcomes from short-term suppression have been reported)
  - Increases activity of seizure foci which may be used for mapping foci during seizure surgery but may also induce seizures

- **Propofol.** A sedative hypnotic. Useful for induction (p. 105). Reduces cerebral metabolism, CBF, and ICP. Has been described for cerebral protection (p. 1203) and for sedation (p. 133). Short half-life permits rapid awakening which may be useful for awake craniotomy (p. 1434). Not analgesic.

- **Lidocaine.** Given IV, suppresses laryngeal reflexes which may help blunt ICP elevations that normally follow endotracheal intubation or suctioning. Anticonvulsant at low doses, may provoke seizures at high concentrations.

- **Esmolol.** Selective beta-1 adrenergic antagonist, blunts the sympathetic response to laryngoscopy and intubation. Less sedating than equipotent doses of lidocaine or fentanyl used for the same purpose. Half-life: 9 minutes. See also dosing, etc. (p. 127)
Dexmedetomidine (Precedex®). Alpha 2 adrenergic receptor agonist, used for control of hypertension postoperatively, as well as for its sedating qualities during awake craniotomy either alone or in conjunction with propofol (p. 105). Also used to help patients tolerate endotracheal tube without sedatives/narcotics to facilitate extubation.

### 4.2.4 Paralytics for intubation

Paralytics (neuromuscular blocking agents (NMBA)): administered to facilitate tracheal intubation and to improve surgical conditions when indicated. Administration of paralytics ideally should always be guided by neuromuscular twitch monitoring. Also see Sedatives & paralytics (p. 132). In addition to paralytics, all conscious patients should also receive a sedative to blunt awareness.

Paralytics should not be given until it has been determined that patient can be ventilated manually, unless treating laryngospasm (may be tested with thiopental). Use with caution in non-fixated patients with unstable C-spine.

Due to long action, pancuronium (Pavulon®) is not indicated as the primary paralytic for intubation, but may be useful once patient is intubated or in low dose as an adjunct to succinylcholine.

#### Drug info: Succinylcholine (Anectine®)

The only depolarizing agent. May be used to secure airway for emergency intubation, but due to possible side effects (p. 135), should not be used acutely following injury or in adolescents or children (a short acting nondepolarizing blocker is preferred). May transiently increase ICP. Prior dosing with 10% of the ED95 dose of a non-depolarizing muscle relaxant reduces muscle fasciculations.

| Intubating dose: 1–1.5 mg/kg (supplied as 20 mg/ml → 3.5–5 cc for a 70 kg patient), onset 60–90 sec, duration 3–10 min, may repeat same dose × 1. |

#### Drug info: Rocuronium (Zemuron®)

Intermediate acting, aminosteroid, non-depolarizing muscle relaxant. The only nondepolarizing neuromuscular blocking agent approved for rapid sequence intubation. Duration of action and onset are dose dependent. (p. 135).

#### Drug info: Vecuronium (Norcuron®)

See details (p. 136).

Aminosteroid with activity similar to that of rocuronium, however, does not cause histamine release and is not approved for rapid sequence intubation.

#### Drug info: Cisatracurium (Nimbex®)

See details (p. 136).

Metabolized by Hoffman degradation (temperature dependent), intermediate acting, no significant increases in histamine.

### 4.3 Anesthetic requirements for intra-operative evoked potential monitoring

For details of intra-operative evoked potential (EP) monitoring itself, see Intra-operative evoked potentials (p. 239).
All volatile anesthetics produce dose-dependent reduction in SSEP peak amplitude and an increase in peak latency. Adding nitrous oxide increases this sensitivity to anesthetic agents.

Anesthesia issues related to intra-operative evoked potential (EPs) monitoring:
1. induction: minimize pentothal dose (produces ≈30 minutes of suppression of EPs), or use etomidate (which increases both SSEP amplitude and latency)\(^1\)
2. total intravenous anesthesia (TIVA) is ideal (i.e. no inhalational agents)
3. nitrous/narcotic technique is a distant second choice
4. if inhalational anesthetic agents are required:
   a) use <1 MAC (maximal alveolar concentration), ideally <0.5 MAC
   b) avoid older agents such as Halothane
5. nondepolarizing muscle relaxants have little effect on EP (in monkeys)\(^12\)
6. propofol has a mild effect on EP: total anesthesia with propofol causes less EP depression than inhalational agents at the same depth of anesthesia\(^13\)
7. benzodiazepines have a mild-to-moderate depressant effect on EPs
8. continuous infusion of anesthetic drugs is preferred over intermittent boluses
9. SSEPs can be affected by hyper- or hypo-thermia, and changes in BP
10. hypocapnia (down to end tidal CO\(_2\) ≈21) causes minimal reduction in peak latencies\(^14\)
11. antiepileptic drugs: phenytoin, carbamazepine and phenobarbital do not affect SSEP\(^15\)

4.4 Malignant hyperthermia

4.4.1 General information
Malignant hyperthermia (MH) is a hypermetabolic state of skeletal muscle due to idiopathic block of Ca\(^{++}\) re-entry into sarcoplasmic reticulum. Transmitted by a multifactorial genetic predisposition. Total body O\(_2\) consumption increases \(×2–3\).

Incidence: 1 in 15,000 anesthetic administrations in pediatrics. 1 in 40,000 adults. 50% had previous anesthesia without MH. Frequently associated with administration of halogenated inhalational agents and the use of succinylcholine (fulminant form: muscle rigidity almost immediately after succinylcholine, may involve masseters → difficulty intubating). Initial attack and recrudescence may also occur post-op. 30% mortality.\(^16\)

4.4.2 Presentation
1. earliest possible sign: increase in end-tidal pCO\(_2\)
2. tachycardia (early) and other arrhythmias
3. with progression:
   a) coagulation disorder (DIC) (bleeding from surgical wound and body orifices)
   b) ABG: increasing metabolic acidosis & decreasing pO\(_2\)
   c) pulmonary edema
   d) elevated body temperature (may reach ≥44°C (111°F) at rate of 1°C/5-min) (normal patients become hypothermic with general anesthesia)
   e) limb muscle rigidity (common, but late)
   f) rhabdomyolysis → elevated CPK & myoglobin (late)
4. terminal:
   a) hypotension
   b) bradycardia
   c) cardiac arrest

4.4.3 Treatment
1. eliminate offending agents (stop the operation, D/C inhalation anesthesia and change tubing on anesthesia machine)
2. dantrolene sodium (Dantrium®) 2.5 mg/kg IV usually effective, infuse until symptoms subside, up to 10 mg/kg
3. hyperventilation with 100% O\(_2\)
4. surface and cavity cooling: IV, in wound, per NG, PR
5. bicarbonate 1–2 mEq/kg for acidosis
6. IV insulin and glucose (lowers K\(^+\), glucose acts as energy substrate)
7. procainamide for arrhythmias
8. diuresis: volume loading + osmotic diuretics
4.4.4 Prevention

1. identification of patients at risk:
   a) only reliable test: 4 cm viable muscle biopsy for in-vitro tests at a few regional test centers (abnormal contracture to caffeine or halothane)
   b) family history: any relative with syndrome puts patient at risk
   c) related traits: 50% of MH patients have heavy musculature, Duchenne type muscular dystrophy, or scoliosis
   d) patients who exhibit masseter spasm in response to succinylcholine

2. in patients at risk: avoid succinylcholine (nondepolarizing blockers preferred if paralysis essential), may safely have non-halogenated anesthetics (narcotics, barbiturates, benzodiazepines, droperidol, nitrous...)

3. prophylactic oral dantrolene: 4–8 mg/kg/day for 1–2 days (last dose given 2 hrs before anesthesia) is usually effective

5 Sodium Homeostasis and Osmolality

5.1 Serum osmolality and sodium concentration

Clinical significance of various serum osmolality values is shown in Table 5.1.

Serum osmolality. May be estimated using Eq (5.1).

\[
\text{Osmolarity (mOsm/L)} = \frac{\text{Na}^+ \cdot \frac{\text{K}^+}{2} + \text{BUN} \cdot \frac{\text{glucose}}{18}}{2}\, \text{with [Na\textsuperscript{+}]} \text{ in mEq/L or mmol/L, and glucose and BUN in mg/dl).}
\]

NB: terms in square brackets [ ] represent the serum concentrations (in mEq/L for electrolytes).

Sodium content. In the diet: usually expressed in grams Na\textsuperscript{+} (not NaCl), a low sodium diet is considered 2 gm of Na\textsuperscript{+} per day or less.

1 teaspoon of table salt (NaCl) has 2.3 gm of Na\textsuperscript{+}.

1 mg NaCl has 17 mEq Na\textsuperscript{+}.

1 mg Na\textsuperscript{+} has 43 mEq Na\textsuperscript{+}.

Normal saline has 0.9 gm of NaCl/100 ml. 3% NaCl has 3 gm NaCl/100 ml.

5.2 Hyponatremia

5.2.1 General information

Key concepts

- definition: serum [Na\textsuperscript{+}] <135 mEq/L. Common etiologies:
  - SIADH: hypotonic hyponatremia (effective serum osmol <275 mOsm/L) with inappropriately high urinary concentration (urine osmol >100 mOsm/L) and euvolemia or hypervolemia
  - cerebral salt wasting (CSW): similar to SIADH but with extracellular fluid volume depletion due to renal sodium loss (urinary [Na\textsuperscript{+}] >20 mEq/L)
- minimum W/U: serum [Na\textsuperscript{+}], serum osmolality, urine osmolality, clinical assessment of volume status. If volume status is high or low: urinary [Na\textsuperscript{+}], TSH (to R/O hypothyroidism)
- treatment: based on acuity, severity, symptoms & etiology; see SIADH (p. 115) or CSW (p. 118) as appropriate
- risk of overly rapid correction: osmotic demyelination (including central pontine myelinolysis)

Classification. [Na\textsuperscript{+}] <135 mEq/L = mild, <130 = moderate, <125 = severe hyponatremia.

Hyponatremia in neurosurgical patients. Chiefly seen in:
- syndrome of inappropriate antidiuretic hormone secretion (p. 114), SIADH (p. 114): dilutional hyponatremia with normal or elevated intravascular volume. The most common type of

*aexcerpted and modified""
Other etiologies of hyponatremia:
- renal failure
- volume overload (e.g. as in congestive heart failure)
- pseudohyponatremia: osmotically active solutes (e.g. glucose, mannitol, marked hyperlipidemia, or hyperproteinemia (which can occur in multiple myeloma)) draw water from cells and also reduce the water fraction of plasma and produce artifically low sodium values (an artifact of indirect lab techniques). For every 100 mg/dl increase of glucose, serum [Na] decreases by 1.6–2.4 mEq/L. It is necessary to measure serum osmolality to rule-out pseudohyponatremia
- postoperative hyponatremia: a rare condition usually described in young, otherwise healthy women undergoing elective surgery and may be related to administration of even only mildly hypotonic fluids (sometimes in modest amounts) and the actions of ADH (which may be increased due to stress, pain or medications)

5.2.2 Evaluation of hyponatremia

Fig. 5.1 shows an algorithm for evaluating the etiology of hyponatremia which drives treatment decisions. Work-up requires assessment of:
1. serum sodium: must be <135 mEq/L to qualify as hyponatremia
2. the effective serum osmolality (AKA tonicity) is shown in Eq (5.2)

\[
\text{effective serum osmolality} = \frac{\text{measured osmolality} - \text{BUN}}{2.8}
\]

and should be used when the blood urea nitrogen (BUN) level is elevated (for a normal [BUN] of 7–18 mg/dl, just subtract 5 from the measured osmolality). Values <275 mOsm/kg indicate hypotonic hyponatremia.

1. urine osmolality: values >100 mOsm/kg are inappropriately high if serum tonicity is <275 mOsm/kg
2. volume status: differentiates SIADH from CSW
   a) clinical assessment: better for hypervolemia (edema, upward trend in patient weights) but is insensitive in identifying extracellular fluid depletion as an etiology of hyponatremia (look for dry mucous membranes, loss of skin turgor, orthostatic hypotension)
   b) normal saline infusion test used in uncertain cases. If baseline urine osmolality is <500 mOsm/kg, it is usually safe to infuse 2 L of 0.9% saline over 24–48 hours. Correction of the hyponatremia suggests extracellular fluid volume depletion was the cause
   c) central venous pressure (CVP) may be used: CVP <5–6 cm H₂O suggests hypovolemia in patients with normal cardiac function

3. check urinary [Na⁺] if volume status is high or low
4. determine duration of hyponatremia:
   a) duration documented as <48 hours is considered acute
   b) hyponatremia of >48 hours duration or of unknown duration is chronic
   c) hyponatremia that occurs outside the hospital is usually chronic and asymptomatic except in marathoners and MDMA (“ecstasy”) drug users

5.2.3 Symptoms

Due to slow compensatory mechanisms in the brain, a gradual decline in serum sodium is better tolerated than a rapid drop. Symptoms of mild ([Na] < 130 mEq/L) or gradual hyponatremia include: anorexia, headache, difficulty concentrating, irritability, dysgeusia and muscle weakness. Severe hyponatremia (<125 mEq/L) or a rapid drop (>0.5 mEq/hr) can cause neuromuscular excitability, cerebral edema, muscle twitching and cramps, nausea/vomiting, confusion, seizures, respiratory arrest and possibly permanent neurologic injury, coma or death.

5.2.4 Syndrome of inappropriate antidiuresis (SIAD)

This term covers excess water retention in the face of hyponatremia, including cases due to inappropriate ADH secretion (SIADH) as well as others without increased circulating levels of ADH (e.g.
heightened response to ADH, certain drugs...). A partial list of etiologies is shown in Table 5.2 (see references for details).

The diagnostic criteria of SIAD is shown in Table 5.3. It is critical to measure serum osmolality to rule-out pseudohyponatremia (p.112), an artifact of indirect lab techniques.
5.2.5 Syndrome of inappropriate antidiuretic hormone secretion (SIADH)

General information

Key concepts

- definition: release of ADH in the absence of physiologic (osmotic) stimuli
- results in hyponatremia with hyperpovolemia (occasionally with euvolemia) with inappropriately high urine osmolality (>100 mOsm/kg of water)
- may be seen with certain malignancies and many intracranial abnormalities
- critical to distinguish from cerebral salt wasting which produces hypovolemia
- treatment: initial guidelines in brief, see details (p.115)
  - avoid rapid correction or overcorrection to reduce risk of osmotic demyelination (p.115). Check serum [Na⁺] q 2-4 hours and do not exceed 1 mEq/L per hour, or 8 mEq/L in 24 hrs or 18 mEq/L in 48 hrs
  - severe ([Na⁺] <125 mEq/L) or severe symptoms: (coma, Sz): start 3% saline at 1-2 mL/kg body weight/hr + furosemide 20 mg IV qd
  - chronic or unknown duration and asymptomatic: fluid restriction (Table 5.4) with dietary salt and protein, and, if necessary, adjuvant drugs (demeclocycline, conivaptan...)

| • abnormal result on water load test:
  a) <80% excretion of 20 ml of water/kg body weight over 5 hours, or
  b) inadequate urinary dilution (<100 mOsm/kg of water) |
| • elevated plasma [ADH] with hyponatremia and euvolemia |

SIADH, AKA Schwartz-Bartter syndrome, was first described with bronchogenic cancer which is one cause of SIAD. SIADH is the release of antidiuretic hormone (ADH), AKA arginine vasopressin (AVP) (p.151), in the absence of physiologic (osmotic) stimuli. Result: elevated urine osmolality, and expansion of the extracellular fluid volume leading to a dilutional hyponatremia which can produce fluid overload (hypervolemia), but SIADH may also occur with euvolemia. For unclear reasons, edema does not occur.

The hyponatremia of SIADH must be differentiated from that due to cerebral salt wasting (CSW) due to differences in treatment recommendations (p.118).

Etiologies: Table 5.2.
Diagnosis of SIADH

In general, 3 diagnostic criteria are: hyponatremia, inappropriately concentrated urine, and no evidence of renal or adrenal dysfunction. In more detail:

1. low serum sodium (hyponatremia): usually <134 mEq/L
2. low effective serum osmolality: <275 mOsm/L
3. high urinary sodium (salt wasting): at least >18 mEq/L, often 50–150. Note: there has not been an adequate explanation of the high urinary sodium in SIADH
4. high ratio of urine:serum osmolality: often 1.5–2.5:1, but may be 1:1
5. normal renal function (check BUN & creatinine): BUN commonly <10
6. normal adrenal function (no hypotension, no hyperkalemia)
7. no hypothyroidism
8. no signs of dehydration or overhydration (in many patients with acute brain disease, there is significant hypovolemia often due to CSW (p.118) and as this is a stimulus for ADH secretion, the ADH release may be “appropriate”10). In uncertain cases, the normal saline infusion test (p.112) may be used.

If further testing is required, the following are options, but are rarely recommended:

1. measure serum or urinary levels of ADH. Rarely indicated since urine osmolality >100 mOsm/kg is usually sufficient to indicate excessive ADH.1 ADH is normally undetectable in etiologies of hyponatremia other than SIADH
2. water-load test: considered to be the definitive test.11 The patient is asked to consume a water load of 20 ml/kg up to 1500 ml. In the absence of adrenal or renal insufficiency, the failure to excrete 65% of the water load in 4 hrs or 80% in 5 hrs indicates SIAD.

CONTRAINDICATIONS: this test is dangerous if the starting serum [Na+] is ≤124 mEq/L or if the patient has symptoms of hyponatremia

Symptoms of SIADH

Symptoms of SIADH are those of hyponatremia (p.112) and possibly fluid overload. If mild, or if descent of [Na+] is gradual, it may be tolerated. [Na+]<120–125 mEq/L is almost always symptomatic. These patients often have a paradoxical (inappropriate) thirst.

Treatment of hyponatremia with SIADH

Management is based on the severity and duration of hyponatremia, and the presence of symptoms. Two caveats:

1. be sure that hyponatremia is not due to CSW (p.118) before restricting fluids
2. avoid too rapid correction and avoid correcting to normal or supranormal (overcorrection) sodium to reduce the risk of osmotic demyelination syndrome

Osmotic demyelination syndrome

A complication associated with some cases of treatment for hyponatremia. While excessively slow correction of acute hyponatremia is associated with increased morbidity and mortality,12 some cases of inordinately rapid treatment have been associated with osmotic demyelination syndrome (which includes central pontine myelinolysis (CPM) a rare disorder of pontine white matter13 ( Fig. 5.2) and extrapontine myelinolysis ( Fig. 5.3), as well as other areas of cerebral white matter). First described in alcoholics,14 producing insidious flaccid quadriplegia, mental status changes, and cranial nerve abnormalities with a pseudobulbar palsy appearance. In one review,15 no patient developed CPM when treated slowly as
outlined below. And yet, the rate of correction correlates poorly with CPM; it may be that the magnitude is another critical variable.\textsuperscript{16} Features common to patients who develop CPM are:\textsuperscript{15}

- delay in the diagnosis of hyponatremia with resultant respiratory arrest or seizure with probable hypoxemic event
- rapid correction to normo- or hyper-natremia (>135 mEq/L) within 48 hours of initiating therapy
- increase of serum sodium by > 25 mEq/L within 48 hours of initiation of therapy
- over-correcting serum sodium in patients with hepatic encephalopathy
- NB: many patients developing CPM were victims of chronic debilitating disease, malnourishment, or alcoholism and never had hyponatremia. Many had an episode of hypoxia/anoxia\textsuperscript{17}
- presence of hyponatremia >24 hrs prior to treatment\textsuperscript{16}

The only definitive treatment is treatment of the underlying cause
- if caused by anemia: usually responds to transfusion
- if caused by malignancy, may respond to antineoplastic therapy
- most drug related cases respond rapidly to discontinuation of the offending drug

Treatment algorithms

Fig. 5.4 depicts an algorithm for selecting the correct SIADH treatment protocol.

Aggressive treatment protocol. Indications (also refer to Fig. 5.4):
1. severe hyponatremia (serum [Na\textsuperscript{+}] < 125 mEq/L)
2. AND either
   a) duration known to be <48 hours
   b) or severe symptoms (coma, seizures)

Treatment
- transfer patient to ICU
- interventions
  - 3% saline: start infusion 1–2 ml/kg body weight per hour (infusion rate may be doubled to 2–4 ml/kg/hr for limited periods in patients with coma or seizures\(^1\))
  - and furosemide (Lasix\(^\circledR\)) 20 mg IV q d (furosemide accelerates the increase in [Na\(^+\)] and prevents volume overload with subsequent increase in atrial natriuretic factor and resultant urinary dumping of the extra Na\(^+\) being administered)
- monitoring and adjustments
  - check serum [Na\(^+\)] every 2–3 hours and adjust infusion rate of 3% saline
    - goal: raise serum sodium by 1–2 mEq/L/hr\(^1\) (use lower end of range for hyponatremia >48 hours duration or unknown duration)
    - limits: do not exceed 8–10 mEq/L in 24 hrs and 18–25 mEq/L in 48 hrs\(^1\) (use lower end of these ranges for hyponatremia >48 hours duration or unknown duration)
  - measure K\(^+\) lost in urine and replace accordingly
- if symptoms of osmotic demyelination occur (early symptoms are lethargy and affective changes, usually after initial improvement): deficits may improve by stopping treatment and modestly lowering the serum sodium e.g. with DDAVP

Intermediate treatment protocol. Indications (also refer to Fig. 5.4):
1. symptomatic nonsevere hyponatremia (serum \([\text{Na}^+]\) = 125–135 mEq/L), or
2. severe hyponatremia (serum \([\text{Na}^+]\) < 125 mEq/L), AND
   a) duration > 48 hours or unknown AND
   b) only moderate symptoms or nonspecific symptoms (e.g. H/A, or lethargy)

Treatment
1. interventions
   a) 0.9% saline (normal saline) infusion
   b) and furosemide (Lasix®) 20 mg IV q d
   c) consider conivaptan for refractory cases
2. monitoring: check serum \([\text{Na}^+]\) every 4 hours and adjust infusion rate of normal saline
3. goals: \([\text{Na}^+]\) increase of 0.5–2 mEq/L/hr
4. limits: do not exceed 8–10 mEq/L in 24 hrs and 18–25 mEq/L in 48 hrs

Routine treatment protocol and maintenance therapy. Indications (also refer to Fig. 5.4):
1. asymptomatic nonsevere hyponatremia (serum \([\text{Na}^+]\) = 125–135 mEq/L), or
2. severe hyponatremia (serum \([\text{Na}^+]\) < 125 mEq/L) AND
   a) duration > 48 hours or unknown AND
   b) asymptomatic

Treatment
1. interventions
   a) fluid restriction Table 5.4 for adults, for peds: 1 L/m^2/day) while encouraging use of dietary salt and protein. Caution restricting fluids in hyponatremia following SAH (p. 1166).
   b) for refractory cases, consider
      1. demeclocycline: a tetracycline antibiotic that partially antagonizes the effects of ADH on the renal tubules.\textsuperscript{21,22,23} Effects are variable, and nephrotoxicity may occur. 300–600 mg PO BID
      2. conivaptan (Vaprisol®): a nonpeptide antagonist of V1A & V2 vasopressin receptors. FDA approved for euvoletic and hypervolemic moderate-to-severe hyponatremia in hospitalized patients (NB: severe symptoms of seizures, coma, delirium... warrants aggressive treatment with hypertonic saline\textsuperscript{1}). Use in the neuro-ICU has been described for treating elevated ICP when serum \([\text{Na}^+]\) is not responding to traditional methods\textsuperscript{24} (off-label use – use with caution). loading dose 20 mg IV over 30 minutes, followed by infusions of 20 mg over 24 hours × 3 days. If serum \([\text{Na}^+]\) are not rising as desired, the infusion may be increased to the maximal dose of 40 mg over 24 hours. Use is approved for up to 4 days total. Caution re drug interactions
         • lithium: not very effective and many side effects. Not recommended

5.2.6 Cerebral salt wasting

Cerebral salt wasting (CSW): renal loss of sodium as a result of intracranial disease, producing hyponatremia and a decrease in extracellular fluid volume.\textsuperscript{11} CAUTION: patients with aneurysmal SAH may have CSW with hyponatremia which mimics SIADH, however there is usually also hypovolemia in CSW. In this setting, fluid restriction may exacerbate vasospasm induced ischemia.\textsuperscript{11,25,26,27}

The mechanism whereby the kidneys fail to conserve sodium in CSW is not known, and may be either a result of an as yet unidentified natriuretic factor or direct neural control mechanisms (see Hyponatremia following SAH (p. 1166)).

Laboratory tests (serum and urinary electrolytes and osmolalities) may be identical with SIADH and CSW.\textsuperscript{28} Furthermore, hypovolemia in CSW may stimulate ADH release. To differentiate: CVP, PCWP, and plasma volume (a nuclear medicine study) are low in hypovolemia (i.e. CSW). Table 5.5 compares some features of CSW and SIADH, the two most important differences being extracellular volume and salt balance. An elevated serum \([\text{K}^+]\) with hyponatremia is incompatible with the diagnosis of SIADH.

Treatment of CSW
- Goals:
  - volume replacement
  - positive salt balance

\textsuperscript{11,25,26,27}
avoid excessively rapid correction of hyponatremia or overcorrection which may be associated with osmotic demyelination (p.115) as with SIADH (p.115).

- **Interventions**
  - Hydrate patient with 0.9% NS at 100–125 ml/hr. For severe cases, 3% saline at 25–50 cc/hr is occasionally required.
  - Do not give furosemide.
  - Salt may also be simultaneously replaced orally.
  - Blood products may be needed if anemia is present.
  - **Medications**
    a) Fludrocortisone acetate acts directly on the renal tubule to increase sodium absorption. Benefits of giving 0.2 mg IV or PO q d in CSW have been reported, but significant complications of pulmonary edema, hypokalemia and HTN may occur.
    b) Urea: an alternative treatment using urea may be applicable to the hyponatremia of either SIADH or CSW, and therefore may be used before the cause has been ascertained: urea (Ureaphil®) 0.5 grams/kg (dissolve 40 gm in 100–150 ml NS) IV over 30–60 mins q 8 hrs. Use NS+20 mEq KCl/L at 2 ml/kg/hr as the main IV until the hyponatremia is corrected (unlike mannitol, urea does not increase ADH secretion). They supplemented with colloids (viz. 250 ml of 5%albumin IV q 8–12 hrs x 72 hrs).

### 5.3 Hypernatremia

#### 5.3.1 General information

Definition: serum sodium >150 mEq/L. In neurosurgical patients, this is most often seen in the setting of diabetes insipidus (DI).

Since normal total body water (TBW) is ≈ 60% of the patient’s normal body weight, the patient’s current TBW may be estimated by Eq (5.3).
The free water deficit to be replaced is given by Eq (5.4). Correction must be made slowly to avoid exacerbating cerebral edema. One half the water deficit is replaced over 24 hours, and the remainder is given over 1–2 additional days. Judicious replacement of deficient ADH in cases of true DI must also be made.

5.3.2 Diabetes insipidus

General information

Key concepts

- due to low levels of ADH (or, rarely, renal insensitivity to ADH)
- high output of dilute urine (<200 mOsmol/L or SG < 1.003) with normal or high serum osmolality and high serum sodium
- often accompanied by craving for water, especially ice-water
- danger of severe dehydration if not managed carefully

Diabetes insipidus (DI) is due to insufficient ADH activity at the kidneys, and results in the excessive renal loss of water and electrolytes. DI may be produced by two different etiologies:

- central or neurogenic DI: subnormal levels of ADH caused by hypothalamic-pituitary axis dysfunction. This is the type most often seen by neurosurgeons
- “nephrogenic DI”: due to relative resistance of the kidney to normal or supra-normal levels of ADH. Seen with some drugs (drugs: l)

Etiologies of DI:\n
1. (neurogenic AKA central) diabetes insipidus
   a) familial (autosomal dominant)
   b) idiopathic
   c) posttraumatic (brain injury, including surgery)
   d) tumor: craniopharyngioma, metastasis, lymphoma...
   e) granuloma: neurosarcoidosis, histiocytosis
   f) infectious: meningitis, encephalitis
   g) autoimmune
   h) vascular: aneurysm, Sheehan’s syndrome (rarely causes DI)

2. nephrogenic diabetes insipidus
   a) familial (X-linked recessive)
   b) hypokalemia
   c) hypercalcemia
   d) Sjögren’s syndrome
   e) drugs: lithium, demeclocycline, colchicine...
   f) chronic renal disease: pyelonephritis, amyloidosis, sickle cell disease, polycystic kidney disease, sarcoidosis

Central DI

85% of ADH secretory capacity must be lost before clinical DI ensues. Characteristic features: high urine output (polyuria) with low urine osmolality, and (in the conscious patient) craving for water (polydipsia), especially ice-water.
**Differential diagnosis of DI:**

1. (neurogenic) diabetes insipidus (true DI)
2. nephrogenic diabetes insipidus
3. psychogenic
   a) idiopathic: from resetting of the osmostat
   b) psychogenic polydipsia (excess free water intake)
4. osmotic diuresis: e.g. following mannitol, or with renal glucose spilling
5. diuretic use: furosemide, hydrochlorothiazide...

Central DI may be seen in the following situations:

1. following transsphenoidal surgery or removal of craniopharyngioma: (usually transient, therefore avoid long-acting agents until it can be determined if long-term replacement is required). Injury to the posterior pituitary or stalk usually causes one of three patterns of DI:
   a) transient DI: supra-normal urine output (UO) and polydipsia which typically normalizes ≈ 12–36 hrs post-op
   b) “prolonged” DI: UO stays supra-normal for prolonged period (may be months) or even permanently: only about one-third of these patients will not return to near-normal at one year post-op
   c) “triphasic response”: least common
      • phase 1: injury to pituitary reduces ADH levels for 4–5 days → DI (polyuria/polydipsia)
      • phase 2: cell death liberates ADH for the next 4–5 days → transient normalization or even SIADH-like water retention (NB: there is a danger of inadvertently continuing vasopressin therapy beyond the initial DI phase into this phase causing significant hemodilution)
      • phase 3: reduced or absent ADH secretion → either transient DI (as in “A” above) or a “prolonged” DI (as in “B” above)
2. central herniation (p.303): shearing of pituitary stalk may occur
3. brain death: hypothalamic production of ADH ceases
4. with certain tumors:
   a) pituitary adenomas: DI is rare even with very large macroadenomas. DI may occur with pituitary apoplexy (p.720)
   b) craniopharyngioma: DI usually only occurs postoperatively since damage to pituitary or lower stalk does not prevent production and release of ADH by hypothalamic nuclei
   c) suprasellar germ cell tumors
d) rarely with a colloid cyst
   e) hypothalamic tumors: Langerhans cell histiocytosis
5. mass lesions pressing on hypothalamus: e.g. a-comm aneurysm
6. following head injury: primarily with basal (clival) skull fractures (p.884)
7. with encephalitis or meningitis
8. drug induced:
   a) ethanol and phenytoin can inhibit ADH release
   b) exogenous steroids may seem to “bring out” DI because they may correct adrenal insufficiency (below) and they inhibit ADH release
9. granulomatous diseases
   a) Wegener’s granulomatosis (p.199): a vasculitis
   b) neurosarcoidosis involving the hypothalamus (p.189)
10. inflammatory: autoimmune hypophysitis (p.1373) or lymphocytic infundibuloneurohypophysitis (distinct conditions)

**Diagnosis**

The following are usually adequate to make the diagnosis of DI, especially in the appropriate clinical setting:

1. dilute urine:
   a) urine osmolality < 200 mOsm/L (usually 50–150) or specific gravity (SG) < 1.003 (may be 1.001 to 1.005). (Note that normally, urine osmolality averages between 500–800 mOsm/L; extreme range: 50–1400.)
   b) or the inability to concentrate urine to > 300 mOsm/L in the presence of clinical dehydration
   c) NB: large doses of mannitol as may be used in head trauma can mask this by producing a more concentrated urine
2. urine output (UO) > 250 cc/hr (peds: > 3 cc/kg/hr)
3. normal or above-normal serum sodium
4. normal adrenal function: DI cannot occur in primary adrenal insufficiency because a minimum of mineralocorticoid activity is needed for the kidney to make free water, thus steroids may "bring out" underlying DI by correcting adrenal insufficiency.

In uncertain cases, plot urine and simultaneous serum osmolality on the graph in Fig. 5.5.
1. low serum osmolality: usually indicates psychogenic polydipsia (pathological drinking of water)
2. if the point falls in the "normal" range, a supervised water deprivation test is needed to determine if the patient can concentrate their urine with dehydration (caution: see below)
3. high serum osmolality:
   - diagnosis of DI is established and no further testing to establish the diagnosis is required
   - further testing is only needed to differentiate central from nephrogenic DI, if desired to differentiate central from nephrogenic DI, give aqueous Pitressin® 5 U SQ
   - in central DI the urine osmolality should double within 1–2 hours
4. plotting more than one data point may help as some patients tend to "vacillate" around the border zones

Water deprivation test
If still unclear, the diagnosis of DI is confirmed by a water deprivation test (CAUTION: perform only under close supervision as rapid and potentially fatal dehydration may ensue in DI). This test is rarely necessary if serum osmolality >298 mOsm/L (Note that in compensated DI, serum osmolality is more likely to be lower and to overlap with normal).35
Stop IVs and make the patient NPO

Monitoring:
- check urine osmolality q hr
- check patient weight q 1 hr

Continue the test until one of the following occurs:
- normal response occurs: urine output decreases, and urine osmolality rises to 600–850 mOsm/L
- 6–8 hours lapse
- urine osmolality plateaus (i.e. changes <30 mOsm in 3 consecutive hours)
- patient loses 3% of body weight

If the patient fails to demonstrate the normal response, then:
- give exogenous ADH (5 U aqueous Pitressin® SQ), which normally increases urine osmolality to >300 mOsm/L
- check urine osmolality 30 and 60 minutes later
- compare highest urine osmolality after Pitressin® to the osmolality just before Pitressin® according to Table 5.6

Treatment of DI

In conscious ambulatory patient
If DI is mild, and the patient’s natural thirst mechanism is intact, instruct patient to drink only when thirsty and they usually “keep up” with losses and will not become overhydrated.

If severe, the patient may not be able to maintain adequate intake of fluid or tolerate the frequent trips to bathroom. In these cases, treatment typically involves a vasopressin analogue. See below for a synopsis of vasopressin analogues. Typically start with either:

1. desmopressin (DDAVP®)
   a) PO: 0.1 mg PO BID, adjust up or down PRN urine output (typical dosage range: 0.1–0.8 mg/d in divided doses)
   b) nasal spray: 2.5 mcg (0.025 ml) by nasal insufflation BID, titrate up to 20 mcg BID as needed (the nasal spray may be used for doses that are multiples of 10 mcg)

   OR

2. ADH enhancing medications (works primarily in chronic partial ADH deficiency. Will not work in total absence of ADH)
   - clofibrate (Atromid S®) 500 mg PO QID
   - chlorpropamide: increases renal sensitivity to ADH
   - hydrochlorothiazide: thiazide diuretics may act by depleting Na+ which increases reabsorption in proximal tubules and shifting fluid away from distal tubules which is where ADH works.

   e.g. Dyazide® 1 PO q d (may increase up to 2 per day PRN)

In conscious ambulatory patient with impaired thirst mechanisms
If thirst mechanisms are not intact in conscious ambulatory patient, they run the risk of dehydration or fluid overload. For these patients:

1. have patient follow UO and daily weights, balance fluid intake and output using antidiuretic medication as needed to keep UO reasonable
2. check serial labs (approximately q weekly) including serum sodium, BUN

In non-ambulatory, comatose/stuporous, or brain-dead patient; see also Medical Management of the Potential Organ Donor (p.313)

1. follow IVs & O’s q 1 hr, with urine specific gravity (SG) q 4 hrs and whenever urine output (UO)> 250 ml/hr
2. labs: serum electrolytes with osmolality q 6 hrs

Table 5.6: Highest urinary osmolality after Pitressin in water deprivation test
3. IV fluid management:

**BASE IV:** D5 1/2 NS + 20 mEq KCl/L at appropriate rate (75–100 ml/hr)

**PLUS:** replace UO above base IV rate ml for ml with 1/2 NS

**NB:** for post-op patients, if the patient received significant intraoperative fluids, then they may have an appropriate post-op diuresis, in this case use 1/2 NS to replace only ≈ 2/3 of UO that exceeds the basal IV rate

4. if unable to keep up with fluid loss with IV (or NG) replacement (usually with UO > 300 ml/hr), then EITHER
   - 5 U arginine vasopressin (aqueous Pitressin®) IVP/IM/SQ q 4–6 hrs (avoid tannate oil suspension due to erratic absorption and variable duration)
   - vasopressin IV drip: start at 0.2 U/min & titrate (max: 0.9 U/min)
   - desmopressin injection SQ/IV titrated to UO, usual adult dose: 0.5–1 ml (2–4 mcg) daily in 2 divided doses

Vasopressin analogues

Table 5.6, Table 5.7 and Table 5.8 shows dosing forms and duration of action of vasopressin analogues.

*a provided by Arnold M. Moses, M.D., used with permission

b onset of antidiuretic action of these preparations is 30–45 minutes following administration (except pituitary powder in oil which takes 2–4 hrs to start working)

c times may vary from patient to patient, but are usually consistent in any individual

d Note: 1 mcg BID of desmopressin is as effective as 4 mcg q d, but would obviously be less expensive
References

Pitressin® is aqueous solution of 8-arginine vasopressin and should be used with caution in patients with vascular disease (especially coronary arteries). Caution soundalikes: sometimes pitocin is confused with pitressin because of similarities of the name.

DDAVP (1-deamino-8-D-arginine vasopressin) AKA desmopressin. More potent and longer acting than vasopressin.
6 General Neurocritical Care

6.1 Parenteral agents for hypertension

**Drug info: Nicardipine (Cardene®)**

Calcium channel blocker (CCB) that may be given IV. Does not require arterial line, does not raise ICP. Does not reduce heart rate, but may be used in conjunction with e.g. labetalol or esmolol if that is desired. Side effects: H/A 15% nausea 5% hypotension 5% reflex tachycardia 3.5%

Start at 5 mg/hr IV (off label: 10 mg/hr may be used in situations where urgent reduction is needed). Increase by 2.5 mg/hr every 5–15 minutes up to a maximum of 15 mg/hr. Decrease to 3 mg/hr once control is achieved. Ampules contain 25 mg and must be diluted before administration.

**Drug info: Nitroglycerin (NTG)**

Raises ICP (less than with nitroprusside due to preferential venous action). Vasodilator, venous > arterial (large coronaries > small). Result: decreases IV filling pressure (pre-load). Does not cause “coronary steal” (cf nitroprusside).

10–20 mcg/min IV drip (increase by 5–10 mcg/min q 5–10 min). For angina pectoris: 0.4 mg SL q 5 min x 3 doses, check BP before each dose.

**Drug info: Labetalol (Normodyne®, Trandate®)**

Blocks α₁ selective, β non-selective (potency < propranolol). ICP reduces or no change. Pulse rate: decreases or no change. Cardiac output does not change. Does not exacerbate coronary ischemia. May be used in controlled CHF, but not in overt CHF. Contraindicated in asthma. Renal failure: same dose. Side effects: fatigue, dizziness, orthostatic hypotension.

**Intravenous (IV)**

Onset 5 mins, peak 10 mins, duration 3–6 hrs.

IV: patient supine; check BP q 5 min; give each dose slow IVP (over 2 min) q 10 minutes until desired BP achieved; dose sequence: 20, 40, 80, 80; then 80 mg (300 mg total). Once controlled, use same total dose IVP q 8 hrs.

IV drip (alternative): add 40 ml (200 mg) to 160 ml of IVF (result: 1 mg/ml); run at 2 ml/min (2 mg/min) until desired BP (usual effective dose = 50–200 mg) or until 300 mg given; then titrate rate (bradycardia limits dose, increase slowly since effect takes 10–20 minutes).

Oral (PO)

Undergoes first pass liver degradation, therefore requires higher doses PO. PO onset: 2 hrs, peak: 4 hrs.

PO: to convert IV → PO, start with 200 mg PO BID. To start with PO, give 100 mg BID, and increase 100 mg/dose q 2 day; max. = 2400 mg/day.

**Drug info: Enalaprilat (Vasotec®)**

An angiotensin-converting enzyme (ACE) inhibitor. The active metabolite of the orally administered drug enalapril (see below). Acts within ≈ 15 mins of administration.

Side effects: hyperkalemia occurs in ≈ 1% Do not use during pregnancy.

IV: start with 1.25 mg slow IV over 5 mins, may increase up to 5 mg q 6 hrs PRN.
Drug info: Esmolol (Brevibloc®)

Cardioselective short-acting beta blocker.\footnote{\textsuperscript{3}} Being investigated for hypertensive emergencies. Metabolized by RBC esterase. Elimination half-life: 9 mins. Therapeutic response (\textgreater 20\% decrease in heart rate, HR \textless 100, or conversion to sinus rhythm) in 72\% Side effects: dose related hypotension (in 20–50\%), generally resolves within 30 mins of D/C. Bronchospasm less likely than other beta blockers. Avoid in CHF.

\[500 \, \text{mcg/kg loading dose over 1 min, follow with 4 min infusion starting with 50 mcg/kg/min. Repeat loading dose and increment infusion rate by 50 mcg/kg/min q 5 mins. Rarely \textgreater 100 mcg/kg/min required. Doses >200 mcg/kg/min add little.}\]

Drug info: Fenoldopam (Corlopam®)

Vasodilator. Onset of action < 5 minutes, duration 30 mins.

IV infusion (no bolus doses): start with 0.1–0.3 mcg/kg/min, titrate by 0.1 mcg/kg/min q 15 min up to a maximum of 1.6 mcg/kg/min.

Drug info: Propranolol (Inderal®)

Main use IV is to counteract tachycardia with vasodilators (usually doesn’t lower BP acutely when used alone), but esmolol and labetalol are more commonly used for this.

IV: load with 1–10 mg slow IVP, follow with 3 mg/hr. PO: 80–640 mg q d in divided doses.

6.2 Hypotension (shock)

6.2.1 Classification

1. hypovolemic: first sign usually tachycardia. \(20–40\%\) of blood volume loss must occur before perfusion of vital organs is impaired. Includes:
   a) hemorrhage (external or internal)
   b) bowel obstruction (with third spacing)
2. septic: most often due to gram negative sepsis
3. cardiogenic: includes MI, cardiomyopathy, dysrhythmias (including A-fib)
4. neurogenic: e.g. paralysis due to spinal cord injury. Blood pools in venous capacitance vessels
5. miscellaneous
   a) anaphylaxis
   b) insulin reaction

6.2.2 Cardiovascular agents for shock

Plasma expanders. Includes:
1. crystalloids: normal saline has less tendency to promote cerebral edema than others; see IV fluids (p. 870), under control of elevated ICP
2. colloids: e.g. hetastarch (Hespan®). \textbf{CAUTION:} repeated administration over a period of days may prolong PT/PTT and clotting times and may increase the risk of rebleeding in aneurysmal SAH (p. 1167).\footnote{\textsuperscript{4}}
3. blood products: expensive. Risk of transmissible diseases or transfusion reaction
Drug info: Dopamine

See Table 6.1 for a summary of the effects of dopamine (DA) at various dosages. DA is primarily a vasoconstrictor ($\beta_1$ effects usually overridden by $\alpha$-activity). 25% of dopamine given is rapidly converted to norepinephrine (NE). At doses $>10$ mcg/kg/min one is essentially giving NE. May cause significant hyperglycemia at high doses.

Start with 2–5 mcg/kg/min and titrate.

<table>

</tr>
</tbody>
</table>

Table 6.1 Dopamine dosage

Drug info: Dobutamine (Dobutrex®)

Vasodilates by $\beta_1$ (primary) and by increased CO from (+) inotropy ($\beta_2$); result: little or no fall in BP, less tachycardia than DA. No alpha release nor vasoconstriction. May be used synergistically with nitroprusside. Tachyphylaxis after $\approx 72$ hrs. Pulse increases $>10\%$ may exacerbate myocardial ischemia, more common at doses $>20$ mcg/kg/min. Optimal use requires hemodynamic monitoring. Possible platelet function inhibition.

Usual range 2.5–10 mcg/kg/min; rarely doses up to 40 used (to prepare: put 50 mg in 250 ml D5 W to yield 200 mcg/ml).

Drug info: Amrinone (Inocor®)

Nonadrenergic cardiotonic. Phosphodiesterase inhibitor, effects similar to dobutamine (including exacerbation of myocardial ischemia). 2% incidence of thrombocytopenia.

0.75 mg/kg initially over 2–3 min, then drip 5–10 mcg/kg/min.

Drug info: Phenylephrine (Neo-Synephrine®)

Pure alpha sympathomimetic. Useful in hypotension associated with tachycardia (atrial tachyarrhythmias). Elevates BP by increasing SVR via vasoconstriction, causes reflex increase in parasympathetic tone (with resultant slowing of pulse). Lack of $\beta$ action means non-inotropic, no cardiac acceleration, and no relaxation of bronchial smooth muscle. Cardiac output and renal blood flow may decrease. Avoid in spinal cord injuries (p. 950).

Pressor range: 100–180 mcg/min; maintenance: 40–60 mcg/min. To prepare: put 40 mg (4 amps) in 500 ml D5 W to yield 80 mcg/ml; a rate of 8 ml/hr = 10 mcg/min.

Drug info: Norepinephrine

Primarily vasoconstrictor (? counterproductive in cerebral vasospasm, ? decreases CBF). $\beta$-agonist at low doses. Increases pulmonary vascular resistance.
6.3 Acid inhibitors

6.3.1 Stress ulcers in neurosurgery

See reference.5

The risk of developing stress ulcers (SU) AKA Cushing’s ulcers is high in critically ill patients with CNS pathology. These lesions are AKA Cushing’s ulcers due to Cushing’s classic treatise.6 17% of SUs produce clinically significant hemorrhage. CNS risk factors include intracranial pathology: brain injury (especially Glasgow Coma scale score <9), brain tumors, intracerebral hemorrhage, SIADH, CNS infection, ischemic stroke, as well as spinal cord injury. The odds are increased with the coexistence of extra-CNS risk factors including: long-term use of steroids (usually >3 weeks), burns >25% of body surface area, hypotension, respiratory failure, coagulopathies, renal or hepatic failure and sepsis.

The pathogenesis of SUs is incompletely understood, but probably results from an imbalance of destructive factors (acid, pepsin & bile) relative to protective factors (mucosal blood flow, mucus-bicarbonate layer, endothelial cell replenishment & prostaglandins).5 CNS pathology, especially that involving the diencephalon or brain stem, can lead to reduction of vagal output which leads to hypersecretion of gastric acid and pepsin. There is a peak in acid and pepsin production 3–5 days after CNS injury.

6.3.2 Prophylaxis for stress ulcers

There is strong evidence that reduction of gastric acid (whether by antacids or agents that inhibit acid secretion) reduces the incidence of GI bleeding from stress ulcers in critically ill patients. Elevating gastric pH >4.5 also inactivates pepsin.

Other therapies that don’t involve alterations of pH that may be effective include sucralfate (see below) and enteral nutrition (controversial).5 Titrated antacids or sucralfate appear to be superior to H2 antagonists in reducing the incidence of SUs.

Routine prophylaxis when steroids are used is not warranted unless one of the following risk factors are present: prior PUD, concurrent use of NSAIDs, hepatic or renal failure, malnourishment, or prolonged steroid therapy >3 weeks.

6.3.3 Possible increased pneumonia and mortality from altering gastric pH

Whereas bringing gastric pH to a more neutral level reduces the risk of SUs, pH >4 permits bacterial colonization of the normally sterile stomach. This may increase the risk of pneumonia from aspiration, and there is a suggestion that mortality may also be increased.7 Sucralfate may be as effective
in reducing bleeding, but may be associated with lower rates of pneumonia and mortality. There is insufficient data to determine the net result of sucralfate compared to no treatment.7

### 6.3.4 Histamine2 (H2) antagonists

**Drug info: Ranitidine (Zantac®)**

- Adult age ≤ 65 yrs: 150 mg PO BID, or 50 mg IVPB q 8 hrs. For age > 65 with normal renal function: 50 mg IV q 12 hrs.
- IV drip (provides a more consistently higher pH without peaks and troughs; some controversy that this may increase gastric bacterial concentration with increased risk of aspiration pneumonia has not been borne out): 6.25 mg/hr (e.g., inject 150 mg into 42 ml of IVF yielding 3.125 mg/ml, run at 2 ml/hr).

**Drug info: Famotidine (Pepcid®)**

- Adult: 20 mg PO q hs for maintenance; 40 mg PO q hs for active ulcer therapy; IV: 20 mg q 12 hrs (for hypersecretory conditions, 20 mg IVPB q 6 hrs). Supplied: 20 & 40 mg tablets, 40 mg/ml suspension, and 20 & 40 mg orally disintegrating tablets as Pepcid RPD. Available OTC in 10 mg tablets as Pepcid AC. Available IV.

**Drug info: Nizatidine (Axid®)**

- 300 mg PO q d or 150 mg PO BID. Supplied: 150 & 300 mg pulvules. Available OTC in 75 mg tablets as Axid AR.

### 6.3.5 Gastric acid secretion inhibitors (proton pump inhibitors)

These agents reduce gastric acid by specific inhibition of the final step in acid secretion by gastric parietal cells (by inhibiting the (H⁺, K⁺)-ATPase enzyme system on the cell surface, the so-called “acid pump”). They block acid secretion regardless of the stimulus (Zollinger-Ellison syndrome, hypergastrinemia…). Full recovery of acid secretion upon discontinuation may not occur for weeks. Not indicated for long-term treatment as the trophic effects of the resultant elevated levels of gastrin may lead to gastric carcinoid tumors.

**Drug info: Omeprazole (Prilosec®)**

- Inhibition of some hepatic P-450 enzymes results in reduced clearance of warfarin and phenytoin. Decreases the effectiveness of prednisone.
- Adult: for peptic ulcers and gastro-esophageal reflux disease (GERD) 20–40 mg PO daily. For Zollinger-Ellison syndrome: 20 mg PO q d to 120 mg PO TID (dose adjusted to keep basal acid output < 60 mEq/hr). Side effects: N/V, H/A, diarrhea, abdominal pain or rash in 1–5% of patients. Supplied: 10, 20 & 40 mg delayed-release capsules. Available OTC in 20.6 mg tablets as Prilosec OTC.
Drug info: **Lansoprazole (Prevacid®)**

Found not to have an affect on a number of other drugs metabolized by cytochrome P-450 including: phenytoin, warfarin and prednisone.  
**Adult:** 15 mg (for duodenal ulcer, GERD, or maintenance therapy) or 30 mg (for gastric ulcer or erosive esophagitis) PO q d, short-term treatment × 4 wks. Supplied: 15 & 30 mg delayed-release capsules.

---

Drug info: **Pantoprazole (Protonix®)**

PO: 40 mg PO q d for up to 8 wks. IV: 40 mg IV q d × 7–10 d. Supplied: PO: 40 mg delayed-release capsules.

---

**6.3.6 Miscellaneous**

Drug info: **Sucralfate (Carafate®)**

Minimally absorbed from GI tract. Acts by coating ulcerated areas of mucosa, does not inhibit acid secretion. This may actually result in a lower incidence of pneumonia and mortality than agents that affect gastric pH (see above).  
1 gm PO QID on an empty stomach. Do not give antacids within one half-hour of sucralfate.

---

**References**

7 Sedatives, Paralytics, Analgesics

7.1 Sedatives and paralytics

7.1.1 Richmond agitation-sedation scale (RASS)

A validated scale\textsuperscript{1,2} that uses positive numbers for agitation and negative numbers for sedation as shown in Table 7.1. Useful for quantitating the desired level of sedation when titrating sedatives for agitated patients.

Procedure for performing RASS assessment:
1. on observation, patient is alert, restless or agitated: score 0 to +4
2. if patient is not alert, state patient’s name and verbally instruct to open eyes and look at speaker: score −1 to −3
3. if no response to verbal stimulus, physically stimulate by shaking shoulder and/or sternal rub: score −4 or −5

7.1.2 Conscious sedation

Use of these agents requires ability to provide immediate emergency ventilatory support (including intubation). Agents include:
1. midazolam (Versed®) (p.870) with fentanyl
2. fentanyl
3. pentobarbital (Nembutal®): a barbiturate. for 70 kg adult: 100 mg slow IVP

Drug info: Methohexital (Brevital®)

More potent and shorter acting than thiopental (useful e.g. for percutaneous rhizotomy where patient needs to be sedated and awakened repeatedly). Lasts 5–7 min. Similar cautions with the added problem that methohexital may induce seizures. May no longer be available in the U.S.

Adult: 1 gm% solution (add 50 ml diluent to 500 mg to yield 10 mg/ml), 2 ml test dose, then 5–12 ml IVP at rate of 1 ml/5 secs, then 2 to 4 ml q 4–7 min PRN.

7.1.3 Sedation

Generally requires intubation and mechanical ventilatory support in the ICU. Doses are generally lower than those used by anesthesiologists for general anesthesia.

**Drug info: Thiopental (Pentothal®)**

A short acting barbiturate. 1st dose causes unconsciousness in 20–30 secs (circulation time), depth increases up to 40 secs, duration = 5 mins (terminated by redistribution), consciousness returns over 20–30 mins.

Side effects: dose related respiratory depression, irritation if extravasated, intra-arterial injection →necrosis, agitation if injected slowly, an antianalgesic, myocardial depressant, hypotension in hypovolemic patients.

Adult: initial concentration should not exceed 2.5%
give 50 mg test dose moderately rapid IV, then if tolerated give 100–200 mg IV over 20–30 secs (500 mg may be required in large patient).

**Drug info: Remifentanil (Ultiva®)**

Ultrashort acting micro-opioid receptor agonist. Potency similar to fentanyl. Rapidly crosses BBB. Onset:< 1 min. Offset: 3–10 mins. Lowers ICP. Metabolism: non-hepatic hydrolysis by nonspecific blood and tissue esterases, no accumulation. Synergy with thiopental, propofol, isoflurane, midazolam requires reducing doses of these agents by up to 75% Side effects: bradycardia, hypotension (these side effects may be blunted by pretreatment with anticholinergics), N/V, muscle rigidity, pruritis (aspecially facial) dose dependent respiratory depression at doses >0.05 mcg/kg/min.

Adult: avoid bolus doses. Start with drip of 0.05 mcg/kg/min. Titrate in 0.025 mcg/kg/min increments to a maximum of 0.1–0.2 mcg/kg/min. Add a sedative if adequate sedation not achieved at maximum dose. Wean infusion in 25% decrements over 10 minutes after extubation. Supplied: vials of 1, 2 or 5 mg powder to be reconstituted to 1 mg/ml solution.

**Drug info: Fentanyl (Sublimaze®)**

Narcotic, potency ≈ 100 × morphine. High lipid solubility → rapid onset. Offset (small doses): 20–30 mins. Unlike morphine and meperidine, does not cause histamine release. Lowers ICP. Side effects: dose dependent respiratory depression, large doses given rapidly may cause chest wall rigidity.

Repeated dosing may cause accumulation. Diminished sensitivity to CO₂ stimulation, may persist longer than the depression of respiratory rate (up to 4 hours).

Adult: 25–100 mcg (0.5–2 ml) IV P, repeat PRN. Supplied: 50 mcg/ml; requires refrigeration.

**Drug info: Propofol (Diprivan®)**

A sedative hypnotic. Also useful in high doses during aneurysm surgery as a neuroprotectant (p. 1203). Protection seems to be less than with barbiturates. Offset time increases after ≈ 12 hours of use.

for sedation: start at 5–10 mcg/kg/min. Increase by 5–10 mcg/kg/min q 5–10 minutes PRN desired sedation (up to a max of 50 mcg/kg/min).

Side effects: include Propofol Infusion Syndrome: hyperkalemia, hepatomegaly, lipemia, metabolic acidosis, myocardial failure, rhabdomyolysis, renal failure and sometimes death. First identified in children, but may occur at any age. NK metabolic acidosis of unknown etiology in a patient on propofol is propofol infusion syndrome until proven otherwise. Use with caution at doses >50 mcg/kg/min or at any dose for >48 hrs. Also note that the lipid carrier provides 1.1 kCal/ml and hypertriglyceridemia may occur.

Supplied: 500 mg suspended in a 50 ml bottle of fat emulsion. The bottle and tubing must be changed every 12 hours since it contains no bacteriostatic agent.
Drug info: Precedex® (Dexmedetomidine)

An alpha-2 adrenoceptor agonist. Acts in locus ceruleus and dorsal root ganglia. Has both sedative and analgesic properties and dramatically reduce the risk of respiratory depression and the amount of narcotic analgesics required. Reduces shivering.

: usual loading dose is 1 mcg/kg IV over 10 minutes (loading dose not needed if patient already sedated with other agents), followed by continuous IV infusion of 0.2–1.0 mcg/kg/hr titrated to desired effect, not to exceed 24 hours (for short sedation or use as a “transition” drug). Side effects: clinically significant bradycardia and sinus arrest have occurred in young, healthy volunteers with increased vagal tone (anticholinergics such as atropine 0.2 mg IV or glycopyrrolate 0.2 mg IV may help). Use with caution in patients with advanced heart block, baseline bradycardia, using other drugs that lower heart rate, and hypovolemia. Supplied: 2 ml vials of 100 mcg/ml to be diluted in 48 ml NS for a final concentration of 4 mcg/ml for IV use.

7.2 Paralytics (neuromuscular blocking agents)

7.2.1 General information

CAUTION: requires ventilation (intubation or Ambu-bag/mask). Reminder: paralyzed patients may still be conscious and therefore able to feel pain, the simultaneous use of sedation is thus required for conscious patients.

Early routine use in head-injured patients lowers ICP (e.g. from suctioning⁴) and mortality, but does not improve overall outcome.⁵

Neuromuscular blocking agents (NMBAs) are classified clinically by time to onset and duration of paralysis as shown in Table 7.2. Additional information for some agents follows the table along with some considerations for neurosurgical patients.

7.2.2 Ultra-short acting paralytics

**Drug info: Succinylcholine (Anectine®)**

The only depolarizing ganglionic blocker (the rest are competitive blockers). Rapidly inactivated by plasma pseudocholinesterases. A single dose produces fasciculations then paralysis. Onset: 1 min. Duration of action: 5–10 min.

**Indications**
Due to significant side effects (see below), use is now limited primarily to the following indications.

- **Adults:** generally recommended only for emergency intubations where the airway is not controlled.
- **In children:** only when intubation is needed with a full stomach, or if laryngospasm occurs during attempted intubation using other agents.

**Side effects**
- **CAUTIONS:** usually increases serum K⁺ by 0.5 mEq/L (on rare occasion causes severe hyperkalemia ([K⁺] up to 12 mEq/L) in patients with neuronal or muscular pathology, causing cardiac complications which cannot be blocked), therefore contraindicated in acute phase of injury following major burns, multiple trauma or extensive denervation of skeletal muscle or upper motor neuron injury. Do not use for routine intubations in adolescents and children (may cause cardiac arrest even in apparently healthy youngsters, many of whom have undiagnosed myopathies). Linked to malignant hyperthermia (p. 108).
- May cause dysrhythmias, especially sinus bradycardia (treat with atropine). May get autonomic stimulation from ACh-like action → HTN, and brady- or tachycardia (especially in peds with repeated doses). The fasciculations may increase ICP, intragastric pressure, and intraocular pressure (contraindicated in penetrating eye injury, especially to anterior chamber; OK in glaucoma).
- Precurarization with a “priming dose” of a nondepolarizing blocker (usually ≈ 10% of the intubating dose, e.g. pancuronium 0.5–1 mg IV 3–5 minutes prior to succinylcholine) in patients with elevated ICP or increased intraocular pressure (to ameliorate further pressure increases during fasciculation phase) and in patients who have eaten recently (controversial). Phase II block (similar to nondepolarizing blocker) may develop with excessive doses or in patients with abnormal pseudocholinesterase.

**Dosing**
- **Adult:** 0.6–1.1 mg/kg (2–3 ml/70 kg) IVP (err on high side to allow time for procedure & to avoid multi-dosing complications), may repeat this dose × 1.
- **Peds (CAUTION: Not recommended for routine use, see above):**
  - Children: 1.1 mg/kg. Infants (<1 mos): 2 mg/kg.
- Supplied: 20 mg/ml concentration.

7.2.3 Short acting paralytics

**Drug info: Rocuronium (Zemuron®)**

In large doses, has speed of onset that approaches succinylcholine. However, in these doses, paralysis usually lasts ≈ 1–2 hrs. Expensive.

- **Adult:** initial dose 0.6–1 mg/kg. May be used as infusion of 10–12 mcg/kg/min.
7.2.4 Intermediate acting paralytics

**Drug info: Vecuronium (Norcuron®)**

Nondepolarizing (competitive) NMBA. Adequate paralysis for intubation within 2.5–3 minutes of administration. About one–third more potent than pancuronium, shorter duration of action (lasts ≈ 30 minutes after initial dose). Unlike pancuronium, very little vagal (i.e. cardiovascular) effects. No CNS active metabolites. Does not affect ICP or CPP. Hepatically metabolized. Due to active metabolites, paralysis has been reported to take 6 hrs to 7 days to recede following discontinuation of the drug after ≥ 2 days use in patients with renal failure. Must be mixed to use.

**Dosing**

Supplied: 10 mg freeze-dried cakes requiring reconstitution. Use within 24 hrs of mixing.
- Adult and children >10 years age: 0.1 mg/kg (for most adults use 8–10 mg as initial dose). May repeat q 1 hr PRN. Infusion: 1–2 mcg/kg/min.
- Pediatric: children (1–10 yrs) require slightly higher dose and more frequent dosing than adult. Infants (7 weeks – 1 yr): slightly more sensitive on a mg/kg basis than adults, takes ≈ 1.5 × longer to recover. Use in neonates and continuous infusion in children is insufficiently studied.

**Drug info: Cisatracurium (Nimbex®)**

Nondepolarizing (competitive) blocker. This isomer of atracurium does not release histamine unlike its parent compound (see below). Provides about 1 hour of paralysis. Also undergoes Hofmann degradation, with laudanosine as one of its metabolites.

- Adult and children >12 years age: 0.15 or 0.2 mg/kg as part of propofol/nitrous oxide/oxygen induction-intubation technique produces muscle paralysis adequate for intubation within 2 or 1.5 minutes, respectively. Infusion: 1–3 mcg/kg/min.
- Pediatric: children (2–12 yrs): 0.1 mg/kg given over 5–10 seconds during inhalational or opioid anesthesia.

7.2.5 Reversal of competitive muscle blockade

Reversal is usually not attempted until patient has at least 1 twitch to a train of 4 stimulus, otherwise reversal may be incomplete if patient is profoundly blocked and blockade may reoccur as the reversal wears off (a response of 1/4 indicates 90% muscle blockade)

- **neostigmine (Prostigmin®):** 2.5 mg (minimum) to 5 mg (maximum) IV (start low, no efficacy from >5 mg and can produce severe weakness especially if the maximum dose is exceeded in the absence of neuromuscular blockade)
- **PLUS** (to prevent bradycardia…),
  - EITHER
    - 0.5 mg atropine for each mg of neostigmine
    - OR
    - 0.2 mg glycopyrrolate (Robinul®) for each mg of neostigmine

7.3 Analgesics

7.3.1 General information

For a discussion of types of pain and pain procedures (p.476).

Three types of pain medication
1. non-opioid pain medication (see below)
   a) nonsteroidal anti-inflammatory drugs: aspirin, ibuprofen…
   b) acetaminophen
2. opioids (p.138)
   a) agonists
   b) partial agonists
   c) mixed agonist/antagonists
3. drugs that are not strictly analgesics, but which act as adjuvants (p.143) when added to any of the above: tricyclic antidepressants, anticonvulsants, caffeine, hydroxyzine, corticosteroids (p.143)

7.3.2 Guiding principles
The key to good pain control is the early use of adequate levels of effective analgesics. For cancer pain, scheduled dosing is superior to PRN dosing, and “rescue” medication should be available. Non-opioid analgesics should be continued as more potent medications and invasive techniques are utilized.

7.3.3 Analgesics for some specific types of pain

Visceral or deafferentation pain
May sometimes be effectively treated with tricyclic antidepressants (p.477). Tryptophan may be effective (p.143). Carbamazepine (Tegretol®) may be useful for paroxysmal, lancinating pain.

Pain from metastatic bone disease
Steroids, aspirin, or NSAIDs are especially helpful, probably by reducing prostaglandin mediated sensitization of A-delta and C fibers, and therefore may be preferred to APAP.

7.3.4 Nonopioid analgesics

Acetaminophen

Table 7.3 Acetaminophen dosing

<table>
<thead>
<tr>
<th>Medication</th>
<th>Dosage</th>
</tr>
</thead>
<tbody>

<tr>
<td>(APAP)</td>
<td>pediatric dose:</td>
</tr>
<tr>
<td>(Tylenol®)</td>
<td>infants: 10–15 mg/kg PO/PR q 4–6 hrs</td>
</tr>
<tr>
<td></td>
<td>children: 1 grain/yr age (= 65 mg/yr up to 650 mg) PO/PR q 4–6 hrs not to exceed 15 mg/kg q 4 hrs</td>
</tr>
</tbody>
</table>

*hepatic toxicity from APAP: usually with doses ≥ 10 gm/day, rare at doses <4000 mg. However, may occur at lower doses (even at high therapeutic doses) in alcoholics, fasting patients, and those taking cytochrome P-450 enzyme-inducing drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs)
The anti-inflammatory properties of NSAIDs is primarily due to inhibition of the enzyme cyclooxygenase (COX) which participates in the synthesis of prostaglandins and thromboxanes. Characteristics of nonselective nonsteroidal anti-inflammatory drugs:

1. all are given orally except ketorolac tromethamine (Toradol®) (see below)
2. no dependence develops
3. additive effect improves the pain relief with opioid analgesics
4. NSAIDs (and APAP) demonstrate a ceiling effect: a maximum dose above which no further analgesia is obtained. For aspirin and APAP, this is usually between 650–1300 mg, and is often higher for other NSAIDs which may also have a longer duration of action
5. risk of GI upset is common, more serious risks of hepatotoxicity, or GI ulceration, hemorrhage, or perforation are less common
6. taking medication with meals or antacids has not been proven effective in reducing GI side effects. Misoprostol (Cytotec®), a prostaglandin, may be effective in mitigating NSAID-induced gastric erosion or peptic ulcer. Contraindicated in pregnancy. 200 mcg PO QID with food as long as patient is on NSAIDs. If not tolerated, use 100 mcg. CAUTION: an abortifacient. Should not be given to pregnant women or women of childbearing potential
7. most reversibly inhibit platelet function and prolong bleeding time (nonacetylated salicylates have less antiplatelet action, e.g. salsalate, trisalicylate, nabumetone). Aspirin, unlike all other
NSAIDs, irreversibly binds to cyclooxygenase and thus inhibits platelet function for the 8–10 day life of the platelet 8. all cause sodium and water retention and carry the risk of NSAID-induced nephrotoxicity11 (by reducing synthesis of renal vasodilator prostaglandins → reduced renal blood flow which can → renal insufficiency, interstitial nephritis, nephrotic syndrome, hyperkalemia) 9. non-aspirin NSAIDs increase the risk of heart attack or stroke12

**Drug info: Ketorolac tromethamine (Toradol®)**

The only parenteral NSAID approved for use in pain control in the U.S. Analgesic effect is more potent than anti-inflammatory effect. Half-life ≈ 6 hrs. May be useful to control pain in the following situations:
1. where the avoidance of sedation or respiratory depression is critical
2. when constipation cannot be tolerated
3. for patients who are nauseated by narcotics
4. where narcotic dependency is a serious concern
5. when epidural morphine has been used and further analgesia is needed without risk of respiratory depression (agonist type narcotics are contraindicated)
6. cautions:
   a) not indicated for use >72 hrs (complications have been reported primarily with prolonged use of the oral form)
   b) use with caution in postoperative patients since (as with most NSAIDs) bleeding time is prolonged by platelet function inhibition (risk of GI or op-site hemorrhage is small, but is increased in patients >75 yrs old, when used >5 days, and when used in higher doses13)
   c) even though IM dosing circumvents the GI system, gastric mucosal irritation and erosions may occur as with all NSAIDs (avoid use with PUD)
   d) as with all NSAIDs, use with caution in patients at risk for renal side effects

**Parenteral:**
For single dose administration: 30 mg IV or 60 mg IM in healthy adult. For multiple dosing: 30 mg IV or IM q 6 hrs PRN. Maximum dosage: 120 mg/day. Parenteral use should not exceed 5 days (3 days may be a better guideline).

For patient weight <50 kg, age >65 yrs, or reduced renal function (creatinine clearance <50 ml/min), all of the above dosages are halved (max daily dose: 60 mg). Creatinine clearance can be estimated using the Cockcroft-Gault equation14 shown in Eq (7.1), with normal values ≥ 60 ml/min.

$$\text{Creatinine clearance} \frac{\text{ml/min}}{72 \text{ years}} = \frac{\text{ideal wt (kg)}}{\text{serum creatinine (mg/dl)}} \times \frac{140}{\text{age (years)}}$$

PO: Indicated only as a continuation of IV or IM therapy, not for routine use as an NSAID. Switching from IM to PO: start with 10 mg PO q 4–6 hrs (combined PO and IM dose should be ≤ 120 mg on the day of transition). Supplied: 10 mg tablets.

7.3.5 Opioid analgesics

**General information**

Narcotics are most commonly used for moderate to severe acute pain or cancer pain (some experts characterize cancer pain as recurrent acute pain and not chronic pain).

Characteristics of narcotics:
1. no ceiling effect (p. 137): i.e. increasing dosage increases the effectiveness (although with weak opioids for moderate pain, side effects may limit dosages to relatively low levels8)
2. with chronic use, tolerance develops (physical and psychological)
3. overdose possible (p. 207), with the potential for respiratory depression with all, and seizures with some

*aNSAIDs increase the risk of cardiovascular thrombotic events (heart attack or stroke)*¹²

*bwhen dosage ranges are given, use the smallest effective dose

*cabbreviations: DS=double strength; SR=slow release; ER=extended release; DOC=drug of choice

³aspirin: has unique effectiveness in pain from bone metastases

⁴ibuprofen: is available as a suspension (PediaProfen®) 100 mg/ml; dose for children 6 mos to 12 yrs age is 5–10 mg/kg with a maximum of 40 mg/kg/day (not FDA approved for children because of possible Reye’s syndrome)

⁵Unlike most NSAIDs, nabumetone does not interfere with platelet function
Mild to moderate pain

Some useful medications are shown in Table 7.5.

Codine and congenor pentazocine, are usually no more effective that ASA or APAP and are usually combined with these drugs.

**Drug info: Tramadol (Ultram®)**

An oral opioid agonist that binds µ-opioid receptors, and is also a centrally acting analgesic that inhibits reuptake of norepinephrine and serotonin. For acute pain, 100 mg is comparable to codeine 60 mg with ASA or APAP. There has been no report of respiratory depression when oral dosing recommendations are followed. Seizures and opioid-like dependence have been reported. 50 to 100 mg PO q 4–6 hrs PRN pain up to a maximum of 400 mg/day (or 300 mg/d for older patients). For moderately severe acute pain, an initial dose of 100 mg followed by 50 mg doses may suffice. Supplied: 50 mg tabs.

\(^a\)all can precipitate withdrawal symptoms in patients physically dependent on agonists
\(^b\)most agonist/antagonist drugs occupy sigma receptors (Stadol>Nubain), which may cause hallucinations
\(^c\)Talwin injectable (for IM use) contains only pentazocine. Talwin® Compound tablets contain ASA, therefore for high PO doses, use Talwin Nx which contains no ASA (Table 7.5)
7.3.6 Adjuvant pain medications

The following may have efficacy in enhancing the effectiveness of opioid analgesics (and thereby may reduce the required dose).

**Tricyclic antidepressants:**
- Tryptophan: an amino acid and a precursor of serotonin, may work by increasing serotonin levels. Requires high doses and has hypnotic effects, therefore 1.5–2 gm given usually q hs. Must give daily MVI as chronic tryptophan therapy depletes vitamin B6.
- Antihistamines: histamines play a role in nociception. Antihistamines, which are also anxiolytic, antiepileptic, and mildly hypnotic, are effective as analgesics or as adjuvants. Hydroxyzine (Atarax®, Vistaril®): start with 50 mg PO q AM and 100 mg PO q hs. May increase up to 200 mg daily.
- Anticonvulsant-class drugs: carbamazepine, clonazepam, phenytoin, gabapentin or pregabalin tend to be more effective in neuropathic pain, e.g. from diabetic neuropathy, trigeminal neuralgia, post-herpetic neuralgia, glossopharyngeal neuralgia, and neuralgias due to nerve injury or infiltration with cancer. See index for entries.
- Phenothiazines: some cause mild reduction in nociception. Most are tranquilizing and antiemetic. Best known for this use is fluphenazine (Prolixin®), usually given with a tricyclic antidepressant for neuropathic pain, Diabetic neuropathy, Treatment (p.545). Phenothiazines may reduce the seizure threshold.
- Corticosteroids: in addition to the reduction of toxic effects of radiation or chemotherapy, they may potentiate narcotic analgesics. There are also a number of nonspecific beneficial effects: increased appetite, sense of well being, antiemetic. Side effects may limit usefulness (p.146).
- Caffeine: although it possesses no intrinsic analgesic properties, doses of 65–200 mg enhance the analgesic effect of APAP, ASA or ibuprofen in for pain including: H/A, oral surgery pain and post-herpetic neuralgia.

---

**Drug info: Avinza® (extended release morphine)**

Once daily oral morphine formulation using a spherical oral drug absorption system (SODAS) (numerous ammonio-methacrylate copolymer beads, ≈ 1 mm dia.). Potential for overdosage and/or abuse.

- Dosage is titrated based on patient’s opioid tolerance and degree of pain. Taken as 1 capsule p. o. q d. Not to be taken “PRN.” Not for post-op pain. CAUTION: To prevent potentially fatal doses of morphine, capsules are to be swallowed whole, and are not to be chewed, crushed or dissolved. However, the contents of the capsule (the beads) may be sprinkled on apple-sauce for those unable to swallow the capsules, but the beads are not to be chewed or crushed. Side effects: Due to the potentially nephrotoxic effect of fumaric acid used in SODAS, the maximum dose of Avinza is 1600 mg/d. Doses ≥ 60 mg are for opioid tolerant patients only. Supplied: 30, 60, 90 & 120 mg capsules.
8 Endocrinology

8.1 Corticosteroids

8.1.1 General information

Under normal, basal conditions, the zona fasciculata of the adrenal cortex secretes 15–25 mg/day of cortisol (hydrocortisone is the name for the identical pharmaceutical compound for administration), and 1.5–4 mg/day of corticosterone. Cortisol has a half-life of ≈ 90 minutes. The release of cortisol by the adrenal glands is stimulated by adrenocorticotropic hormone (ACTH) from the pituitary which in turn is stimulated by corticotropin releasing hormone (CRH) from the hypothalamus.

8.1.2 Replacement therapy

In primary adrenocortical insufficiency (Addison’s disease), both glucocorticoids and mineralocorticoids must be replaced. In secondary adrenal insufficiency caused by deficient corticotropin (ACTH) release by the pituitary, mineralocorticoid secretion is usually normal and only glucocorticoids need to be replaced.

Table 8.1 shows equivalent daily corticosteroid doses for replacement therapy. Physiologic replacement (in the absence of stress) can be accomplished with either:

1. hydrocortisone: 20 mg PO q AM and 10 mg PO q PM
2. or prednisone: 5 mg PO q AM and 2.5 mg PO q PM

Cortisol and cortisone are useful for chronic primary adrenocortical insufficiency or for Addisonian crisis. Because of mineralocorticoid activity, use for chronic therapy of other conditions (e.g. hypopituitarism) may result in salt and fluid retention, hypertension and hypokalemia.

8.1.3 Hypothalamic-pituitary-adrenal axis suppression

General information

Chronic steroid administration suppresses the hypothalamic-pituitary-adrenal (HPA) axis, and eventually causes adrenal atrophy. When the HPA is suppressed, if exogenous steroids are abruptly

*a* doses given are daily doses. Steroids listed are used primarily as glucocorticoids: equivalent glucocorticoid PO or IV dose is given; IM may differ

*b* IM route recommended only for emergencies where IV access cannot be rapidly obtained

*Sterapred Uni-Pak® contains 21 tabs of 5 mgs prednisone and tapers dosage from 30 to 5 mgs over 6 days; “DS” contains 10 mg tabs and tapers from 60 mg to 10 mg over 6 days; “DS 12-Day” contains 48 10 mg tabs and tapers from 60 mg to 20 mg over 12 days

*Medrol Dosepak® contains 21 tabs of 4 mgs methylprednisolone and tapers dosage from 24 mg/d to 4 mg/d over 6 days
stopped or if acute illness develops (which increases the steroid requirements), symptoms of adrenocortical insufficiency (AI) may ensue. Table 8.2. Severe cases of AI may progress to Addisonian crisis (p.147). Recovery of adrenal cortex lags behind the pituitary, so basal ACTH levels increase before cortisol levels do.

HPA suppression depends on the specific glucocorticoid used, the route, frequency, time, and duration of treatment. Suppression is unlikely with <40 mg prednisone (or equivalent) given in the morning for less than 7 days, or with every-other-day therapy of <40 mg for 5 weeks. Some adrenal atrophy may occur after 3–4 days of high dose steroids, and some axis suppression will almost certainly occur after 2 weeks of 40–60 mg hydrocortisone (or equivalent) daily. After a month or more of steroids, the HPA axis may be depressed for as long as one year.

Measuring morning plasma hydrocortisone can evaluate the degree of recovery of basal adrenocortical function, but does not assess adequacy of stress response.

Steroid withdrawal

See reference.¹

In addition to the above dangers of hypocortisolism in the presence of HPA suppression, too rapid a taper may cause a flare-up of the underlying condition for which steroids were prescribed.

When the risk of HPA suppression is low (as is the case with short courses of steroids for less than 5–7 days generally prescribed for most neurosurgical indications) abrupt discontinuation usually carries a low risk of AI. For up to 2 weeks of use, steroids are usually safely withdrawn by tapering over 1–2 weeks. For longer treatment, or when withdrawal problems develop, use the following conservative taper:

1. make small decrements (equivalent to 2.5–5 mg prednisone) every 3–7 d. Patient may experience mild withdrawal symptoms of²:
   a) fatigue
   b) anorexia
   c) nausea
   d) orthostatic dizziness

2. “backtrack” (i.e. increase the dose and resume a more gradual taper) if any of the following occur:
   a) exacerbation of the underlying condition for which steroids were used
   b) evidence of steroid withdrawal symptoms (Table 8.2)
   c) intercurrent infection or need for surgery; see Stress doses (p.146)

3. once “physiologic” doses of glucocorticoid have been reached (about 20 mg hydrocortisone/day or equivalent (Table 8.1):
   a) the patient is switched to 20 mg hydrocortisone PO q AM (do not use long acting preparations)
   b) after ≈2–4 weeks, a morning cortisol level is checked (prior to the AM hydrocortisone dose), and the hydrocortisone is tapered by 2.5 mg weekly until 10 mg/d is reached (lower limits of physiologic)
   c) then, every 2–4 weeks, the AM cortisol level is drawn (prior to AM dose) until the 8 AM cortisol is >10 mcg/100 ml, indicating return of baseline adrenal function
   d) when this return of baseline adrenal function occurs:
      • daily steroids are stopped, but stress doses must still be given when needed (see below)
      • monthly cosyntropin stimulation (p.735) tests are performed until normal. The need for stress doses of steroids ceases when a positive test is obtained. The risk for adrenal insufficiency persist ≈2 years after cessation of chronic steroids (especially the first year)

Table 8.2 Symptoms of adrenal insufficiency (AI)

- fatigue
- weakness
- arthralgia
- anorexia
- nausea
- hypotension
- orthostatic dizziness
- hypoglycemia
- dyspnea
- Addisonian crisis (p.147) (if severe; with risk of death)
Steroid stress doses
During physiologic “stress” the normal adrenal gland produces ≈ 250–300 mg hydrocortisone/day. With chronic glucocorticoid therapy (either at present, or within last 1–2 yrs), suppression of the normal “stress-response” necessitates supplemental doses.

In patients with a suppressed HPA axis:
- for mild illness (e.g. UTI, common cold), single dental extraction: double the daily dose (if off steroids, give 40 mg hydrocortisone BID)
- for moderate stress (e.g. flu), minor surgery under local anesthesia (endoscopy, multiple dental extractions...): give 50 mg hydrocortisone BID
- for major illness (pneumonia, systemic infections, high fever), severe trauma, or emergency surgery under general anesthesia: give 100 mg hydrocortisone IV q 6–8 hrs for 3–4 days until the stress is resolved
- for elective surgery, see Table 8.3 for guidelines

8.1.4 Steroid side effects
Although deleterious side effects of steroids are more common with prolonged administration, some can occur even with short treatment courses. Some evidence suggests that low-dose glucocorticoids (≤ 10 mg/d of prednisolone or prednisone equivalent) for rheumatoid arthritis does not increase osteoporotic fractures, blood pressure, cardiovascular disease, or peptic ulcers, but weight gain and skin changes are common. Possible side effects include:
- cardiovascular and renal
  ○ hypertension
  ○ sodium and water retention
  ○ hypokalemic alkalosis
- CNS
  ○ progressive multifocal leukoencephalopathy (PML) (p.331)
  ○ mental agitation or “steroid psychosis”
  ○ spinal cord compression from spinal epidural lipomatosis (p.1408): rare
  ○ pseudotumor cerebri, idiopathic intracranial hypertension (IIH) (p.766)
- endocrine
  ○ caution: because of growth suppressant effect in children, daily glucocorticoid dosing over prolonged periods should be reserved for the most urgent indications
  ○ secondary amenorrhea
  ○ suppression of hypothalamic-pituitary-adrenal axis: reduces endogenous steroid production, risk of adrenal insufficiency with steroid withdrawal (see above)
  ○ Cushingoid features with prolonged usage (iatrogenic Cushing’s syndrome): obesity, hypertension, hirsutism...
- GI: risk increased only with steroid therapy > 3 weeks duration and regimens of prednisone > 400–1000 mg/d or dexamethasone > 40 mg/d
  ○ gastritis and steroid ulcers: incidence lowered with the use of antacids and/or H2 antagonists (e.g. cimetidine, ranitidine...)
  ○ pancreatitis

</table>
intestinal or sigmoid diverticular perforation: incidence ≈ 0.7%. Since steroids may mask signs of peritonitis, this should be considered in patients on steroids with abdominal discomfort, especially in the elderly and those with a history of diverticular disease. Abdominal x-ray usually shows free intraperitoneal air

- inhibition of fibroblasts
- impaired wound healing or wound breakdown
- subcutaneous tissue atrophy
- metabolic
  - glucose intolerance (diabetes) and disturbance of nitrogen metabolism
  - hyperosmolar nonketotic coma
  - hyperlipidemia
  - tend to increase BUN as a result of protein catabolism
- ophthalmologic
  - posterior subcapsular cataracts
  - glaucoma
- musculoskeletal
  - avascular necrosis (AVN) of the hip or other bones: usually with prolonged administration —cushingoid habitus and increased marrow fat within the bone (prednisone 60 mg/d for several months is probably the minimum necessary dose, whereas 20 mg/d for several months will probably not produce AVN). Many cases blamed on steroids may instead be due to alcohol use, cigarette smoking, liver disease, underlying vascular inflammation...
  - osteoporosis: may predispose to vertebral compression fractures which occur in 30–50% of patients on prolonged glucocorticoids. Steroid induced bone loss may be reversed with cyclical administration of etidronate in 4 cycles of 400 mg/d for 14 days followed by 76 days of oral calcium supplements of 500 mg/d (not proven to reduced rate of VB fractures)
  - muscle weakness (steroid myopathy): often worse in proximal muscles
- infectious
  - immunosuppression: with possible superinfection, especially fungal, parasitic
  - possible reactivation of TB, chickenpox
- hematologic
  - hypercoagulopathy from inhibition of tissue plasminogen activator
  - steroids cause demargination of white blood cells, which may artifactually elevate the WBC count even in the absence of infection
- miscellaneous
  - hiccups: may respond to chlorpromazine (Thorazine®) 25–50 mg PO TID–QID 2–3 days (if symptoms persist, give 25–50 mg IM)
  - steroids readily cross the placenta, and fetal adrenal hypoplasia may occur with the administration of large doses during pregnancy

8.1.5 Hypocortisolism

General information

AKA adrenal insufficiency.

Assessment: 8 A.M. serum cortisol level is the best way to test for hypocortisolism. Each lab should provide a lower limit of normal for their lab, which may be broken down further by age and gender.

Addisonian crisis

General information

AKA adrenal crisis. An adrenal insufficiency emergency.

Symptoms: mental status changes (confusion, lethargy, or agitation), muscle weakness.

Signs: postural hypotension or shock, hyperthermia (as high as 105°F, 45.6°C)

Labs

Hyponatremia, hyperkalemia, hypoglycemia.

Treatment of Addisonian crisis

If possible, draw serum for cortisol determination (do not wait for these results to institute therapy). Give fluids sufficient for dehydration and shock.
For “glucocorticoid emergency”
- hydrocortisone sodium succinate (Solu-Cortef®): 100 mg IV STAT and then 50 mg IV q 6 hrs
  AND
- cortisol acetate 75–100 mg IM STAT, and then 50–75 mg IM q 6 hrs

For “mineralocorticoid emergency”
  Usually not necessary in secondary adrenal insufficiency (e.g. panhypopituitarism)
  - desoxycorticosterone acetate (Doca®): 5 mg IM BID OR
  - fludrocortisone (Florinef®): 0.05- 0.2 mg PO q d

methylprednisolone is NOT recommended for emergency treatment.

8.2 Hypothyroidism
8.2.1 General information
Chronic primary hypothyroidism may result in (non-pathologic) enlargement of the pituitary gland. Plasma TSH determination will distinguish primary hypothyroidism (high TSH) from secondary hypothyroidism (low TSH). Wound healing and cardiac function may be compromised, and surgery under general anesthesia should be postponed if possible until thyroid levels are normalized. Effects of anesthesia may be markedly prolonged, and dosages should be adjusted accordingly.

8.2.2 Thyroid replacement
Caution in patients with adrenal insufficiency
Primary hypothyroidism may be associated with immunologic destruction of adrenal cortex (Schmidt syndrome). Secondary hypothyroidism may be associated with and may mask reduced adrenal function. Thyroid replacement without adrenal replacement in patients with adrenal insufficiency (as may occur in panhypopituitarism) may precipitate adrenal crisis (thus give ≈ 300–400 mg hydrocortisone IV over 24 hrs in addition to thyroid replacement).

8.2.3 Routine thyroid replacement dosing

**Drug info: Levothyroxine (Synthroid®)**

Almost pure T4 (contains no T3 as most T3 is produced peripherally from T4).

Dose required to prevent myxedema coma (not to achieve euthyroidism):
- Maintenance: 0.05 mg po q d
- when patient has been hypothyroid: start at 0.05 mg po q d and increase by 0.025 mg every 2–3 weeks

For euthyroidism (approximate dose, follow levels and clinical evaluation):
- for most adults < 60 years age: 0.18 mg/day
- for elderly patients: 0.12 mg/day

**Drug info: Desiccated thyroid (e.g. Armour thyroid®)**

Typical dose: 60 mg (1 grain) to 300 mg daily.

**Thyroid replacement in myxedema coma**

Myxedema coma is an emergency of hypothyroidism and carries 50% mortality.

Symptoms: altered mental status or unresponsiveness.
Signs: hypotension, bradycardia, hyponatremia, hypoglycemia, hypothermia, hypoventilation, occasionally seizures.

Treatment
Drugs may need to be given IV due to reduced gastric motility.

1. general supportive care:
   a) hypotension: treat with IV fluids (responds poorly to pressors until thyroid replacement accomplished)
   b) hyponatremia: will correct with thyroid replacement; avoid hypertonic saline
   c) hypoglycemia: IV glucose
   d) symptoms of hypocortisolism: thyroid replacement may precipitate adrenal crisis (see caution above); give 300–400 mg hydrocortisone IV over 24 hrs
   e) hypothermia: avoid active warming since this increases metabolic demand, use blankets to warm gradually
   f) hypoventilation: check ABG, intubate if necessary

2. thyroid replacement (for average-sized adult):
   a) IV replacement: 0.5 mg of levothyroxine IV, followed by 0.05–0.2 mg/d IV until patient able to tolerate PO or NG meds
   b) nasogastric replacement: liothyronine (Cytomel®) is primarily T³, has a rapid onset of action, much shorter half-life than T4, and should be reserved for emergencies.

8.3 Pituitary embryology and neuroendocrinology

8.3.1 Embryology and derivation of the pituitary gland
The posterior pituitary (neurohypophysis) derives from downward evagination of neural crest cells (brain neuroectoderm) from the floor of the third ventricle. The residual recess in the floor of the third ventricle is called the median eminence. The anterior pituitary gland (adenohypophysis) develops from an evagination of epithelial ectoderm of the oropharynx, the evagination is known as Rathke’s pouch and is eventually separated from the oropharynx by the sphenoid bone. Cleft-like remnants of Rathke's pouch separates the adenohypophysis and neurohypophysis. The adenohypophysis is comprised of the pars distalis (anterior lobe), the pars intermedia (intermediate lobe) and the pars tuberalis (extension of adenohypophyseal cells on the anterior aspect of the pituitary stalk). The pituitary gland is functionally outside the blood-brain barrier.

8.3.2 Pituitary hormones, their targets and their controls
General information
The pituitary gland releases 8 hormones, 6 from the anterior pituitary, 2 from the posterior pituitary (Fig. 8.1). The anterior pituitary is one of only two sites in the body having a portal circulation (the other being the liver). 6 hypothalamic hormones released in a pulsatile fashion are conveyed in blood from hypothalamic capillaries through this portal circulation via the pituitary stalk to a second capillary bed in the anterior pituitary where they control release of hormones by adenohypophyseal gland cells.

Hormones released from the posterior pituitary (ADH & oxytocin) are synthesized in neurons in the hypothalamus (not gland cells) and are conveyed along their axons also in the pituitary stalk to the posterior pituitary gland where they are released.

The complete homeostatic loop (including negative feedback of the hypothalamic hormones) will not be covered here, and the reader is referred to physiology texts.

Propiomelanocortin (POMC), AKA proopiomelanocortin
241 amino acid polypeptide hormone precursor synthesized primarily in corticotroph cell of the anterior pituitary (but also found in the hypothalamus). Contains amino acid sequences for ACTH, alpha-melanocyte-stimulating hormone (α-MSH), β-lipotropin, γ-lipotropin, β-endorphin and met-enkephalin.

Hormone action

- Thyrotropin releasing hormone (TRH)
  - Thyrotropin (thyroid stimulating hormone)
    - Growth hormone (GH)
      - Somatotropin
    - Luteinizing hormone (LH)
      - Follicle stimulating hormone (FSH)
    - Thyroid protein synthesis, thermogenesis
    - Kidneys
      - Water retention, arterial constriction
      - Breasts
        - Milk letdown reflex in lactation
      - Uterine contractions

- Corticotropin releasing hormone (CRH)
  - Corticotropin (adrenocorticotropic hormone) (ACTH)
    - Cortisol
    - Somatostatin (SRIH)
      - Insulin antagonism
      - Chondrocyte proliferation
      - IGF-1

- Gonadotropin releasing hormone (GnRH)
  - Gonads
    - Secondary sex characteristics
      - Germ cell function
        - ♂: Testosterone
        - ♀: Estriadiol

- Growth hormone releasing hormone (GH-RH)
  - Liver & other tissues
    - Cell proliferation
      - Insulin-like growth factor-I (IGF-1)

- Epiphyses of long bones to cavernous sinus

Fig. 8.1 Pituitary neuroendocrinology
Corticotropin AKA adrenocorticotrophic hormone (ACTH)

A 39 amino acid trophic hormone synthesized from POMC. The first 13 amino acids at the amino terminal of ACTH are identical to α-MSH. Active half-life is ≈ 10 minutes. Produces a diurnal peak in cortisol (the highest peak occurs in the early morning, with a second, lesser peak in the late afternoon) and also increases in response to stress.

Control: CRH from the hypothalamus stimulates the release of ACTH.

Prolactin (PRL)

AKA somatomammotropin. 199 amino-acid protein weighing 23,000 daltons. Levels are higher in females than males, and are higher still in pregnancy (see Table 46.3). Secreted in pulsatile fashion with a frequency and amplitude that varies during menstrual cycle (range: 5–27 ng/ml) (≈ 9 pulses/24 hours in the late luteal phase, ≈ 14 pulses/24 hours in the late follicular phase, the pulse amplitude increases from early to late follicular and luteal phases). There is also diurnal variation: levels begin to rise 1 hour after the onset of sleep, peak ≈ 5:00–7:00 AM, and nadir in midmorning after awakening. Heterogeneity of the molecule may produce different results between bioassays and immunoassays.

Control: PRL is the only pituitary hormone predominantly under inhibitory control from the hypothalamus by prolactin inhibitory factors (PRIFs), with dopamine being the primary PRIF. Prolactin releasing factors (PRFs) include: thyrotropin-releasing hormone (TRH) and vasoactive intestinal peptide (VIP). The physiologic role of PRFs is not established. For DDx of hyperprolactinemia see Table 46.4.

Growth hormone (GH)

A 191 amino-acid polypeptide trophic hormone. GH normally has pulsatile secretion (≈ 5–10 pulses/24 hours, primarily at night, up to 30 mcg/L), levels may be undetectable (<0.2 mcg/L) by standard assays between pulses.13 Insulin-like growth factor-1 (IGF-1) (formerly AKA somatomedin-C) is the protein secreted primarily by the liver in response to GH that is responsible for most of GH’s systemic effects (see levels (p.736)). GH also acts directly on epiphyseal end-plates of long bone to stimulate chondrocyte proliferation.

Control: GH is under dual hypothalamic control via the hypophysial portal system. GH-releasing hormone (GHRH) from the arcuate nucleus stimulates pituitary secretion and synthesis of GH and induces GH gene transcription. Somatostatin from the periventricular nucleus suppresses GH release only, and has no effect on synthesis. GH release is also stimulated by ghrelin,14 a peptide synthesized primarily in the GI tract in response to certain nutrients (may act partially or totally via hypothalamic GHRH).

Thyrotropin AKA thyroid stimulating hormone (TSH)

Glycoprotein trophic hormone secreted by thyrotrph cells of the anterior pituitary.

Control: TSH is also under dual hypothalamic control. TRH stimulates production and release of TSH. Somatostatin inhibits the release of TSH.

Gonadotropins

Follicle stimulating hormone (FSH) and luteinizing hormone (LH) (AKA lutropin) are released from the pituitary in response to gonadotropin releasing hormone 1 (GnRH, formerly luteinizing hormone releasing hormone LH-RH) synthesized primarily in the preoptic area of the hypothalamus.

Antidiuretic hormone (ADH)

AKA arginine vasopressin (AVP). The major source of this nanopeptide hormone is the magnocellular portion of the supraoptic nucleus of the hypothalamus. It is conveyed along axons in the supraoptic-hypophysial tract to the posterior pituitary gland where it is released into the systemic circulation. All actions of ADH result from binding of the hormone to specific membrane bound receptors on the surface of target cells.15 One of the major effects of ADH is to increase the permeability of the distal renal tubules resulting in increased reabsorption of water, diluting the circulating blood and producing a concentrated urine. The most powerful physiologic stimulus for ADH release is an increase in serum osmolality, a less potent stimulus is a reduction of intravascular volume. ADH is also released in glucocorticoid deficiency, and is inhibited by exogenous glucocorticoids and adrenergic drugs. ADH is also a potent vasoconstrictor.
Oxytocin

A nonapeptide. Oxytocin is a neurotransmitter as well as a hormone. The hypothalamus is the main source of pituitary oxytocin which is stored in nerve endings in the neurohypophysis and is involved in the milk letdown reflex for breastfeeding as well as in uterine contraction during labor.

References

9 Hematology

9.1 General information
Circling blood volumes for adults and peds are shown in Table 9.1.

9.2 Blood component therapy
9.2.1 Massive transfusions
Definition: replacement of >1 blood volume (in average adult ≈ 20 U) in <24 hrs for adult, or >2 × circulating blood volume in peds, may cause dilution of effective platelets and coagulation factors. When operating on a pediatric patient, you can usually safely replace up to 1.5 × the circulating blood volume before problems with coagulopathy ensue.

Blood component therapy required for massive transfusions:
1. PRBCs
2. platelets (4 U in adult)
3. FFP

9.2.2 Cellular component
Red blood cell therapy
General information
Major histocompatibilities of blood are shown in Table 9.2.

Whole blood
1 U (≈ 510 cc) = 450 cc blood + 63 cc preservative.
Recommended transfusion criteria:
• exchange transfusions in neonates
• acute burn debridement and grafting in children

Packed red blood cells (PRBCs)
Recommended transfusion criteria:
1. acute blood loss ≥15% of patient’s blood volume
2. in asymptomatic patient: hemoglobin (Hb) ≤ 8 gm or Hct ≤ 24%

3. symptoms of anemia at rest
4. preoperative Hb \( \leq 15 \) gm or Hct <45% in the neonate

Amount to transfuse:

Adult: 1 U (250–300 cc) raises Hct by 3–4%  
For pediatrics, use Eq (9.1).

\[
\text{ml of PRBC to transfuse} = \frac{\text{estimated blood volume} \times \text{Hct increment desired} \times \%}{70} \text{ ml}
\]

(where the Hct of PRBCs ranges 70–80%)

Give no faster than 2–3 cc/kg/hr.

Autologous blood transfusion

Predonated whole blood may be stored 35 days. PRBCs may be stored 42 days.

Patients may donate every 3 days to 1 week as long as they maintain Hct \( \geq 34\% \) (supplement with ferrous sulfate). The following patients require physician release before donating: patients with coronary artery disease, angina, cerebrovascular disease, seizure disorder, pregnancy (because of possible vasovagal episode) or patients with malignancy.

Try to time last donation >72 hrs prior to surgery to allow patient to replenish some of the depleted RBCs before surgery.

9.2.3 Platelets

General information

Normal platelet count (PC) is 150K-400K (abbreviation used here: 150K = 150,000/m\( m^3 \) = 150 \( \times \) 10^9/l). Thrombocytopenia is defined as PC<150K. Bleeding (spontaneously or with invasive procedures) is rarely a problem with PC>50K. Spontaneous hemorrhage is very likely with PC<5K. Spontaneous intracranial hemorrhage is uncommon with PC>30K, and is more common in adults than children. Based on patients with ITP, the risk of fatal hemorrhage in patients with PC<30K is 0.0162–0.0389 cases per patient-year \(^1\) (risk of death from infection is higher). Intracranial bleeding is usually subarachnoid or intraparenchymal, with petechial hemorrhages common.

1 unit of platelets contains 5.5 \( \times \) 10^10 (minimum) to 10 \( \times \) 10^11 platelets. The volume of 6 units is 250–300 ml. Platelets may be stored up to 5 days.

Recommended platelet transfusion criteria

Indications for platelet transfusion \(^2\):

1. thrombocytopenia due to ↓ production (with or without increased destruction) (the most common causes are aplastic anemia and leukemia)
   a) PC<10K even if no bleeding (prophylactic transfusion to prevent bleeding)
   b) PC<20K and bleeding
   c) PC<30K and patient at risk for bleeding: complaints of H/A, presence of confluent (c.f. scattered) petechiae, continuous bleeding from a wound, increasing retinal hemorrhage
   d) PC<50K AND
      - major surgery planned within 12 hours
      - PC rapidly falling
      - patient<48 hours post-op
      - patient requires lumbar puncture
      - acute blood loss of>1 blood volume in <24 hours

2. platelet transfusions have limited usefulness when thrombocytopenia is due to platelet destruction (e.g. by antibodies as in ITPP) or consumption (if production is adequate or increased, platelet transfusion usually will not be useful)

3. documented platelet dysfunction in a patient scheduled for surgery or in a patient with advanced hepatic and/or renal insufficiency (consider pharmacologic enhancement of platelet function, e.g. desmopressin \(^3\))

Other indications for platelet transfusion:

1. patients who have been on Plavix® or aspirin who need urgent surgery that cannot be postponed for \( \approx \) 5 days to allow new platelets to be synthesized
Dosage

Approximately 25% of platelets are lost just with transfusion.

- Peds: 1 U/m² raises PC by ≈ 10K, usually give 4 U/m².
- Adult: 1 U raises platelet count by ≈ 5–10K. Typical dose for thrombocytopenic bleeding adult: 6–10 U (usual order: “8-pack”). Alternatively, 1 U of pheresed platelets may be given (obtained from a single donor by apheresis, equivalent to 8–10 U of pooled donor platelets).

Check PC 1–2 hrs after transfusion. The increase in PC will be less in DIC, sepsis, splenomegaly, with platelet antibodies, or if the patient is on chemotherapy. In the absence of increased consumption, platelets will be needed q 3–5 days.

9.2.4 Plasma proteins

FFP (fresh frozen plasma)

General information

1 bag = 200–250 ml (usually referred to as a “unit”, not to be confused with 1 unit of factor activity which is defined as 1 ml). FFP is plasma separated from RBCs and platelets, and contains all coagulation factors and natural inhibitors. FFP has an out-date period of 12 months. The risk of AIDS and hepatitis for each unit of FFP is equal to that of a whole unit of blood.

Recommended transfusion criteria

Recommendations (modified²):

1. history or clinical course suggestive of coagulopathy due to congenital or acquired coagulation factor deficiency with active bleeding or pre-op, with PT>18 sec or APTT>1.5 × upper limit of normal (usually>55 sec), fibrinogen functioning normally and level>1 g/l, and coagulation factor assay <25% activity
2. proven coagulation factor deficiency with active bleeding or scheduled for surgery or other invasive procedure
   a) congenital deficiency of factor II, V, VII, XI or XII
   b) deficiency of factor VII or IX if safe replacement factors unavailable
   c) von Willebrand’s disease unresponsive to DDAVP
   d) multiple coagulation factor deficiency as in hepatic dysfunction, vitamin K depletion or DIC
3. reversal of warfarin (Coumadin®) (p.166) effect (PT>18 sec, or INR>1.6) in patient actively bleeding or requiring emergency surgery or procedure with insufficient time for vitamin K to correct (which usually requires >6–12 hrs)
4. deficiency of antithrombin III, heparin cofactor II, or protein C or S
5. massive blood transfusion: replacement of>1 blood volume (≈ 5 L in 70kg adult) within several hours with evidence of coagulation deficiency as in (1) and with continued bleeding
6. treatment of thrombotic thrombocytopenic purpura, hemolytic uremic syndrome
7. because of associated hazards and suitable alternatives, the use of FFP as a volume expander is relatively contraindicated

Dosage

Usual starting dose is 2 bags of FFP (400–600 ml). If PT is 18–22 secs or APTT is 55–70 secs, 1 bag may suffice. Doses as high as 10–15 ml/kg may be needed for some patients. Monitor PT/PTT (or specific factor assay) and clinical bleeding. Since factor VII has a shorter half-life (≈ 6 hrs) than the other factors, PT may become prolonged before APTT.

Remember: if patient is also receiving platelets, that for every 5–6 units of platelets the patient is also receiving coagulation factors equivalent to ≈ 1 bag of FFP.

Albumin and plasma protein fraction (PPF, AKA Plasmanate®)

Usually from outdated blood, treated to inactivate hepatitis B virus. Ratio of albumin:globulin percentage in “albumin” is 96%/4% in PPF it is 83%/17%. Available in 5% (oncotically and osmotically equivalent to plasma) and 25% (contraindicated in dehydrated patients). 25% albumin may be diluted to 5% by mixing 1 volume of 25% albumin to 4 volumes of DS W or 0.9% NS (caution: mixing with sterile water will result in a hypotonic solution that can cause hemolysis and possible renal failure).

Expensive for use simply as a volume expander (≈ $60–80 per unit). Indicated only when total protein <5.2 gm% (otherwise, use crystalloid which is equally effective). Rapid infusion (>10 cc/min) has been reported to cause hypotension (due to Na-acetate and Hageman factor fragments). Use in ARDS is controversial. In neurosurgical patients, may be considered as an adjunct for volume
expansion (along with crystalloids) for hyperdynamic therapy (p.1186) when the hematocrit is <40% following SAH where there is concern about increasing the risk of rebleeding e.g. with the use of hetastarch (p.1165).

Cryoprecipitate
Recommended transfusion criteria:
1. hemophilia A
2. von Willebrand disease
3. documented fibrinogen/factor VIII deficiency
4. documented disseminated intravascular coagulation (DIC): along with other modes of therapy

Prothrombin complex concentrate (PCC) (Kcentra® and others)
Derived from fresh-frozen human plasma, contains clotting factors II, VII, IX and X, with protein C & S to prevent thrombosis. Primary indication is to be given IV to reverse warfarin in emergency situations. However it is also used in other settings. Requires much lower volume than FFP to work. Also, when the INR gets down to about 1.4, PCC will continue to reduce the INR whereas FFP will have little or no benefit.

Optimal dosing is not known. Doses of 15-50 IU/kg have been given to hemophiliacs but the clotting deficit differs in vitamin-K depletion than in clotting factor absence. A reasonable dose that is often used is 25 IU/kg.

9.2.5 Anticoagulation considerations in neurosurgery

General information
Most of these issues have not been studied in a rigorous, prospective fashion. Yet, these questions frequently arise. The following is to be considered a framework of guidelines, and is not to be construed as a standard of care. Table 9.3 acts as an index to the topics discussed below.

Contraindications to heparin
Contraindications to heparin therapy are constantly being reevaluated. Massive PE producing hemodynamic compromise should be treated with anticoagulation in most cases despite intracranial risks. Contraindications to full anticoagulation with heparin include:
- recent severe head injury
- recent craniotomy: see below
- patients with coagulopathies
- hemorrhagic infarction
- bleeding ulcer or other inaccessible bleeding site

Table 9.3 Anticoagulation issues in neurosurgery

Managing patients who are already anticoagulated who need a neurosurgical procedure
- warfarin (Coumadin®) (p.157)
- heparin (p.160)
- LMW-heparin (p.160)
- antiplatelet drugs (aspirin, Plavix, NSAIDs) (p.160)

Recommendations for DVT prophylaxis in neurosurgical patients (p.168)
- uncontrollable hypertension
- severe hepatic or renal disease
- <4–6 hours before an invasive procedure (see below)
- brain tumor: see below

**Patients with unruptured (incidental) cerebral aneurysms**

Anticoagulation may not increase the risk of hemorrhage (i.e. rupture), however, should rupture occur, anticoagulation would most likely increase volume of hemorrhage and thus increase morbidity and mortality.

The decision to start/continue anticoagulant depends on the indication for the drugs, the size of the aneurysm (a small aneurysm <4 mm is not as worrisome). Patients needing Plavix® for drug-eluting cardiac stents should probably be left on their drugs.

**Patients on anticoagulation/antiplatelet drugs who develop SAH**

Coumadin and antiplatelet drugs are usually reversed.

**In patients with brain tumor**

Some authors are reluctant to administer full-dose heparin to a patient with a brain tumor, although a number of studies found no higher risk in these patients when treated with heparin or oral anticoagulation (PT should be followed very closely, one study recommended maintaining PT ≈ 1.25 × control).

**Post-operatively following craniotomy**

Requires individualization based on the reason for the craniotomy. Surgery for parenchymal lesions where the surgery disrupts small vessels (e.g. brain tumor) is probably higher risk for hemorrhage than e.g. aneurysm surgery (expert opinion). Options:

- Full anticoagulation: most neurosurgeons would probably not fully anticoagulate patients <3–5 days following craniotomy, and some recommend at least 2 weeks. However, one study found no increased incidence of bleeding when anticoagulation was resumed 3 days post craniotomy.
- Low-dose (prophylactic) anticoagulation: either with mini-dose heparin (5000 U SQ 2 hrs prior to craniotomy and continuing q 12 hrs post-op × 7 d) or enoxaparin (Lovenox) (30 mg SQ BID or as a single dose of 40 MG SQ q d). – RPDB study: assessed safety (not efficacy), 55 patients undergoing craniotomy for tumor received mini-dose heparin as indicated had no increased bleeding tendency by any of the parameters measured. RPNB study: incidence of post-op hemorrhage increased to 11% with enoxaparin.

**Management of anticoagulants prior to neurosurgical procedures**

Pre-operative laboratory assessment of the coagulation pathway and platelet function is routinely used even though these studies rarely contribute critical information in the patient with a negative history for bleeding tendencies. There are no randomized studies to assess the value of coagulation laboratory measurements to patient care. This section encompasses the use of antiplatelet and anticoagulation medicines, their monitoring, and their reversal.

Table 9.4 summarizes this information.

**Warfarin**

Management guidelines

Patients on warfarin who must be anticoagulated as long as possible (e.g. mechanical heart valves) may be “bridged” to LMW heparin injections, e.g. Lovenox (p.165), as follows: stop warfarin at least 3 days prior to the procedure, and begin self-administered LMW heparin injections which are discontinued as outlined in Table 9.4.

Patients with less critical anticoagulation needs (e.g. chronic a-fib) can usually stop the warfarin at least 4–5 days before the procedure, and a PT/INR is then checked on admission to the hospital. Patients must be advised that during the time that they are not anticoagulated, they are at risk of possible complications from the condition for which they are receiving the agents (annual risk for mechanical valve: ≈ 6% for a-fib: depends on several factors including age & history of prior stroke, an average for patients >65 years age is ≈ 5–6% see details (p.1304).

**Abbr eviations:** PCC = prothrombin complex concentrate, IV = intravenous, SQ = subcutaneous, aPTT = partial thromboplastin time, DVT = deep venous thrombosis, HIT = heparin induced thrombocytopenia, ACT = activated clotting time, AT = anti-thrombin, CrCl = creatinine clearance

*a* Hold time is the recommended time to wait after discontinuing the drug before doing an elective operation in order to eliminate the effects of the drug

*b* Intravenous vitamin K has a more rapid onset than subcutaneous vitamin K and current formulations, made with mice lecithin and glycol, seem to have a lower complication profile than older formulations containing polyethylated castor oil.
For non-emergent neurosurgical procedures

For procedures where post-op mass effect from bleeding would pose serious risk (which includes most neurosurgical operations), it is recommended that the PT should be $\approx \leq 13.5$ sec (i.e., upper limits of normal) or the INR should be $\approx \leq 1.4$ (e.g., for reference, this INR is considered safe for performing a percutaneous needle liver biopsy). See also reversal of anticoagulation (p. 166).

For emergent neurosurgical procedures

Give FFP (start with 2 units) and vitamin K (10–20 mg IV at $\leq 1$ mg/min) as soon as possible; see also reversal of anticoagulation (p. 166). The timing of surgery is then based on the urgency of the situation and the nature of the procedure (e.g., the decision might be to evacuate a spinal epidural hematoma in an acutely paralyzed patient before anticoagulation is fully reversed).

Heparin

For emergencies: if it would be deleterious to wait 4–6 hours after discontinuing heparin and then repeating the PTT to verify that anticoagulation has been corrected, then heparin can be reversed with protamine (p. 166).

For non-emergencies

IV heparin: stop the drip $\approx 4$–6 hours prior to the planned procedure. Option: recheck PTT just prior to starting the procedure.

“Mini-dose” SQ heparin: not mandatory to stop for craniotomy, but if desired to discontinue, then give last dose $\geq 12$ hours prior to surgery.

Low-molecular weight heparins (LMWH)

For emergencies: can be reversed with protamine (p. 166).

Non-emergencies: See Table 9.4. Longer times are needed in renal failure. A factor Xa level can be used to check anticoagulation status, but this usually must be sent out, making it unsuitable for acute management.

Antiplatelet drugs and neurosurgical procedures

Platelet mechanics and platelet function tests

Platelets are important for maintaining vascular endothelial integrity and are constantly involved with hemostasis in conjunction with coagulation factors. Severe thrombocytopenia can result in petechial hemorrhages or spontaneous intracerebral hemorrhage (ICH). Vascular wall disturbance is the initial stimulus for platelet deposition and activation. Platelets adhere to collagen via surface receptors GPIb-V-IX and von Willebrand factor. This adhesion sets off a cascade of reactions, which result in platelet aggregation forming a hemostatic plug. Historically, bleeding time (BT) was used as the screening test for abnormalities of platelet function. Due to unreliability, many institutions have replaced the BT with the platelet function assay (PFA) using the PFA-100 (platelet function analyzer). There are limited studies confirming its use according to the International Society of Thrombosis and Hemostasis.$^{12,13}$

In the PFA-100, primary hemostasis is simulated under “high-shear” flow by movement of citrated blood through a membrane-impregnated capillary in two collagen-coated cartridges; one stimulates platelets with adenosine diphosphate (ADP) and the other with epinephrine.$^{14}$ This interaction with the collagen induces a platelet plug, which closes an aperture. Results are reported as

The recommended minimum interval between last dose and procedure is based on renal function and procedure risk. Generally, neurosurgical procedures including minor procedures such as LPs are considered interventions with a high bleeding risk.
cases, 5 persist. Agents available PF A cartridges detect P2Y 12 receptor blockade in patients on theinopyridine drugs. 100 works for testing with aspirin but not with thienopyridine drug class (e.g. clopidogrel). Newly such as von Willebrand disease as well as for monitoring the e closure time in seconds. This method is eligible as a screening test for prim ary hemostatic disease exact antiplatelet mechanism is unclear.

Herbal products and supplements. Herbal products and supplements often affect platelet aggregation and the coagulation cascade by means that cannot be detected by laboratory tests. The increasing popularity of these unregulated products requires screening patients for their use. There are limited studies regarding the use of herbal supplements in neurosurgery and for an elective operation waiting 7–14 days after cessation of their use is warranted.

Fish Oil (Omega-3 Fatty Acids) is widely used among the cardiac and general population for treatment of dyslipidemia and hypertriglyceridemia. Fish oil may affect platelet aggregation by a reduc tion in arachidonic acid and thromboxane and adenosine diphosphate receptor blockade. Fish oil may also potentially lengthen bleeding times.23,24,25

Garlic (Allium sativum) has increased in popularity as a supplement. Purported benefits include: lowering blood pressure, preventing infection and myocardial infarction, and treating hypercholesterolemia. Garlic has an antiplatelet affect through ADP receptor blockade, and reducing calcium and thromboxane.26 There is particular concern with garlic as it may potentiate the antiplatelet or anti coagulant affect of aspirin or warfarin.27

Ginkgo (Ginkgo biloba) has also become a popular supplement found in many formulations from capsules to energy drinks. Ginkgo has been used to treat a number of ailments including memory loss, depression, anxiety, dizziness, claudication, erectile dysfunction, tinnitus and headache. Ginkgo affects bleeding via an antiplatelet affect and antagonism of platelet-activating factor.28,29 See Ginkgo biloba under Spontaneous subdural hematoma (p.901).

Ginseng (Panax ginseng) has also been found to have antiplatelet activity through thromboxane inhibition and platelet-activating factor.10 Some authors also advocate cautious use of ginger and vitamin E when planning surgery, but the exact antiplatelet mechanism is unclear.25

Herbal products and supplements often affect platelet aggregation and the coagulation cascade by means that cannot be detected by laboratory tests. The increasing popularity of these unregulated products requires screening patients for their use. There are limited studies regarding the use of herbal supplements in neurosurgery and for an elective operation waiting 7–14 days after cessation of their use is warranted.

Garlic has an antiplatelet affect through ADP receptor blockade, and reducing calcium and thromboxane.26 There is particular concern with garlic as it may potentiate the antiplatelet or anti coagulant affect of aspirin or warfarin.27

Ginger (Zingiber officinale) has been used to treat a number of ailments including memory loss, depression, anxiety, dizziness, claudication, erectile dysfunction, tinnitus and headache. Ginger affects bleeding via an antiplatelet affect and antagonism of platelet-activating factor.28,29 See Ginger under Spontaneous subdural hematoma (p.901).

Some authors also advocate cautious use of ginger and vitamin E when planning surgery, but the exact antiplatelet mechanism is unclear.25

Reversal of antiplatelet drugs: While heparin and warfarin can be reliably and measurably reversed, the situation is less clear with antiplatelet agents.21 Agents used pre-op to reverse these drugs include: Desmopressin (p.166) (DDAVP®)16,17 and FFP.16

Reversal of Plavix for emergency surgery (p.154): platelets may be given, however, Plavix effects persists for up to a couple of days after the last dose, and can actually inhibit platelets given after the drug is discontinued (the half-life of aspirin is lower and should not be an issue after 1 day). In cases with continued oozing in the first day or so after discontinuing Plavix, the following regimen is an option:

1. recombinant activated coagulation factor V II (rF V IIa): even though the defect is in the platelets, with continued oozi ng in the first day or so af ter discontinuing Plavix, the fol lowi ng regimen is an option: 2. platelets every 8 hours for 24 hours, either

A) 6 U of regular platelets

B) if patient is on fluid or volume restriction: 1 unit of pheresed platelets

Herbal products and supplements. Herbal products and supplements often affect platelet aggregation and the coagulation cascade by means that cannot be detected by laboratory tests. The increasing popularity of these unregulated products requires screening patients for their use. There are limited studies regarding the use of herbal supplements in neurosurgery and for an elective operation waiting 7–14 days after cessation of their use is warranted.

Fish Oil (Omega-3 Fatty Acids) is widely used among the cardiac and general population for treatment of dyslipidemia and hypertriglyceridemia. **Anticoagulants**

See also platelet function inhibitors (p. 164).

**Warfarin**

**Drug info: Warfarin (Coumadin®)**

An oral vitamin K antagonist. To anticoagulate average weight patient, give 10 mg PO q d × 2–4 days, then ≈ 5 mg q d. Follow coagulation studies, titrate to PT = 1.2–1.5 × control (or INR ≈ 2–3) for most conditions (e.g. DVT, single TIA). Higher PT ratios of 1.5–2 × control (INR ≈ 3–4) may be needed for recurrent systemic embolism, mechanical heart valves… (the recommended ranges for the International Normalized Ratio (INR) are shown in Table 9.7).

Starting warfarin: During the first ≈ 3 days of warfarin therapy, patients may actually be hypercoagulable (secondary to reduction of vitamin-K dependent anticoagulation factors protein C and protein S), putting them at risk of “Coumadin necrosis.” Therefore patients should be “bridged” by starting either lovenox (p. 165) which can be self-administered as an outpatient, or heparin (with a therapeutic PTT).

Supplied: scored tabs of 1, 2, 2.5, 5, 7.5 and 10 mg. IV form: 5 mg/vial.

**Heparin**

**Drug info: Heparin**

Full anticoagulation in an average weight patient, give 5000 U bolus IV, follow with 1000 U/hr IV drip. Titrate to therapeutic anticoagulation of APTT = 2–2.5 × control (for DVT, some recommend 1.5–2 × control)4

prophylactic AKA low-dose (“mini-dose”) heparin: 5000 IU SQ q 8 or 12 hrs. Routine monitoring of APTT is usually not done, although occasionally patients may become fully anticoagulated on this regimen.

Side effects: (see Anticoagulant considerations in neurosurgery above): hemorrhage, thrombosis (heparin activates anti-thrombin III and can cause platelet aggregation) which can result in MIs, DVTs, PEs, strokes, etc. Heparin induced thrombocytopenia (HIT): transient mild thrombocytopenia is fairly common in the first few days after initiating heparin therapy, however severe thrombocytopenia occurs in 1–2% of patients receiving heparin >4 days (usually has a delayed onset of 6–12 days, and is due to consumption in heparin-induced thrombosis or to antibodies formed against a heparin-platelet protein complex). The incidence of HIT in SAH is 5–6% and was similar with enoxaparin.43 Consider use of fondaparinux in thrombocytopenic patients. Chronic therapy may cause osteoporosis.

**Low molecular weight heparins**

See references 44,45.

Low molecular weight heparins (LMWH) (average molecular weight = 3000–8000 daltons) are derived from unfractionated heparin (average MW = 12,000–15,000 daltons). LMWHs differ from unfractionated heparin because they have a higher ratio of anti-factor Xa to anti-factor IIa (antithrombin) activity which theoretically should produce antithrombic effects with fewer hemorrhagic complications. Realization of this benefit has been very minor in clinical trials. LMWH have greater bioavailability after sub-Q injection leading to more predictable plasma levels which eliminates the need to monitor biologic activity (such as APTT). LMWH have a longer half-life and therefore require
fewer doses per day. LMWH have a lower incidence of thrombocytopenia. More effective in DVT prophylaxis than warfarin in orthopedic surgery.46

Spinal epidural hematomas: There have been a number of case reports of spinal epidural hematomas occurring in patients on LMWH (primarily enoxaparin) who also underwent spinal/epidural anesthesia or lumbar puncture, primarily in elderly women undergoing orthopedic surgery. Some have had significant neurologic sequelae, including permanent paralysis.47 The risk is further increased by the use of NSAIDs, platelet inhibitors, or other anticoagulants, and with traumatic or repeated epidural or spinal puncture.

Available low molecular weight heparins. Drugs include:

- enoxaparin (Lovenox®): see below
- dalteparin (Fragmin®): 2500 anti-Xa U SQ q d
- ardeparin (Normiflo®): half-life = 3.3 hrs. 50 anti-Xa U/kg SQ q 12 hrs
- danaparoid (Orgaran®): a heparinoid. Even higher anti-Xa:anti-IIa ratio than LMWHs. Does not require laboratory monitoring. 750 anti-Xa U SQ BID
- tinzaparin (Logiparin®, Innohep®): not available in U.S. 175 anti-Xa U per kg SQ once daily

### Drug info: Enoxaparin (Lovenox®)

dosage established following hip replacement is 30 mg SQ BID×7–14 days (alternative: 40 mg SQ q d). Pharmacokinetics: After SQ injection, peak serum concentration occurs in 3–5 hrs. Half-life: 4.5 hrs.

### Direct thrombin inhibitors

### Drug info: Dabigatran (Pradaxa®, Rendix®)

An oral anticoagulant in the class of direct thrombin inhibitors. Administered as the prodrug dabigatran etexilate. Must be stopped 24 hrs prior to surgery.

Reversal of anticoagulation: Praxbind (idarucizumab) IV for emergencies. Reverses pradaxa within 4 hrs, lasts 24 hrs.48

### Drug info: Bivalirudin (Angiomax® or Angiox®)

A reversible direct thrombin inhibitor (DTI) that increases the rapidity of plasminogen activator-mediated recanalization. No effective reversal.

: IV loading dose of 0.5 mg/kg IV, followed by continuous infusion of 1.75 mg/kg/hr. Intraarterial: inject 15 mg in 10 ml of heparinized saline via a microcatheter.

### Factor Xa inhibitors

### Drug info: Fondaparinux (Arixtra®)

A synthetic analog of the pentasaccharide binding sequence of heparin. Increases factor Xa inhibition without affecting factor IIa (thrombin).49 Unlike heparin, fondaparinux does not bind to other plasma proteins or platelet factor-4 and does not cause heparin-induced thrombocytopenia (HIT) and can therefore be used in patients with HIT. May be more effective than enoxaparin (Lovenox®) for preventing post-op DVTs. Side effects: Bleeding is the most common side effect (may be increased by concurrent NSAID use). Contraindicated with severe renal impairment (CrCl<30 ml/min).50

Coagulopathies

Correction of coagulopathies or reversal of anticoagulants
Also refer to recommended normal values for coagulation studies in neurosurgery (p. 157).

Platelets
See indications and administration guidelines (p. 154).

Fresh frozen plasma
To reverse warfarin anticoagulation, use the following as a starting point and recheck PT/PTT afterwards:
• when patient is “therapeutically anticoagulated” start with 2–3 units FFP (approximately 15 ml/kg is usually needed)
• for severely prolonged PT/PTT, start with 6 units FFP

Prothrombin complex concentrate (PCC)
Warfarin induced anticoagulation may be reversed up to 4 or 5 times more quickly with PCC (Kcentra) (contains coag factors II, IX, and X) than with FFP. Patient may become hyperthrombotic with this.

Drug info: Vitamin K (Mephyton®)

To reverse elevated PT from warfarin, give aqueous colloidal solution of vitamin K1 (phytonadione, Mephyton®). Doses >10 mg may produce warfarin resistance for up to 1 week. FFP may be administered concurrently for more rapid correction (see above). See recommended levels of PT (p. 157).

adult: start with 10–15 mg IM; the effect takes 6–12 hrs (in absence of liver disease). Repeat dose if needed. The average total dose needed to reverse therapeutic anticoagulation is 25–35 mg.

IV administration has been associated with severe reactions (possibly anaphylactic), including hypotension and even fatalities (even with proper precautions to dilute and administer slowly), therefore IV route is reserved only for situations where other routes are not feasible and the serious risk is justified. IV (when IM route not feasible): 10–20 mg IV at a rate of injection not to exceed 1 mg/min (e.g. put 10 mg in 50 ml of D5 W and give over 30 minutes).

Drug info: Protamine sulfate

For heparin: 1 mg protamine reverses ≈ 100 U heparin (give slowly, not to exceed 50 mg in any 10 min period). Therapy should be guided by coagulation studies.

Reversal of low molecular weight heparins (LMWH): slow IV injection of a 1% solution of protamine can also be used to reverse LMWHs as follows:
• Enoxaparin (Lovenox®): ≈ 60% of Lovenox can be reversed with 1 mg of protamine for every mg of Lovenox given (maximum dose = 50 mg) within the last 8 hrs, and 0.5 mg of protamine for every mg of Lovenox given from 8–12 hrs prior. Protamine is probably not needed for Lovenox given >12 hrs earlier.
• Dalteparin (Fragmin®) or ardeparin (Normiflo®): 1 mg of protamine for every 100 anti-Xa IU of the LMWH (maximum dose = 50 mg) with a second infusion of 0.5 mg protamine for every 100 anti-Xa IU of LMWH if the APTT remains elevated 2–4 hours after the first dose is completed.
• Danaparoid and Hirudin: no known reversing agent.

Drug info: Desmopressin (DDAVP®)

Causes an increase in factor III coagulant activity and von Willebrand factor which helps coagulation and platelet activity in hemophilia A and in von Willebrand’s disease Type I (where the factors are normal in makeup but low in concentration, but may cause thrombocytopenia in von Willebrand’s disease Type III where factors may be abnormal or missing).

0.3 mcg/kg (use 50 ml of diluent for doses ≤ 3 mcg, use 10 ml for doses >3 mcg) given over 15–30 minutes 30 minutes prior to a surgical procedure.
Elevated pre-op PTT
In a patient with no history of coagulopathy, a significantly elevated pre-op PTT is commonly due to either a factor deficiency or to lupus anticoagulant. Work-up:
1. mixing study
2. lupus coagulant

If the mixing study corrects the elevated PTT, then there is probably a factor deficiency. Consult a hematologist.

Lupus anticoagulant: If the test for lupus anticoagulant is positive, then the major risk to the patient with surgery is not bleeding, rather it is thromboembolism. Management recommendations:
1. as soon as feasible post-op, start patient on heparin (p.164) or LMW heparin (p.164), e.g. Lovenox
2. at the same time start warfarin, and maintain therapeutic anticoagulation for 3–4 weeks (the risk of DVT/PE is actually highest in the first few weeks post-op)
3. mobilize as soon as possible post-op
4. consider vena-cava interruption filter in patients for whom anticoagulation is contraindicated

Disseminated intravascular coagulation (DIC)
Abnormal intravascular coagulation which consumes clotting factors and platelets, coupled with abnormal activation of fibrinolytic system. Head trauma is an independent risk factor for DIC, possibly because the brain is rich in thromboplastin which may be released into systemic circulation with trauma. Other risk factors: shock, sepsis.

Presentation
Diffuse bleeding, cutaneous petechia, shock.

Labs
1. fibrinogen degradation products (FDP)>16 mcg/ml (1–8 = normal; 8–16 = borderline; 32 = definitely abnormal; some labs require >40 for diagnosis of DIC) (the most common abnormality)
2. fibrinogen <100 mcg/dl (some use 130)
3. PT>16; PTT>50
4. platelets <50,000 (relatively uncommon)

Chronic DIC
PT & PTT may be normal; platelet & fibrinogen low, fibrin split products elevated.

Treatment
1. remove inciting stimulus if possible (treat infections, debride injured tissue, stop transfusions if suspected)
2. vigorous fluid resuscitation
3. anticoagulants, if not contraindicated (p.156)
4. FFP if PT or PTT elevated, or fibrinogen <130
5. platelet transfusion if platelet count <100 K

Pseudo-DIC
Increased fibrin split products, normal fibrinogen.
Seen in conditions such as liver failure.

Thromboembolism in neurosurgery
Deep-vein thrombosis (DVT)
DVT is of concern primarily because of the potential for material (clot, platelet clumps…) to dislodge and form emboli (including pulmonary emboli, (PE)) which may cause pulmonary infarction, sudden death (from cardiac arrest), or cerebral infarction (from a paradoxical embolus, which may occur in the presence of a patent foramen ovale, see Cardiogenic brain embolism (p.1304)). The reported mortality from DVT in the LEs ranges from 9–50%53 DVT limited to the calf has a low threat (<1%) of embolization, however, these clots later extend into the proximal deep veins in 30–50% of cases, from where embolization may occur (in 40–50%), or they may produce postphlebitic syndrome.

Neurosurgical patients are particularly prone to developing DVTs (estimated risk: 19–50%) due at least in part to the relatively high frequency of the following:
1. long operating times of some procedures
2. prolonged bed rest pre- and/or post-op
3. alterations in coagulation status
   a) in patients with brain tumors (see below) or head injury
      • related to the condition itself
      • due to release of brain thromboplastins during brain surgery
   b) increased blood viscosity with concomitant “sludging”
      • from dehydration therapy sometimes used to reduce cerebral edema
      • from volume loss following SAH (cerebral salt wasting)
   c) use of high-dose glucocorticoids

Specific “neurological” risk factors for DVT and PE include:
1. spinal cord injury (p.952)
2. brain tumor: autopsy prevalence of DVT=28% of PE=8.4% Incidence using 125I-fibrinogen:
   meningioma 72% malignant glioma 60% metastasis 20% Risk may be reduced by pre-op use of aspirin
3. subarachnoid hemorrhage
4. head trauma: especially severe TBI (p.918)
5. stroke: incidence of PE=1–19.8% with mortality of 25–100%
6. neurosurgical operation: risk is higher following craniotomy for supratentorial tumors (7% of 492 patients) than p-fossa tumors (0 out of 141)

Prophylaxis against DVT
Options include:
1. general measures
   a) passive range of motion
   b) ambulate appropriate patients as early as possible
2. mechanical techniques (minimal risk of complications):
   a) pneumatic compression boots (PCBs) or sequential compression devices (SCDs): reduces the incidence of DVTs and probably PEs. Do not use if DVTs already present. Continue use until patient able to walk 3–4 hrs per day
   b) TED Stockings® (TEDS) applies graduated pressure, higher distally. As effective as PCB. No evidence that the benefit is additive.
   c) electrical stimulation of calf muscles
   d) rotating beds
3. anticoagulation; see also contraindications and considerations of anticoagulation in neurosurgery (p.156)
   a) full anticoagulation is associated with perioperative complications
   b) “low-dose” anticoagulation (low-dose heparin): 5000 IU SQ q 8 or 12 hrs, starting 2 hrs pre-op or on admission to hospital. Potential for hazardous hemorrhage within brain or spinal canal has limited its use
   c) low molecular weight heparins and heparinoids (p.164): not a homogeneous group. Efficacy in neurosurgical prophylaxis has not been determined
   d) aspirin: role in DVT prophylaxis is limited because ASA inhibits platelet aggregation, and platelets play only a minor role in DVT
4. combination of PCBs and “mini-dose” heparin starting on the morning of post-op day 1 (with no evidence of significant complications)

Recommendations
Recommended prophylaxis varies with the risk of developing DVT, as illustrated in Table 9.8. See also details of prophylaxis in cervical spinal cord injuries (p.952).

Diagnosis of DVT
(For PE, see below). The clinical diagnosis of DVT is very unreliable. A patient with the “classic signs” of a hot, swollen, and tender calf, or a positive Homans’ sign (calf pain on dorsiflexion of the ankle) will have a DVT only 20–50% of the time. 50–60% of patients with DVT will not have these findings.

Laboratory tests
• contrast venography: the “gold standard”, however it is invasive and carries risk of iodine reaction, occasionally produces phlebitis, not readily repeated
Doppler ultrasound with high-resolution real-time B-mode imaging: 95% sensitive and 99% specific for proximal DVT. Less effective for calf DVT. As a result, it is recommended that patients with initially negative studies undergo repeat studies over the next 7–10 days to R/O proximal extension. Requires more skill on the part of the tester than IPG. May be used in immobilized or casted LE (unlike IPG). Widely accepted as the non-invasive test of choice for DVT.

Impedance plethysmography (IPG): looks for reduced electrical impedance produced by blood flow from the calf following relaxation of a pneumatic tourniquet. Good in detecting proximal DVT, not sensitive for calf DVT. A positive study indicates DVT that should be treated, a negative study can occur with non-occlusive DVT or with good collaterals, and should be repeated over a 2-week period.

125I-fibrinogen: radiolabeled fibrinogen is incorporated into the developing thrombus. Better for calf DVT than proximal DVT. Expensive, and many false positives. Risk of HIV transmission has resulted in withdrawal of use.

D-dimer (a specific fibrin degradation product): high levels are associated with DVT and PE.

Treatment of DVT
1. bed rest, with elevation of involved leg(s)
2. unless anticoagulation is contraindicated (p. 156): start heparin as outlined in Anticoagulation (p. 156), aim for APTT = 1.5–2 x control; or fixed dose of LMW heparinoids, e.g. tinzaparin (Logiparin®) or in the U.S. enoxaparin (Lovenox®) (p. 165). Simultaneously initiate warfarin therapy. Heparin can be stopped after ~5 days.
3. in patients where anticoagulation is contraindicated, consider inferior vena cava interruption or placement of a filter (e.g. Greenfield filter)
4. in non-paralyzed patients, cautiously begin to ambulate after ~7–10 days
5. wear anti-embolic stocking on affected LE indefinitely (limb is always at risk of recurrent DVT)

Pulmonary embolism (PE)
See reference.

Prevention of PE
Prevention of PE is best accomplished by prevention of DVT (p. 168).

Presentation of PE
Post-op PE generally occurs 10–14 days following surgery. The reported incidence ranges from 0.4–5% A series (on a service with routine use of elastic stockings and, in high risk patients, “mini-dose” heparin) found a post-op incidence of ~0.4% with a doubling of this number if only patients with major pathology (brain tumor, head trauma, or cerebrovascular or spinal pathology) were considered (another series dealing only with brain tumors found a 4% incidence). Clinical diagnosis is nonspecific (diagnostic diagnosis of symptoms is large, and ranges from atelectasis to MI or cardiac tamponade).

*a abbreviations: DVT = deep venous thrombosis, PCB = pneumatic compression device, TEDS = TED (thromboembolic disease) Stockings®, ICH = intracerebral hemorrhage, SAH = subarachnoid hemorrhage

*b see specifics regarding DVT prophylaxis in cervical SCI (p. 952)
Common findings: sudden dyspnea (the most frequent finding), tachypnea, tachycardia, fever, hypotension, 3rd or 4th heart sound. Triad (rare): hemoptysis, pleuritic chest pain, dyspnea. Auscultation: pleuritic friction rub or rales (rare). Shock and CHF (mimics MI) indicates massive life-threatening PE. Mortality reported ranges from 9–60% with a significant number of deaths within the first hour.

Diagnosis of PE
A negative D-dimer test (see above) reliably excludes PE in patients with a low clinical probability of PE or in those with nondiagnostic VQ scan. Alternatively, one can check for DVT utilizing IPG, Doppler, or venography (see above). If positive, this indicates a possible source of PE, and since the treatment is similar for both, no further search for PE need be made and treatment is started. If negative, further testing may be needed (e.g. VQ scan, see below).

Laboratory tests
D-dimer: see above.

General diagnostic tests
None are very sensitive or specific.
- EKG: “classic” S1Q3T3 is rare. Usually just nonspecific-ST & T changes occur. Tachycardia may be the only finding
- CXR: normal in 25–30% When abnormal, usually shows infiltrate and elevated hemidiaphragm
- ABG: not very sensitive. pO2 > 90 on room air virtually excludes massive PE

Specific radiographic evaluation
- Test of choice: contrast enhanced chest CT. Occasionally chest CTA may be employed. Can provide insight into alternate diagnoses
- Pulmonary angiogram: historically, the “gold standard.” Invasive, expensive, and labor intensive. 3–4% risk of significant complications. Not indicated in most cases
- Ventilation-perfusion scan (VQ scan): CXR is also needed. A perfusion defect with no ventilation defect in a patient with no previous history of PE strongly suggests acute PE. Equivocal studies occur when an area of malperfusion corresponds to an area of reduced ventilation (on ventilation scan) or infiltrate (on CXR). Probabilities of PE based on VQ scan are shown in Table 9.9. A technically adequate normal VQ scan virtually rules out PE. Patients with low or intermediate probability scans should have a test for DVT or quantitative D-dimer (see above). If test for DVT is positive, treat; if it is negative, the choice is to follow serial IPG or Doppler studies for 2 weeks, or (rarely) to do a pulmonary angiogram
- Thin-section contrast-enhanced chest CT: more accurate in patients with COPD who often have an indeterminate VQ scan

Treatment
If diagnosis is seriously entertained, start heparin – unless contraindicated (p.156) – without waiting for results of diagnostic studies. For an average 70 kg patient, begin with 5000–7500 unit IV bolus, followed by 1000 U/hr drip (less for smaller patient). Follow PTT and titrate drip rate for PTT 1.5 to 2× control.

The use of heparin shortly after surgery and in patients with brain tumors is controversial, and vena caval interruption may be an alternate consideration (e.g. Greenfield filter).

Patients with massive PEs may be hemodynamically unstable. They usually require ICU care, often with PA catheter and pressors.

9.3 Extramedullary hematopoiesis

9.3.1 General information

In chronic anemias (especially thalassemia major, AKA Cooley’s anemia), low hematocrit results in chronic over-stimulation of bone marrow to produce RBCs. This results in systemic bony abnormalities, cardiomyopathy (due to hemochromatosis caused by increased breakdown of defective RBCs).

Pertinent to the CNS, there are three sites where extramedullary hematopoiesis (EMH) can cause findings:

- skull: produces “hair-on-end” appearance on skull x-ray
- vertebral bodies: may result in epidural cord compression* (see below)
- choroid plexus

9.3.2 Epidural cord compression from EMH

The exuberant tissue is very radiosensitive, however, the patient may be somewhat dependent on the hematopoietic capacity of the tissue.

9.3.3 Treatment

Surgical excision followed by radiation therapy has been the recommended treatment. Repeated blood transfusions may help reduce EMH and may be useful post-op instead of RTX except for refractory cases.71

Surgery on these patients is difficult because of:

1. low platelet count
2. poor condition of bone
3. cardiomyopathy: increased anesthetic risk
4. anemia, coupled with the fact that most of these patients are “iron-toxic” from multiple previous transfusions
5. total removal of the mass is not always possible

10 Neurology for Neurosurgeons

10.1 Dementia

Definition. Loss of intellectual abilities previously attained (memory, judgement, abstract thought, and other higher cortical functions) severe enough to interfere with social and/or occupational functioning. Memory deficit is the cardinal feature, however, the DSM-IV definition requires impairment in at least one other domain (language, perception, visuospatial function, calculation, judgement, abstraction, problem-solving skills). Affects 3–11% of community-dwelling adults >65 yrs of age, with a greater presence among institutionalized residents.

Risk factors: advanced age, family history of dementia, and apolipoprotein E-4 allele.

Delirium vs. dementia (critical distinction). Delirium AKA acute confusional state. Distinct from dementia, however, patients with dementia are at increased risk of developing delirium. A primary disorder of attention that subsequently affects all other aspects of cognition. Often represents life-threatening illness, e.g. hypoxia, sepsis, uremic encephalopathy, electrolyte abnormality, drug intoxication, MI. 50% of patients die within 2 yrs of this diagnosis.

Unlike dementia, delirium has acute onset, motor signs (tremor, myoclonus, asterixis), slurred speech, altered consciousness (hyperalert/agitated or lethargic, or fluctuations), hallucinations may be florid. EEG shows pronounced diffuse slowing.

Brain biopsy for dementia. Clinical criteria are usually sufficient for the diagnosis of most dementias. Biopsy should be reserved for cases of a chronic progressive cerebral disorder with an unusual clinical course where all other possible diagnostic methods have been exhausted and have failed to provide adequate diagnostic certainty. Biopsy may disclose CJD, low grade astrocytoma, and AD among others. The high incidence of CJD among patients selected for biopsy under these criteria necessitates appropriate precautions; see Creutzfeldt-Jakob disease (p.367). In a report of 50 brain biopsies performed to assess progressive neurodegenerative disease of unclear etiology, the diagnostic yield was only 20% (6% were only suggestive of a diagnosis, 66% were abnormal but nonspecific, 8% were normal). The yield was highest in those with focal MRI abnormalities. Among the 10 patients with diagnostic biopsies, the biopsy result led to a meaningful therapeutic intervention in only 4.

Recommendations. Based on the above, the following recommendations are made for patients with an otherwise unexplained neurodegenerative disease:
1. those with a focal abnormality on MRI: stereotactic biopsy
2. those without focal abnormality (possibly including SPECT or PET scan): brain biopsy should only be performed within an investigative protocol

Recommendations for specimen. Ideally the biopsy specimen should:
1. be large enough (usually 1 cm³)
2. be taken from an affected area
3. include grey and white matter, pia and dura
4. be handled carefully to minimize artifact (electrocautery should not be used on the specimen side of the incision)

10.2 Headache

10.2.1 General information

Headache (H/A) may be broadly categorized as follows:
1. chronic recurring headaches
   a) vascular type (migraine): see below
   b) muscle contraction (tension) headaches
2. headache due to pathology
   a) systemic pathology
   b) intracranial pathology: a wide variety of etiologies including:
      • subarachnoid hemorrhage: sudden onset, severe, usually with vomiting, apoplexy, focal deficits possible; see differential diagnosis of paroxysmal H/A (p.1158)
increased intracranial pressure from any cause (tumor, communicating hydrocephalus, inflammation, pseudotumor cerebri...)  
- irritation or inflammation of meninges: meningitis  
- tumor (p.590): with or without elevated ICP  
c) local pathology of the eye, nasopharynx, or extracranial tissues (including giant cell arteritis (p.195)  
d) following head trauma: postconcussive syndrome (p.923)  
e) following craniotomy: “syndrome of the trephined” (p.1431)

A severe new H/A, or a change in the pattern of a longstanding or recurrent H/A (including developing associated N/V, or an abnormal neurologic exam) warrants further investigation with CT or MRI.

Unilateral H/A that never changes side over a period ≥1 year warrants an MRI; this would be atypical in migraine and may be a presentation of an occipital AVM (p.1239).

10.2.2 Migraine

General Information

Migraine attacks usually occur in individuals predisposed to the condition, and may be activated by factors such as bright light, stress, diet changes, trauma, administration of radiologic contrast media (especially angiography) and vasodilators.

Classification

Based on the 1962 ad hoc committee on headache (H/A). See also index under Headache, e.g. for: crash migraine (thunderclap headache) (p.1158), post-myelogram headache (p.1508)...

Common migraine

Episodic H/A with N/V and photophobia, without aura or neurologic deficit.

Classic migraine

Common migraine + aura. May have H/A with occasional focal neurologic deficit(s) that resolve completely in ≤24 hrs.

Over half of the transient neurologic disturbances are visual, and usually consist of positive phenomena (spark photopsia, stars, complex geometric patterns, fortification spectra) which may leave negative phenomena (scotoma, hemianopia, monocular or binocular visual loss...) in their wake. The second most common symptoms are somatosensory involving the hand and lower face. Less frequently, deficits may consist of aphasia, hemiparesis, or unilateral clumsiness. A slow march-like progression of deficit is characteristic. The risk of stroke is probably increased in patients with migraine.10

Complicated migraine

Occasional attacks of classic migraine with minimal or no associated H/A, and complete resolution of neurologic deficit in ≤30 days.

Migraine equivalent

Neurologic symptoms (N/V, visual aura, etc.) without H/A (acephalgic migraine). Seen mostly in children. Usually develops into typical migraine with age. Aura may be shortened by opening and swallowing contents of a 10 mg nifedipine capsule.11

Hemiplegic migraine

H/A typically precedes hemiplegia which may persist even after H/A resolves.

Cluster headache

AKA histaminic migraine. Actually a neurovascular event, distinct from true migraine. Recurrent unilateral attacks of severe pain. Usually oculofrontal or oculotemporal with occasional radiation into the jaw, usually recurring on the same side of the head. Ipsilateral autonomic symptoms (conjunctival injection, nasal congestion, rhinorrhea, lacrimation, facial flushing) are common. Partial Horner’s
syndrome (ptosis and miosis) sometimes occurs. Male:female ratio is $\approx 5:1$. 25% of patients have a personal or family history of migraine.

Headaches characteristically have no prodrome, last 30–90 minutes, and recur one or more times daily usually for 4–12 weeks, often at a similar time of day, following which there is typically a remission for an average of 12 months.\textsuperscript{12}

Prophylaxis for cluster H/A is only minimally effective:
1. $\beta$-adrenergic blockers are less effective
2. lithium: becoming drug of choice (response rate 60–80%). 300 mg PO TID and follow levels (desired: 0.7–1.2 mEq/L)
3. occasionally ergotamines are used
4. naproxen (Naprosyn®)
5. methysergide (Sansert®) 2–4 mg PO TID is effective in 20–40% of cases, must cycle patient off the drug to prevent retroperitoneal fibrosis, etc. (also see below)

Treatment for cluster H/A (prophylaxis is only minimally effective):
Treatment is difficult because there is no prodrome and the H/A often stop after 1–2 hrs. Treatment of acute attacks includes:
- 100% $\text{O}_2$ by face mask with patient sitting for $\leq 15$ min or until attack aborted
- ergotamine: see below
- SQ sumatriptan: usually aborts attack within 15 minutes (see below)
- steroids: see below
- refractory cases may be considered for:
  - percutaneous radiofrequency sphenopalatine ganglion blockade\textsuperscript{13}
  - occipital nerve stimulation\textsuperscript{14}
  - hypothalamic deep brain stimulation

Basilar artery migraine
Essentially restricted to adolescence. Recurrent episodes lasting minutes to hours of transient neurologic deficits in distribution of vertebrobasilar system. Deficits include: vertigo (most common), gait ataxia, visual disturbance (scotomata, bilateral blindness), dysarthria, followed by severe H/A and occasionally nausea and vomiting.\textsuperscript{15} Family history of migraine is present in 86%

10.3 Parkinsonism
10.3.1 General information
Parkinsonism may be primary or secondary to other conditions. All result from a relative loss of dopamine mediated inhibition of the effects of acetylcholine in the basal ganglia.

10.3.2 Idiopathic paralysis agitans (IPA)
Clinical
Classical Parkinson’s disease AKA shaking palsy. Affects $\approx 1\%$ of Americans $> age 50$ yrs,\textsuperscript{16} it is frequently underdiagnosed.\textsuperscript{17} Male:female ratio is 3:2. Not clearly environmentally or genetically induced, but may be influenced by these factors.

The classic triad is shown in Table 10.1. Other signs may include: postural instability, micrographia, mask-like facies. Gait consists of small, shuffling steps (marche à petits pas) or festinating gait.

Clinically distinguishing IPA from secondary parkinsonism (see below)
May be difficult early. IPA generally exhibits gradual onset of bradykinesia with tremor that is often asymmetrical, and initially responds well to levodopa. Other disorders are suggested with rapid progression of symptoms, when the initial response to levodopa is equivocal, or when there is early midline symptoms (ataxia or impairment of gait and balance, sphincter disturbance...), or the

presence of other features such as early dementia, sensory findings, profound orthostatic hypotension, or abnormalities of extraocular movements.\textsuperscript{18,19}

### Pathophysiology

Degeneration primarily of pigmented (neuromelanin-laden) dopaminergic neurons of the pars compacta of the substantia nigra, resulting in reduced levels of dopamine in the neostriatum (caudate nucleus, putamen, globus pallidus). This decreases the activity of inhibitory neurons with predominantly D2 class of dopamine receptors which project directly to the internal segment of the globus pallidus (GPI), and also increases (by loss of inhibition) activity of neurons with predominantly D1 receptors which project indirectly to the globus pallidus externa (GP\textsubscript{e}) and subthalamic nucleus.\textsuperscript{20} The net result is increased activity in GPI which has inhibitory projections to the thalamus which then suppresses activity in the supplemental motor cortex among other locations.

Histologically: Lewy bodies (eosinophilic intraneuronal hyaline inclusions) are the hallmark of IPA.

### 10.3.3 Secondary parkinsonism

#### General information

The differential diagnosis of Parkinson’s disease includes the following etiologies of secondary parkinsonism or Parkinson-like conditions (sometimes of these are occasionally referred to as “Parkinson plus” syndromes or parkinsonian disorders) (see above for distinguishing features):

1. olivopontocerebellar degeneration (OPC)
2. striato-nigral degeneration (SND): more aggressive than parkinsonism
3. postencephalitic parkinsonism: followed an epidemic of encephalitis lethargica (von Economo disease) in the 1920s, victims are no longer living. Distinguishing features: oculogyric crisis, tremor involves not only extremities but also trunk and head, asymmetrical, no Lewy bodies
4. progressive supranuclear palsy (PSNP): impaired vertical gaze (see below)
5. multiple system atrophy (Shy-Drager syndrome): see below
6. drug induced: includes:
   a) prescription drugs (elderly females seem more susceptible)
      i. antipsychotics (AKA neuroleptics): haloperidol (Haldol\textsuperscript{®}) which works by blocking postsynaptic dopamine receptors
      ii. phenothiazine antiemetics: prochlorperazine (Compazine\textsuperscript{®})
      iii. metoclopramide (Reglan\textsuperscript{®})
      iv. reserpine
   b) MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine): a commercially available chemical intermediate which is also a by-product of the synthesis of MPPP (a meperidine analog) that was synthesized and self-injected by a graduate student,\textsuperscript{21} and later produced by illicit drug manufacturers to be sold as “synthetic heroin” and unwittingly injected by some IV drug abusers in northern California in 1983\textsuperscript{22} (there is also a case report of a chemist who worked with MPTP who developed parkinsonism).\textsuperscript{23} MPTP was subsequently discovered to be a potent neurotoxin for dopaminergic neurons (with continued toxic effects that persisted for years\textsuperscript{24}). As a rule, the response to levodopa is dramatic, but short-lived with frequent side effects. In contrast to classic IPA, the locus coeruleus and dorsal motor vagus nucleus were essentially normal, and the symptoms differ slightly
c) there is an as yet unproven assertion that methylenedioxymethamphetamine (MDMA) AKA “ecstasy” (on the street), may hasten the onset of Parkinsonism (a study demonstrating a link had to be withdrawn because of a mislabeling of drugs)
7. toxic: poisoning with
   a) carbon monoxide: symmetric low densities in the globus pallidus on CT
   b) manganese: may be seen in miners, welders, and pyrotechnics workers. Manganese is excreted by the liver, people with hepatic insufficiency are more susceptible. Imaging: symmetrical high signal abnormalities on T1WI primarily in the globus pallidus with essentially no findings on T2WI or GRASS (almost pathognomonic)
8. ischemic (lacunes in basal ganglia): produces so-called arteriosclerotic parkinsonism AKA vascular parkinsonism: “lower-half” parkinsonism (gait disturbance predominates\textsuperscript{17}). Also causes pseudobulbar deficits, emotional lability. Tremor is rare
9. posttraumatic: parkinsonian symptoms may occur in chronic traumatic encephalopathy, see dementia pugilistica (p. 924). There are usually other features not normally present in IPA (e.g. cerebellar findings)
10. normal pressure hydrocephalus (NPH): urinary incontinence (p.404)
11. neoplasm in the region of the substantia nigra
12. Riley-Day (familial dysautonomia)
13. parkinson-dementia complex of Guam: classic IPA+amyotrophic lateral sclerosis (ALS). Pathologically has features of parkinsonism and Alzheimer’s disease but no Lewy bodies nor senile plaques
14. Huntington’s disease (HD): whereas adults typically show chorea, when HD manifests in a young person it may resemble IPA
15. (spontaneous) intracranial hypotension (p.389) may present with findings mimicking IPA

Multiple system atrophy (MSA)
AKA Shy-Drager syndrome. Parkinsonism (indistinguishable from IPA), PLUS idiopathic orthostatic hypotension, PLUS other signs of autonomic nervous system (ANS) dysfunction (ANS findings may precede parkinsonism and may include urinary sphincter disturbance and hypersensitivity to noradrenaline or tyramine infusions). Degeneration of preganglionic lateral horn neurons of thoracic spinal cord. Unlike IPA, most do not respond to dopa therapy. NB: classic IPA may eventually produce orthostatic hypotension from inactivity or as a result of progressive autonomic failure.

Progressive supranuclear palsy (PSNP)
AKA Steele-Richardson-Olszewski syndrome.
Triad:
1. progressive supranuclear ophthalmoplegia (chiefly vertical gaze): paresis of voluntary vertical eye movement, but still moves to vertical doll’s eyes maneuver
2. pseudobulbar palsy (mask-like facies with marked dysarthria and dysphagia, hyperactive jaw jerk, emotional incontinence usually mild)
3. axial dystonia (especially of neck and upper trunk)

Associated findings: subcortical dementia (inconstant), motor findings of pyramidal, extrapyramidal and cerebellar systems. Average age of onset: 60 yrs. Males comprise 60% Response to anti-parkinson drugs is usually very short lived. Average survival after diagnosis: 5.7 yrs.

Differentiating from Parkinson’s disease (IPA):
Patients with PSNP have a pseudo-parkinsonism. They have mask facies, but do not walk bent forward (they walk erect), and they do not have a tremor. They tend to fall backwards.

Course
1. early:
   a) many falls: due to dysequilibrium + downgaze palsy (can’t see floor)
   b) eye findings may be normal initially, subsequently may develop difficulty looking down (especially to command, less to following), calorics have normal tonic component but absent nystagmus (cortical component)
   c) slurred speech
   d) personality changes
   e) difficulty eating: due to pseudobulbar palsy + inability to look down at food on plate
2. late:
   a) eyes fixed centrally (no response to oculocephalics or oculovestibulars): ocular immotility is due to frontal lobe lesions
   b) neck stiffens in extension (retrocollis)

Treatment for Parkinson’s disease
Medical treatment for Parkinson’s disease is beyond the scope of this book.

Surgical treatment
Before the introduction of L-dopa in the late 1960’s, stereotactic thalamotomy was widely used for Parkinson’s disease. The location ultimately targeted for lesioning was the ventrolateral nucleus. The procedure worked better for relieving the tremor than for the bradykinesia, however it was the latter symptom that was most disabling. This procedure cannot be done bilaterally without significant risk to speech function. The procedure fell out of favor when more effective drugs became available.26
See Surgical treatment of Parkinson’s disease (p.1524) for further information.
10.4 Multiple sclerosis

**Key concepts**
- an idiopathic demyelinating disease of the CNS producing exacerbating and remitting symptoms disseminated in space and time
- classic clinical findings: optic neuritis, paresthesias, INO and bladder symptoms
- diagnostic criteria (McDonald criteria) use clinical and/or lab results (MRI, CSF...) to stratify patients as: MS, probable MS, or not MS
- MRI: multiple usually enhancing lesions involving optic nerves & white matter of brain (especially periventricular white matter), cerebellum and spinal cord

10.4.1 General information
An idiopathic demyelinating disease (thus affecting only white matter) of the cerebrum, optic nerves, and spinal cord (especially the corticospinal tracts and the posterior columns). Does not affect peripheral myelin. Pathologically produces multiple plaques of various age in diffuse locations in the CNS, especially in the periventricular white matter. Lesions initially evoke an inflammatory response with monocytes and lymphocytic perivascular cuffing, but with age settle down to glial scars.

10.4.2 Epidemiology
Usual age of onset: 10–59 years, with the greatest peak between ages 20–40 years. The female: male incidence is approximately 2:1.\(^2^7\) Prevalence varies with latitude, and is <1 per 100,000 near the equator, and is \(\approx 30–80\) per 100,000 in the northern U.S. and Canada.

10.4.3 Classification
Typically causes exacerbations and remissions in various locations in the CNS (dissemination in space and time). Common symptoms: visual disturbances (diplopia, blurring, field cuts or scotoma), spastic paraparesis, and bladder disturbances. Nomenclature for the time course of MS is shown in Table 10.2.\(^2^8\) Relapsing-remitting MS is the most common pattern (\(\geq 70\%\)) at onset, and has the best response to therapy, but >50% of cases eventually become secondary progressive MS. Only 10% have primary progressive MS, and these patients tend to be older at onset (40–60 years) and frequently develop progressive myelopathy.\(^2^9\) Progressive relapsing MS is very uncommon. Deficits present >6 months usually persist.

10.4.4 Clinical signs and symptoms

Visual disturbances
Disturbances of visual acuity may be caused by optic or retrobulbar neuritis which is the presenting symptom of MS in 15% of cases, and which occurs at some time in 50% of MS patients. The percentage of patients with an attack of optic neuritis and no prior attack that will go on to develop MS ranges from 17–87% depending on the series. Symptoms: acute visual loss in one or both eyes with mild pain (often on eye movement).

Diplopia may be due to internuclear ophthalmoplegia (INO) (p.565) from a plaque in the MLF. INO is an important sign because it rarely occurs in other conditions besides MS or brainstem stroke.

Motor findings
Extremity weakness (mono, para, or quadriplegia) and gait ataxia are among the most common symptoms of MS. Spasticity of the lower extremities is often due to pyramidal tract involvement. Scanning speech results from cerebellar lesions.

Sensory findings
Posterior column involvement often causes loss of proprioception. Paresthesias of extremities, trunk, or face occur. Hermitte’s sign (electric shock-like pain radiating down the spine on neck flexion) is common, but is not pathognomonic. Trigeminal neuralgia occurs in ≈2% and is more often bilateral and occurs at a younger age than the population in general.

Mental disturbances
Euphoria (la belle indifférence) and depression occur in ≈50% of patients.

Reflex changes
Hyperreflexia and Babinski signs are common. Abdominal cutaneous reflexes disappear in 70–80%.

GU symptoms
Urinary frequency, urgency, and incontinence are common. Impotence in males and reduced libido in either sex is often seen.

10.4.5 Differential diagnosis
The plethora of possible signs and symptoms in MS causes the differential diagnosis to extend to almost all conditions causing focal or diffuse dysfunction of the CNS. Conditions that may closely mimic MS clinically and on diagnostic testing include:
1. acute disseminated encephalomyelitis (ADEM) (p.182): generally monophasic. May also have CSF-OCB (p.182). Corpus callosum involvement is uncommon
2. CNS lymphoma (p.710)
3. other closely related demyelinating diseases: e.g. Devic syndrome (p.1409)
4. vasculitis
5. encephalitis: patients are usually very ill
6. chronic white matter changes: seen in older patients

10.4.6 Diagnostic criteria
No single clinical feature or diagnostic test is adequate for the accurate diagnosis of MS. Therefore, clinical information is integrated with paraclinical studies. Diagnosing MS after a single, acute remitting clinically isolated syndrome (CIS) is very risky. 50–70% of patients with a CIS suggestive of MS will have multifocal MRI abnormalities characteristic of MS. The presence of these MRI abnormalities increases the risk of developing MS in 1–3 years (with greater prognostic significance than CSF-OCB). The more MRI lesions, the higher the risk. Criteria for the diagnosis of MS follows.
Definitions

The following definitions are used in the classification system that follows:

1. attack (exacerbation, relapse): neurologic disturbance lasting >24 hrs typical of MS when clinicopathological studies determine that the cause is demyelinating or inflammatory lesions

2. remission: ≥30 days should separate the onset of the first attack from the onset of a second

3. historical information: reporting of symptoms by the patient (confirmation by observer desirable), adequate to locate a lesion of MS, and has no other explanation (i.e. manifestations must not be attributable to another condition)

4. clinical evidence (signs): neuro dysfunction recorded by competent examiner

5. paraclinical evidence: tests or procedures demonstrating CNS lesion which has not produced signs; e.g. Uhthoff phenomenon or sign (worsening of symptoms with hot bath or shower), BAER, imaging procedures (CT, MRI), expert urological assessment

6. typical of MS: signs & symptoms (S/S) known to occur frequently in MS. Thus excludes gray matter lesions, peripheral nervous system lesions, and non-specific complaints such as H/A, depression, convulsive seizures, etc.

7. separate lesions: S/S cannot be explained on basis of single lesion (optic neuritis of both eyes simultaneously or within 15 days represents single lesion)

8. laboratory support: in this study, the only considerations were CSF oligoclonal bands (CSF-OCB) (see below) (OCB must not be present in serum) or increased CSF IgG production (CSF-IgG) (serum IgG must be normal). This assumes that syphilis, SSPE, sarcoidosis, etc. have been ruled out

Diagnosis of MS

The 2010*McDonald MS Diagnostic criteria* are shown in Table 10.3.

MRI

MRI is the preferred imaging study in evaluating MS and can demonstrate dissemination of lesions in time and space. Recommended brain MRI criteria for diagnosing MS are shown in Table 10.3. MRI shows multiple white matter abnormalities in 80% of patients with MS (compared to 29% for CT). Lesions are high signal on T2, and acute lesions tend to enhance with gadolinium more than old lesions do. Periventricular lesions may blend in with the signal from CSF in the ventricles on T2, these lesions are shown to better advantage on FLAIR (fluid attenuation) MRI (p.229). These lesions are ovoid and are oriented perpendicular to the ependymal surface and are sometimes called Dawson’s fingers (after neuropathologist James Dawson).

Spinal cord lesions normally show little or no swelling, should be ≥3 mm but <2 vertebral segments, occupy only a portion of the cross-section of the cord, and must be hyperintense on T2.

Specificity of MRI is ≈94% however, encephalitis as well as UBOs seen in aging may mimic MS lesions. DWI should be normal, however plaques can sometimes exhibit “shine through” (p.323) so the ADC map must be checked to rule-out infarct.

Focal tumefactive demyelinating lesions (TDL) may occur in isolation or, more commonly, in patients with established MS (concentric sclerosis of Balo). TDL may represent an intermediate position between MS and ADEM (p.182). TDLs tend to be symmetric. TDLs may enhance, and show perilesional edema (but less than MS) and thus be mistaken for neoplasms. Biopsy results may be confusing. MRS may not be able to differentiate from neoplasm.

CSF

CSF analysis can support the diagnosis in some cases, but cannot document dissemination of lesions in time or space. The CSF in MS is clear and colorless. The OP is normal. Total CSF protein is <55 mg/dl in ≈75% of patients, and <108 mg/dl in 99.7% (values near 100 should prompt a search for an alternative diagnosis). The WBC count is ≤5 cells/mcl in 70% of patients, and only 1% have a count >20 cells/mcl (high values may be seen in the acute myelitis).

In ≈90% of patients with MS, CSF-IgG is increased relative to other CSF proteins, and a characteristic pattern occurs. Agarose gel electrophoresis shows a few IgG bands in the gamma region (oligoclonal bands) that are not present in the serum (higher resolution isoelectric focusing can demonstrate 10–15 bands). CSF-OCB are not specific for MS, and can occur in CNS infections and less commonly with strokes or tumors. The predictive value of the absence of IgG in a patient with suspected MS has not been satisfactorily elucidated.
Recommended criteria have been published, most of which pertain to specifics of laboratory analysis, pertinent clinical excerpts are shown in Table 10.4.

### 10.5 Acute disseminated encephalomyelitis

AKA ADEM. Acute demyelinating condition, has been associated with relatively recent history of vaccination. Like MS, may also demonstrate oligoclonal bands in CSF. ADEM is generally monophasic, and lesions occur within a couple of weeks. There is usually a good response to high-dose IV corticosteroids.

### 10.6 Motor neuron diseases

#### 10.6.1 General information

Degenerative diseases of motor neurons. See also comparison of upper motor neuron (UMN) with lower motor neuron (LMN) (p.504) and the paralysis they produce. Five subtypes of which ALS is the most common (see below).
Three patterns of involvement:
1. mixed UMN & LMN degeneration: amyotrophic lateral sclerosis (ALS) (see below). The most common of the motor neuron diseases
2. UMN degeneration: primary lateral sclerosis. Rare, onset after age 50. No LMN signs. Slower progression than ALS (yrs to decades). Pseudobulbar palsy is common. Usually does not shorten longevity. May present with falling due to balance problems or low back and neck pain due to axial muscle weakness
3. LMN degeneration: progressive muscular atrophy (PMA) and spinal muscular atrophy (SMA)

10.6.2 Amyotrophic lateral sclerosis

Key concepts
- degeneration of anterior horn cells and corticospinal tracts in the cervical spine and medulla (bulb) of unknown etiology
- a mixed upper and lower motor neuron disease (UMN → mild spasticity in LES; LMN → atrophy and fasciculations in UEs)
- clinically: progressive muscle wasting, weakness, and fasciculations
- no cognitive, sensory, nor autonomic dysfunction

In the U.S. amyotrophic lateral sclerosis (ALS) is AKA Lou Gehrig’s disease named after the New York Yankee first baseman who announced that he had the disease in 1939. AKA motor neuron disease (singular).

Epidemiology
See reference.30
  Prevalence: 4–6/100,000. Incidence: 0.8–1.2/100,000.
  Familial in 8–10% of cases. Familial cases usually follow autosomal dominant inheritance, but occasionally demonstrate a recessive pattern.
  Onset usually after 40 years of age.

Pathology
Etiology is not known with certainty. Histology: degeneration of anterior horn alpha-motoneurons (in the spinal cord and in brain stem motor nuclei) (LMNs) and corticospinal tracts (UMNs). Produces mixed UMN & LMN findings, with a great deal of variability depending on which predominates at any given time.

Table 10.4 CSF criteria for MS

<table>
<thead>
<tr>
<th>1. qualitative assessment of IgG is the most informative analysis and is best performed using IEF with some form of immunodetection (blotting or fixation)</th>
</tr>
</thead>
<tbody>
<tr>
<td>2. analysis should be performed on unconcentrated CSF and must be compared to simultaneously run serum sample in the same assay</td>
</tr>
<tr>
<td>3. runs should use the same amount of IgG from serum and CSF</td>
</tr>
<tr>
<td>4. each run should contain positive and negative controls</td>
</tr>
<tr>
<td>5. quantitative analysis should be made in terms of one of the 5 recognized staining patterns for OCB</td>
</tr>
<tr>
<td>6. an individual experienced in the techniques should report the results</td>
</tr>
<tr>
<td>7. all other tests performed on the CSF (including WBC, protein &amp; glucose, lactate) should be taken into consideration</td>
</tr>
<tr>
<td>8. evaluation using light chains for immunodetection may be helpful in certain cases to resolve equivocal oligoclonal IgG patterns</td>
</tr>
<tr>
<td>9. if clinical suspicion is high but CSF results are equivocal, negative or show only a single band, consider repeating the LP</td>
</tr>
<tr>
<td>10. to measure IgG levels, nonlinear formulas that consider integrity of the blood-CSF barrier should be used (e. g. the ratio of CSF to serum albumin (AKA Qalb) is a measure of leakiness)</td>
</tr>
<tr>
<td>11. labs analyzing CSF should have internal as well as external quality assessment controls</td>
</tr>
<tr>
<td>12. quantitative IgG is a complementary test, but is not a substitute for qualitative IgG testing which has the highest sensitivity and specificity</td>
</tr>
</tbody>
</table>
Clinical

Characterized by progressive muscle wasting, weakness, and fasciculations. Involvement is of voluntary muscles, sparing the voluntary eye muscles and urinary sphincter. Classically, presents initially with weakness and atrophy of the hands (lower motor neuron) with spasticity and hyperreflexia of the lower extremities (upper motor neuron). However, LEs may be hyporeflexic if the lower motor neuron deficits predominate. Dysarthria and dysphagia are caused by a combination of upper and lower motor neuron pathology. Tongue atrophy and fasciculations may also occur.

Although cognitive deficits are generally considered to be absent in ALS, in actuality 1–2% of cases are associated with dementia, and cognitive changes may occasionally predate the usual features of ALS.

Differential diagnosis

At times, it may be very difficult to distinguish ALS from cervical spondylotic myelopathy; see discussion of differentiating features (p.1086).

Diagnostic studies

EMG

Not absolutely necessary to make diagnosis in most cases. Fibrillations and positive sharp waves are found in advanced cases (may be absent early, especially if upper motor neuron pathology predominates). LMN findings in the LE in the absence of lumbar spine disease, or fibrillation potentials in the tongue are suggestive of ALS.

LP (CSF)

May have slightly elevated protein.

Treatment

Much of care is directed towards minimizing disability:

1. risk of aspiration may be reduced with
   a) tracheostomy
   b) gastrostomy tube to allow continued feeding
   c) vocal cord injection with Teflon
2. noninvasive ventilation: e.g. BiPAP spasticity that occurs when upper motor neuron deficits predominate may be treated (usually with short-lived response) with:
   a) baclofen (p.1530): also may relieve the commonly occurring cramps
   b) diazepam
3. riluzole (Rilutek®): inhibits presynaptic release of glutamate. Doses of 50-200 mg/d increases tracheostomy-free survival at 9 & 12 months, but the improvement is more modest or may be nonexistent by ≈18 months.

Prognosis

Most patients die within 5 years of onset (median survival: 3–4 yrs). Those with prominent oropharyngeal symptoms may have a shorter life-span usually due to complications of aspiration.

10.7 Guillain-Barré syndrome

10.7.1 General

Key concepts

- acute onset of peripheral neuropathy with progressive muscle weakness (more severe proximally) with areflexia, reaches maximum over 3 days to 3 weeks
- cranial neuropathy: also common, may include facial diplegia, ophthalmoplegia
- little or no sensory involvement (paresthesias are not uncommon)
- onset often 3 days-5 weeks following viral URI, immunization, Campylobacter jejuni enteritis, or surgery
- pathology: focal segmental demyelination with endoneural monocytic infiltrate
- elevated CSF protein without pleocytosis (albuminocytologic dissociation)
Guillain-Barré syndrome (GBS) AKA acute polyradiculonueropathy, among others, is actually a collection of syndromes having inflammatory polyradiculoneuropathy in common. Its most frequent form is acute inflammatory demyelinating polyradiculoneuropathy (AIDP). First described as an ascending paralysis, most forms are characterized by symmetric weakness and areflexia. Mild cases may present only with ataxia, whereas fulminant cases may ascend to complete tetraplegia with paralysis of respiratory muscles and cranial nerves. There are also a number of variants.

GBS is the most common acquired demyelinating neuropathy. Incidence is \( \approx 1–3/100,000 \). The lifetime risk for any one individual getting GBS is \( \approx 1/1,000 \).

GBS is triggered by both humoral and cell mediated autoimmune response to an immune sensitizing event. Frequent (but not essential) antecedents: viral infection, surgery, immunization, mycoplasma infection, enteral infection with Campylobacter jejuni (\( \approx 4 \) days of intense diarrhea). Higher frequency in the following conditions than in general population: Hodgkin’s disease, lymphoma, lupus.

Most cases involve antibodies to gangliosides and glycolipids in peripheral myelin (axon antibodies occur in some forms). For unknown reasons serum creatine kinase can be mildly elevated, and may correlate with muscle type pain.\(^{53}\)

10.7.2 Diagnostic criteria

See reference.\(^{54}\)

Features required for diagnosis:
- progressive motor weakness of more than 1 limb (from minimal weakness ± ataxia to paralysis, may include bulbar or facial or EOM palsy). Unlike most neuropathies, proximal muscles are affected more than distal
- areflexia (usually universal, but distal areflexia with definite hyporeflexia of biceps and knee jerks suffices if other features consistent)

Features strongly supportive of diagnosis:
- clinical features (in order of importance)
  - progression: motor weakness peaks at 2 wks in 50% by 3 wks in 80% and by 4 wks in >90%
  - relative symmetry
  - mild sensory symptoms/signs (e.g. mild paresthesias in hands or feet)
  - cranial nerve involvement: facial weakness in 50% usually bilateral. GBS presents initially in EOMs or other Cr. N. in <5% of cases. Oropharyngeal muscles may be affected
  - recovery usually by 2–4 wks after progression stops, may be delayed by months (most patients recover functionally)
  - autonomic dysfunction (may fluctuate): tachycardia and other arrhythmias, postural hypotension, HTN, vasomotor symptoms
  - afibrile at onset of neuritic symptoms
  - variants (not ranked):
    - fever at onset of neuritic symptoms
    - severe sensory loss with pain
    - progression >4 wks
    - cessation of progression without recovery
    - sphincter dysfunction (usually spared): e.g. bladder paralysis
    - CNS involvement (controversial): e.g. ataxia, dysarthria, Babinski signs
- CSF: albuminocytologic dissociation (↑ protein without pleocytosis)
  - protein: elevated after 1 wk of symptoms, >55 mg/dl
  - cells: 10 or fewer mononuclear leukocytes/ml
  - variants
    - no CSF protein rise 1–10 wks after onset (rare)
    - 11–50 monocytes/ml
    - electrodiagnostics: 80% have NCV slowing or block at some time (may take several weeks in some). NCV usually <60% of normal, but not in all nerves

Features casting doubt on diagnosis:
- marked, persistent, asymmetry of weakness
- persistent bowel or bladder dysfunction
- >50 monocytes/ml CSF
- PMNs in CSF
- sharp sensory level

Features of conditions in the differential diagnosis (see below)
10.7.3 Guillain-Barré variants

General information

A number of variants have been described (some may simply be incomplete forms of typical Guillain-Barré). Autonomic dysfunction may occur in some.

Miller-Fisher variant of GBS

Ataxia, areflexia and ophthalmoplegia. May also have ptosis. 5% of cases of GBS. Serum marker: anti-GQ1b antibodies.

Acute motor axonal neuropathy (AMAN)

This variant and AIDP are the most common to follow Campylobacter jejuni enteritis.

Pharyngeal-cervical-brachial variant

Facial, oropharyngeal, cervical, and UE weakness, sparing the LEs.

Pure sensory variant

Sensory loss accompanied by areflexia.

Atypical GBS

May be accompanied by rhabdomyolysis.

10.7.4 Differential diagnosis

Also see conditions in the differential diagnosis under Myelopathy (p. 1407)

1. Guillain-Barré syndrome (including one of its variants)
2. critical illness polyneuropathy (p. 542): EMG: ↓ CMAP & SNAP
3. current hexacarbon abuse: volatile solvents (n-hexane, methyl n-butyl ketone), glue sniffing
4. acute intermittent porphyria (AIP): a disorder of porphyrin metabolism. CSF protein is not elevated in AIP. Recurrent painful abdominal crises are common. Check urine delta-aminolevulinic acid or porphobilinogen
5. recent diphtheritic infection: diphtheritic polyneuropathy has a longer latency and a slower crescendo of symptoms
6. lead neuropathy: UE weakness with wrist drop. May be asymmetrical
7. poliomyelitis: usually asymmetric, has meningeal irritation
8. hypophosphatemia (may occur in chronic IV hyperalimentation)
9. botulism: difficult to distinguish clinically from GBS. Normal NCV and a facilitating response to repetitive nerve stimulation on electrodiagnostics
10. toxic neuropathy (e.g. from nitrofurantoin, dapsone, thallium or arsenic)
11. tick paralysis: may cause an ascending motor neuropathy without sensory impairment. Careful examination of the scalp for tick(s)
12. chronic immune demyelinating polyradiculoneuropathy (CIDP) AKA chronic relapsing GBS, chronic relapsing polyneuritis. ICD9: 357.81 chronic inflammatory demyelinating polyneuritis. Similar to GBS, but long time course (symptoms must be present ≥ 2 mos). CIDP produces progressive, symmetrical, proximal & distal weakness, depression of muscle stretch reflexes, and variable sensory loss. Cranial nerves are usually spared (facial muscles may be involved). Balance difficulties are common. Need for respiratory support is rare. Peak incidence: age 40–60 yrs. Electrodiagnostics and nerve biopsy findings are indicative of demyelination. CSF findings are similar to GBS (see above). Most respond to immunosuppressive therapy (especially prednisolone & plasmapheresis) but relapses are common. Refractory cases may be treated with IV gamma-globulin, cyclosporin-A, total body lymphoid irradiation or interferon-α
13. critical illness myopathy: ICD9: 359.81 chronic illness myopathy. Muscles not excitable with direct stimulation. EMG: low or normal CMAP with normal SNAP. Muscle biopsy: abnormalities may range from Type II fiber atrophy to necrosis (severe necrosis may not recover)
14. motor neuron disease (p. 182): AKA ALS. Hyperreflexia in LEs
15. myasthenia gravis: weakness worsens towards the end of the day and with repeat efforts. Positive assay for circulating anti-acetylcholine receptor antibodies
16. spinal cord injury
10.7.5 Imaging

No characteristic finding, however, diffuse enhancement of cauda equina and nerve roots occurs in up to 95% of cases. Thought to be due to disruption of the blood-nerve barrier from inflammation. Conspicuous nerve root enhancement correlates with pain, GBS disability grade, and duration of recovery.

10.7.6 Treatment

Immunoglobulins may be helpful. In severe cases, early plasmapheresis hastens the recovery and reduces the residual deficit. Its role in mild cases is uncertain. Steroids are not helpful. Mechanical ventilation and measures to prevent aspiration are used as appropriate. In cases of facial diplegia, the eyes must be protected from exposure (neuroparalytic) keratitis.

10.7.7 Outcome

Recovery may not be complete for several months. 35% of untreated patients have residual weakness and atrophy. Recurrence of GBS after achieving maximal recovery occurs in ≈ 2%.

10.8 Myelitis

10.8.1 General information

AKA acute transverse myelitis (ATM). The terminology is confusing: myelitis overlaps with “myelopathy.” Both are pathologic conditions of the spinal cord. Myelitis indicates inflammation, and etiologies include: infectious/post-infectious, autoimmune, and idiopathic. Myelopathy is generally reserved for compressive, toxic, or metabolic etiologies; see also differential diagnosis (p.1407).

10.8.2 Etiology

Many so-called “causes” remain unproven. Immunologic response against the CNS (most likely via cell mediated component) is the probable common mechanism. Animal model: experimental allergic encephalomyelitis (requires myelin basic protein of CNS, not peripheral). Generally accepted etiologies include (items with an asterisk * may be more properly associated with myelopathy rather than myelitis):

1. infectious and post-infectious
   a) primary infectious myelitis
      • viral: poliomyelitis, myelitis with viral encephalomyelitis, herpes zoster, rabies
      • bacterial: including tuberculoma of spinal cord
      • spirochetal: AKA syphilitic myelitis. Causes syphilitic endarteritis
      • fungal (aspergillosis, blastomycosis, cryptococcosis)
      • parasitic (Echinococcus, cysticercosis, paragonimiasis, schistosomiasis)
   b) post-infectious: including post-exanthematous, influenza
2. post-traumatic
3. physical agents
   a) decompression sickness (dysbarism)
   b) electrical injury*
   c) post-irradiation
4. paraneoplastic syndrome (remote effect of cancer): most common primary is lung, but prostate, ovary and rectum have also been described*
5. metabolic
   a) diabetes mellitus*
   b) pernicious anemia*
   c) chronic liver disease*
6. toxins
   a) cresyl phosphates*
   b) intra-arterial contrast agents*
   c) spinal anesthetics
   d) myelographic contrast agents
   e) following chemonucleolysis*
7. arachnoiditis
8. autoimmune
   a) multiple sclerosis (MS), especially Devic syndrome (p.1409)
   b) following vaccination (smallpox, rabies)
9. collagen vascular disease
   a) systemic lupus erythematosus
   b) mixed connective tissue disease

10.8.3 Clinical
Presentation
34 patients with ATM: age of onset ranged 15–55 yrs, with 66% occurring in 3rd and 4th decade. 12 patients (35%) had a viral-like prodrome. Presenting symptoms are shown in Table 10.5, with other presenting symptoms of unspecified frequency including: fever and rash.

Presenting level
The levels at presentation in 62 patients with ATM are shown in Table 10.6. The thoracic level is the most common sensory level. Infrequently, ATM is the presenting symptom of MS (~3–6% of patients with ATM develop MS).

Progression
Progression is usually rapid, with 66% reaching maximal deficit by 24 hrs, however the interval between first symptom and maximal deficit varies from 2 hrs-14 days. Findings at the time of maximal deficit are shown in Table 10.7.

10.8.4 Evaluation
Imaging should be done to rule-out a compressive lesion. Myelogram, CT & MRI: no characteristic finding. One paper reports 2 patients with fusiform cord enlargement. MRI may be able to demonstrate the area of involvement within the cord. MRI may show the “central dot sign”, an area of high signal on axial T2WI usually centrally located with a small dot of isointense signal in the core of the hyperintensity.

CSF: normal during acute phase in 38% of LPs. Remainder (62%) had elevated protein (usually >40 mg%) or pleocytosis (lymphocytes, PMNs, or both) or both.

**Evaluation scheme**

In a patient developing acute myelopathy/paraplegia, especially when ATM is considered likely, the first test of choice is an emergency MRI. If not readily available, a myelogram (with CT to follow) directed at the region of the sensory level is performed (CSF may be sent in this circumstance once block is ruled out).

10.8.5 Treatment

No treatment has been studied in a randomized controlled trial.
1. steroids: not beneficial for all causes of myelitis,<sup>69</sup> especially with ASIA A (complete loss of spinal cord function).<sup>30</sup> Rx: high-dose IV methylprednisolone 3-5 days (doses quoted include 500 mg/d, and 1000 mg/d<sup>71</sup>). The decision to introduce additional treatment measures is based on the response to steroids and the MRI appearance after ≈ 5 days of steroids
2. plasma exchange (PLEX) for patients that do not respond to steroids within 3-5 days
3. other forms of immune suppression may be attempted for failure of above therapies, including: cyclophosphamide (usually under the direction of an oncologist)
4. in cases of focal spinal cord enlargement, surgical decompression may be considered in cases that fail to respond to the above

10.8.6 Prognosis

In a series of 34 ATM patients with ≥ 5 yrs follow-up (F/U)<sup>64</sup>: 9 patients (26%) had good recovery (ambulate well, mild urinary symptoms, minimal sensory and UMN signs); 9 (26%) had fair recovery (functional gait with some degree of spasticity, urinary urgency, obvious sensory signs, paraparesis); 11 (32%) poor (paraplegic, absent sphincter control); 5 (15%) died within 4 mos of illness. 18 patients (62% of survivors) became ambulatory (in these cases, all could walk with support by 3–6 mos).

In a series of 59 patients<sup>68</sup> (F/U period unspecified): 22 (37%) had good recovery; 14 (24%) poor; 3 died in acute stage (respiratory insufficiency in 2, sepsis in 1). Recovery occurred between 4 weeks and 3 mos after onset (no improvement occurred after 3 mos).

10.9 Neurosarcoidosis

10.9.1 General

**Key concepts**

- neurologic involvement of sarcoidosis (a systemic granulomatous disease)
- may produce multiple cranial nerve palsies
- the most common neurologic manifestation is diabetes insipidus
- corticosteroids are beneficial for systemic as well as neurologic involvement

Sarcoidosis is a granulomatous disease that is usually systemic, and may include the CNS (so-called neurosarcoidosis AKA neurosarcoi). Only 1–3% of cases have CNS findings without systemic manifestations.<sup>72</sup> The cause of the disease is unknown. An exaggerated cellular immune response for
unknown reasons is the currently favored hypothesis. Organs commonly involved include lungs, skin, lymph nodes, bones, eyes, muscles, and parotid glands.

10.9.2 Pathology
CNS sarcoidosis primarily involves the leptomeninges, however parenchymal invasion often occurs. Adhesive arachnoiditis with nodule formation may also occur (nodules have a predilection for the posterior fossa). Diffuse meningitis or meningoencephalitis may occur, and may be most pronounced at the base of the brain (basal meningitis) and in the subependymal region of the third ventricle (including the hypothalamus).

Constant microscopic features of neurosarcoidosis include noncaseating granulomas with lymphocytic infiltrates. Langhans giant cells may or may not be present.

10.9.3 Epidemiology
Incidence of sarcoidosis is $\approx 3$–$50$ cases/100,000 population; neurosarcoidosis occurs in $\approx 5\%$ of cases (reported range: 1–27%). In one series, the median age of onset of neurologic symptoms was 44 years.

10.9.4 Clinical findings
Clinical findings include multiple cranial nerve palsies in 50–70% (particularly facial n., including diplegia), peripheral neuropathy, and myopathy. Occasionally the lesions may produce mass effect, and hydrocephalus may result from adhesive basal arachnoiditis. Patients may have low grade fever. Intracranial hypertension is common and may be dangerous. Hypothalamic involvement may produce disorders of ADH (diabetes insipidus, disordered thirst). Rare involvement of the pituitary may produce pituitary insufficiency. Seizures occur in 15%.

0.4% of patients with sarcoidosis develop spinal cord involvement, and in 16% of these, the spinal cord was the only identifiable site of involvement.

10.9.5 Laboratory
CBC: mild leukocytosis and eosinophilia may occur.

Serum angiotensin-converting enzyme (ACE): abnormally elevated in 83% of patients with active pulmonary sarcoidosis, but in only 11% with inactive disease. False positive rate: 2–3% may also be elevated in primary biliary cirrhosis.

CSF: similar to any subacute meningitis: elevated pressure, mild pleocytosis (10–200 cells/mm$^3$) mostly lymphocytes, elevated protein (up to 2,000 mg/dl), mild hypoglycorrhachia (15–40 mg/dl), CSF ACE is elevated in $\approx 55\%$ of cases with neurosarcoidosis (normal in patients with sarcoidosis not involving the CNS).

No organisms are recovered on culture or gram stain.

10.9.6 Imaging
CXR
Usually demonstrates characteristic findings of sarcoidosis (hilar adenopathy, mediastinal lymph nodes...).

MRI
Gadolinium enhancement of the leptomeninges and/or optic nerve may be the only abnormal finding(s). Meningeal enhancement was seen in 38% of neurosarcoidosis patients. Lesions may be solitary or multiple, and may be located intra- or extraparenchymal, periventricular, and/or in basal cisterns. Lesions may be seen on FLAIR that would otherwise have been missed. Hydrocephalus may occur.

Galium scan
Nuclear medicine scan with 67Ga citrate (p. 236). Described findings include:
1. Panda sign: uptake in lacrimal glands, parotid glands & nasopharynx (normal). Not specific for sarcoidosis
2. lambda distribution: uptake in hilar lymph nodes
3. leopard man sign: diffuse dappled pattern due to uptake in soft tissues, skin, muscles, mediastinum, and lacrimal glands
10.9.7 Differential diagnosis

Differentiating granulomatous angiitis (GA) from neurosarcoidosis that involves only the CNS can be done on histologic criteria: the inflammatory reaction in sarcoidosis is not limited to the region immediately surrounding blood vessels as it is in GA, where extensive disruption of the vessel wall may occur.

10.9.8 Diagnosis

Making the diagnosis is relatively easy when systemic involvement occurs: characteristic findings on CXR, biopsy of skin or liver nodules, muscle biopsy, serum ACE assay.

Isolated neurosarcoidosis may be more difficult to diagnose, and may require biopsy (see below).

10.9.9 Biopsy

In uncertain cases, biopsy may be indicated. Whenever possible, MRI should be used to localize a supratentorial region of involvement. If a mass lesion cannot be biopsied, a meningeal biopsy may be done and should include all layers of meninges and cerebral cortex. Cultures and stains for fungus and acid-fast bacteria (TB) should be performed in addition to microscopic examination.

10.9.10 Treatment

Antibiotics have not been proven to be of benefit. Immunosuppression primarily with corticosteroids are beneficial for systemic as well as neurologic involvement. Therapy may be initiated with prednisone 60 mg PO qd in adults, and tapered based on response. Therapy with cyclosporine may allow a reduction in steroid dosage in refractory cases. Treatment for unresponsive cases include: methotrexate, cytoxan, cyclophosphamide, azathioprine, low dose XRT. CSF shunting is indicated if hydrocephalus develops.

10.9.11 Prognosis

Usually a benign disease. Peripheral and cranial nerve palsies recover slowly.

11 Neurovascular Disorders and Neurotoxicology

11.1 Posterior reversible encephalopathy syndrome (PRES)

11.1.1 General information

AKA reversible posterior leukoencephalopathy syndrome (RPLS). A group of encephalopathies with characteristic pattern of widespread vasogenic brain edema seen on CT or MRI with some predominance in the parietal and occipital regions.\(^1\) The most common PRES pattern involves watershed zones with involvement of the cortex, subcortical and deep white matter to a variable extent.\(^1\) A small number of patients with PRES will go on to infarction. Patients may present with headache, seizures, mental status changes and focal neurologic deficit. Intracerebral hemorrhage (ICH) and SAH may occur in up to 15%\(^1\).

11.1.2 Associated findings and conditions

Includes:

1. hypertensive encephalopathy: commonly seen in the setting of subacute blood pressure elevations (as may occur with malignant hypertension). Imaging studies show symmetric confluent lesions with mild mass effect and patchy enhancement primarily in the subcortical white matter of the occipital lobes\(^2\) which may produce cortical blindness
   a) moderate to severe hypertension is seen in \(\approx 75\%\) of patients with PRES\(^1\) although the upper limits of autoregulation are often not reached
   b) in addition to hemispheric patterns of edema isolated brain stem and cerebellar edema have been described. Posterior fossa edema has been reported to cause obstructive hydrocephalus in a severe case\(^3\)

2. preeclampsia/eclampsia associated with cerebral edema.\(^4\) The condition is often temporary, but (permanent) infarctions also occur. Restricted diffusion on MR imaging is seen in 11–26% of cases. Abnormal DWI areas on MRI may be associated with a worse prognosis\(^5\)
   a) may present (e.g. with blindness) during pregnancy complicated by preeclampsia or eclampsia\(^6\)
   b) may develop 4–9 days post-partum and may be associated with vasospasm\(^7\) even in patients not meeting clinical criteria for the diagnosis of eclampsia
   c) toxemia is attributed to the placenta. Delivery and removal of the placenta is felt to be curative\(^8\)

3. infection, sepsis and shock: blood pressure was normal in 40% (edema was greater in the normotensive patients). Gram positive organisms predominate\(^9\)

4. autoimmune disease: PRES has been described in patients with lupus, scleroderma, Wegener’s granulomatosis and polyarteritis nodosa.\(^1\) These patients often receive regimens of immunosuppressive medications (tacrolimus, cyclosporine), which have also been linked to cases of PRES

5. cancer chemotherapy: PRES occurs in patients receiving multi-drug high dose chemotherapy most commonly for hematopoietic malignancies

6. transplantation: PRES has been reported both with bone marrow and solid organ transplantation
   a) incidence: 3–16% with bone marrow transplantation depending on the preconditioning regimen and whether or not it is myeloablative\(^1\)
   b) highest incidence in the first month following allogeneic bone marrow transplant\(^1\)
   c) lower incidence following solid organ transplants. Occurs earlier following liver transplantation, usually within 2 months. Occurs later in renal transplants\(^1\)

7. cyclosporine post-transplant neurotoxicity\(^9\)

11.1.3 Treatment

Disordered autoregulation mandates tight control of blood pressure to reduce the risk of ICH. The underlying cause needs to be addressed (i.e. control HTN, hold immunosuppressives or chemotherapeutics, delivery of the placenta, etc.).

11.2 Crossed cerebellar diaschisis

Hypometabolism of cerebellar cortex contralateral to a cerebral hemispheric lesion (lesions include: stroke, brain tumor...). Lesions in the motor cortex, anterior corona radiata, and thalamus produce the most marked suppression of metabolism. Theory: hypometabolism is due to disconnection of
cerebro-ponto-cerebellar pathways → decreased oxygen and glucose consumption → decreased CO₂ production → local arterial constriction (down-regulation of cerebellar blood flow).

11.3 Vasculitis and vasculopathy
11.3.1 General information

The vasculitides are a group of disorders characterized by inflammation and necrosis of blood vessels. Vasculitis may be primary or secondary. Those that may affect the CNS are listed in Table 11.1, all of these cause tissue ischemia (even after the inflammation is quiescent) that may range in effect from neuropraxia to infarction.

11.3.2 Giant cell arteritis (GCA)

Key concepts

- formerly often referred to as temporal arteritis
- a chronic vasculitis of large and medium caliber vessels, primarily involving cranial branches of the arteries arising from the aortic arch
- age >50 years; affects women twice as often as men
- important possible late complications: blindness, stroke, thoracic aortic aneurysms and aortic dissections
- temporal artery biopsy is recommended for all patients suspected of GCA
- corticosteroids are the drug of choice for treatment

AKA temporal arteritis (TA), AKA cranial arteritis. A chronic granulomatous arteritis of unknown etiology involving primarily the cranial branches of the aortic arch (especially the external carotid artery (ECA)), which if untreated, may lead to blindness. Takayasu’s arteritis is similar to GCA, but tends to affect large arteries in young women; it has 2 phases: inflammatory (treated with corticosteroids) and stenotic (treated with arterial bypasses).

Epidemiology

Seen almost exclusively in Caucasians >50 yrs age (mean age of onset is 70). Incidence: 17.8 per 100,000 people ≥ 50 years old (range: 0.49 – 23). Prevalence: ≈ 223 (autopsy incidence may be much higher).

⁴KEY: 0 = uncommon or unreported; ++ = not uncommon; ++ = common; ICH = intracerebral hemorrhage; SAH = subarachnoid hemorrhage

⁵see section that follows for these topics

⁶PAN: a group of disorders, frequencies may vary by subgroup
Pathology
Discontinuous (so-called “skip lesions”) inflammatory reaction of lymphocytes, plasma cells, macrophages, ± giant cells (if absent, intimal proliferation may be prominent); predominantly in media of involved arteries. Arteries preferentially involved include the ophthalmic and posterior ciliary branches and the entire distribution of the external carotid system (of which the STA is a terminal branch). Other arteries in the body may be involved (reported involvement of abdominal aorta, femoral, brachial and mesenteric arteries are rarely symptomatic). Unlike PAN, GCA generally spares the renal arteries.

Clinical
Various combinations of symptoms of giant cell arteritis are listed in Table 11.2. Onset is usually insidious, although occasionally it may be abrupt. Details of some findings:
1. H/A: the most common presenting symptom. May be nonspecific or located in one or both temporal areas, forehead, or occiput. May be superficial or burning with paroxysmal lancinating pain
2. symptoms relating to ECA blood supply (strongly suggestive of GCA, but not pathognomonic): jaw claudication, tongue, or pharyngeal muscles
3. ophthalmologic symptoms: due to arteritis and occlusion of branches of ophthalmic artery or posterior ciliary arteries a) symptoms include: amaurosis fugax (precedes permanent visual loss in 44%), blindness, visual field cuts, diplopia, ptosis, ocular pain, corneal edema, chemosis b) blindness: incidence is ≈ 7% and once it occurs, recovery of sight is unlikely
d) thoracic aortic aneurysms: 17 times as likely in GCA. Annual CXRs are adequate for screening
5. temporal arteries on physical examination may exhibit tenderness, swelling, erythema, reduced pulsations, or nodularity. Normal in 33%
6. the presence of systemic symptoms correlates with a lower incidence of blindness or stroke

Differential diagnosis
1. periarteritis nodosa (PAN) (p. 199)
2. hypersensitivity vasculitis
3. atherosclerotic occlusive disease
4. malignancy: shares systemic also has symptoms of low grade fever, malaise and weight loss
5. infection
6. trigeminal neuralgia (p. 479)
7. ophthalmoplegic migraine
8. dental problems

Evaluation

Laboratory studies
1. ESR > 40 mm/hr (usually > 50) by Westergren method (if > 80 mm/hr with above clinical syndromes, highly suggestive of GCA). ESR is normal in up to 22.5%.
2. C-reactive protein: another acute phase reactant that is more sensitive than ESR. Has the advantage that it can be performed on frozen sera.
3. CBC: may show mild normochromic anemia.
4. Rheumatoid factor, ANA, and serum complement usually normal.
5. LFTs abnormal in 30% (usually elevated alkaline phosphatase).
6. Tests for rheumatoid factor and ANA are usually negative.
7. Temporal artery angiography not helpful (angiography elsewhere indicated if suspicion of large artery involvement exists).
8. CT: usually not helpful, one report described calcified areas corresponding to the temporal arteries.

Temporal artery biopsy
Sensitivity and specificity are shown in Table 11.3.

Indications and timing
Current recommendations: temporal artery biopsy in all patients suspected of having GCA. May be controversial. Arguments for: toxicity of a long course of steroids in an elderly patient, and a high rate of false initial responses of other illnesses to steroids. Arguments against: since a negative biopsy cannot exclude the diagnosis, cases with a negative biopsy but a strong clinical suspicion are often treated as though they have GCA. In general, however, biopsy is considered prudent before embarking on a long course of high-dose steroid therapy. Complications of biopsy are rare and include bleeding, infection, and only in the setting of active vasculitis has scalp necrosis been reported (not linked to biopsy).

In general, perform biopsy before starting steroids if biopsy can be done immediately. Otherwise, start steroids to preserve vision and perform biopsy usually within 1 week (pathologic changes can be seen after more than 2 weeks of therapy, therefore do not withhold steroids to await biopsy).

Technique of temporal artery biopsy
Biopsy side of involvement if laterality exists. The yield is increased by removing a portion of artery that is involved clinically (a tender or inflamed segment). Mark the frontal branch of the STA with a skin marker (spare the main trunk and parietal branch if possible). Infiltrate local anesthetic. The incision is made parallel to the artery and if possible behind the hairline. The incision is taken down to the fascia of the temporalis muscle, to which the STA is superficial. Optimal length of STA biopsy: 4–6 cm (if an abnormal segment of STA can be palpated, some say that a smaller biopsy to include this area may be sufficient, but this is probably unreliable as the muscle may be tender, etc.). Step-sectioning by pathologist through the entire length of the biopsy specimen also increases the yield. Frozen sections can be performed. Biopsy of the contralateral side if the first side is negative in cases where clinical suspicion is high increases the yield only by 5–10%.

Treatment
No known cure. Steroids can produce symptomatic relief and usually prevent blindness (progression of ocular problems 24–48 hrs after institution of adequate steroids is rare). Totally blind patients or those with longstanding partial visual loss are unlikely to respond to any treatment.
1. For most cases:
   a) Start with prednisone, 40–60 mg/d PO divided BID-QID (qod dosing is usually not effective in initial management).
   b) If no response after 72 hrs, and diagnosis certain, ↑ to 10–25 mg QID.

</tr>
<tr>
<td>predictive value</td>
</tr>
</tbody>
</table>
c) once response occurs (usually within 3–7 days), give entire dose as q AM dose for 3–6 weeks until symptoms resolved and ESR normalizes (occurs in 87% of patients within ≈ 4 weeks) or stabilizes at <40–50 mm/hr
d) once quiescent, a gradual taper is performed to prevent exacerbations: reduce by 10 mg/d q 2–4 weeks to 40 mg/d, then by 5 mg/d q 2–4 wks to 20 mg/d, then by 2.5 mg/d q 2–4 wks to 5–7.5 mg/d which is maintained for several months, followed by 1 mg/d decrements q 1–3 mos (usual length of treatment is 6–24 mos; do not D/C steroids when ESR normalizes)
e) if symptoms recur during treatment, prednisone dose is temporarily increased until symptoms resolve (isolated rise in ESR is not sufficient reason to increase steroids)
f) patients should be followed closely for ≈ 2 years
2. in severely ill patients: methylprednisolone, 15–20 mg IV QID
3. anticoagulant therapy: controversial
4. acute blindness (onset within 24–36 hrs) in a patient with giant cell arteritis:
   a) consider up to 500 mg methylprednisolone IV over 30–60 mins (no controlled studies show reversal of blindness)
   b) some have used intermittent inhalation of 5% carbon dioxide and oxygen

Outcome
Complications of steroid therapy occur in ≈ 50% of patients. Most are not life threatening, and include vertebral compression fractures in ≈ 36% peptic ulcer disease in ≈ 12% proximal myopathy, cataracts, exacerbation of diabetes; also see Possible deleterious side effects of steroids (p.146).

11.3.3 Polymyalgia rheumatica (PMR)

General information
PMR and giant cell arteritis (GCA) (p.195) may be different points on a continuum of the same disease. Both have in increased frequency of HLA-DR4 and systemic monocyte activation. 15% of patients with PMR eventually develop GCA.

Epidemiology
See reference.11
Both GCA & PMR occur in people ≥50 years old. The incidence increases with age and peaks between 70–80 years and is higher at higher latitudes.11
PMR is more common than GCA. Prevalence: 500/100,000.26 Incidence: 52.5 per 100,000 people ≥ age 50, higher in females (61.7) than males (39.9).27

Features
See reference.11
- an inflammatory condition of unknown etiology
- clinical characteristics
  a) aching and morning stiffness in the cervical region and shoulder & pelvic girdles lasting > 1 month. The pain usually increases with movement
     ○ shoulder pain: present in 70–95% of patients. Radiates toward elbow
     ○ hip & neck pain: 50–70% Hip pain radiates towards knees
  b) age ≥ 50 years
  c) ESR ≥ 40 mm/hr (7–20% have normal ESR26)
  d) usually responds rapidly to low dose corticosteroids (≤ 20 mg prednisone/day) see below
  e) systemic symptoms (present in ≈ 33%): fever, malaise or fatigue, anorexia and weight loss
- favorable prognosis: usually remits in 1–3 years

Treatment
PMR responds to either to low doses of steroids26 (10–20 mg prednisone/day) or sometimes to NSAIDs (response to steroids is much more rapid). The initial dose of steroids is maintained for 2–4 weeks, and then by ≤ 10% of the daily dose every 1–2 weeks11 while observing for signs of GCA.
11.3.4 Other vasculitides

Periarteritis nodosa

AKA polyarteritis nodosa. Actually a group of necrotizing vasculitides, including:

- classic periarteritis nodosa (PAN): a multisystem disease with inflammatory necrosis, thrombosis (occlusion), and hemorrhage of arteries and arterioles in every organ except lung & spleen. Nodules may be palpated along medium sized muscular arteries. Commonly produces mononeuritis multiplex, weight loss, fever, and tachycardia. Peripheral nerve manifestations are attributed to arteritic occlusion of vasa nervorum. CNS manifestations are uncommon and include H/A, seizures, SAH, retinal hemorrhages, and stroke in ≈ 13%.

- allergic angiitis and granulomatosis (Churg-Strauss syndrome)

- systemic necrotizing vasculitis

These patients do better when treated with cyclophosphamide rather than steroids.

Wegener’s granulomatosis

General information

A systemic necrotizing granulomatous vasculitis involving the respiratory tract (lung → cough/hemoptysis, and/or nasal airways → serosanguinous nasal drainage ± septal perforation—characteristic “saddle nose deformity”) and frequently the kidneys (no reported cases of kidney involvement without respiratory). Nasal obstruction and crusting are the usual initial findings. Arthralgia (not true arthritis) is present in >50%.

Neurologic involvement usually consists of cranial nerve dysfunction (usually II, III, IV, & VI; less often V, VII, & VIII; and least commonly IX, X, XI, & XII) and peripheral neuropathies, with diabetes insipidus (occasionally preceding other symptoms by up to 9 months). Focal lesions of the brain and spinal cord occur less frequently.

Differential diagnosis

Differential diagnosis includes:

- “lethal midline granuloma” (may be similar or identical to polymorphic reticulosis) may evolve into lymphoma. May cause fulminant local destruction of the nasal tissue. Differentiation is crucial as this condition is treated by radiation; one should avoid immune suppression (e.g. cyclophosphamide). Probably does not involve true granulomas. Renal and tracheal involvement do not occur.

- fungal disease: Sporothrix schenckii & Coccidioides may cause identical syndrome

- other vasculitides: especially Churg-Strauss syndrome (asthma and peripheral eosinophilia usually seen), and PAN (granulomas usually lacking)

Evaluation

Biopsy of upper airways consists of removing all crusts, and obtaining as much friable mucosa as possible. This tissue should be fixed in formaldehyde and examined pathologically within 24 hrs (do not freeze). A sample should also be cultured (including fungal and acid-fast cultures). Renal biopsy should not be done when more specific tissue is available from the upper airway.

Treatment

Untreated, Wegener’s granulomatosis is rapidly fatal, with a median survival of 5 months, and more than 90% of patients are dead within 2 years of diagnosis. For fulminating disease: prednisone 60–80 mg/d until disease is controlled (documented by decreasing ESR and improvement of serum creatinine).

When disease is stable: cyclophosphamide (Cytoxan®) ≈ 2 mg/kg daily (takes 2–3 weeks to have an effect). Continue 1 year beyond last evidence of active disease. Low-dose weekly methotrexate may be an acceptable alternative to cyclophosphamide in selected patients.

11.3.5 Lymphomatoid granulomatosis

Rare; affects mainly the lungs, skin (erythematous macules or indurated plaques in 40%) and nervous system (CNS in 20% peripheral neuropathies in 15%). Sinuses, lymph nodes, and spleen are usually spared.
11.3.6 Behçet’s syndrome

Relapsing ocular lesions and recurrent oral and genital ulcers, with occasional skin lesions, thrombophlebitis, and arthritis. H/A occur in >50% Neurologic involvement includes pseudotumor, cerebellar ataxia, paraplegia, seizures, and dural sinus thrombosis. Only 5% have neurologic symptoms as the presenting complaint.

86% have CSF pleocytosis and protein elevation. Cerebral angiography is usually normal. CT may show focal areas of enhancing low density.

Steroids usually ameliorate ocular and cerebral symptoms, but usually have no effect on skin and genital lesions. Uncontrolled trials of cytotoxic agents → some benefit. Thalidomide may be effective (uncontrolled studies), but carries risk of serious adverse effects (teratogenicity, peripheral neuropathy…).31

Although painful, the disease is usually benign. Neurologic involvement portends a worse prognosis.

11.3.7 Isolated CNS vasculitis

General information

AKA isolated angitis of the CNS. Rare (≈ 20 cases reported as of 1983); limited to vessels of CNS. Small vessel vasculitis is always present → segmental inflammation and necrosis of small leptomeningeal and parenchymal blood vessels with surrounding tissue ischemia or hemorrhage.10

Presentation

Combinations of H/A, confusion, dementia, and lethargy. Occasionally seizures. Focal and multifocal brain disturbance occurs in >80% Visual symptoms are frequent (secondary either to involvement of choroidal and retinal arteries, or to involvement of visual cortex → visual hallucinations).

Evaluation

ESR & WBC count are usually normal. CSF may be normal or have pleocytosis and/or elevated protein. CT may show enhancing areas of low density.

Angiography (required for diagnosis): characteristically shows multiple areas of symmetrical narrowing (“string of pearls” configuration). If normal, it does not exclude diagnosis.

Histological diagnosis (recommended): all biopsy material should be cultured. Brain parenchymal biopsy infrequently shows vasculitis. Leptomeningeal biopsy invariably shows involvement.

Treatment and outcome

Reportedly fatal if untreated, but may smolder for years.

Rarity of this condition makes treatment uncertain. Recommended: cyclophosphamide (Cytoxan®) 2 mg/kg/d and prednisone 1 mg/kg/d qod therapy.

NB: this condition is thought to be T-cell mediated, but prednisone causes more B-cell suppression, therefore breakthrough during prednisone therapy is not uncommon.

11.3.8 Hypersensitivity vasculitis

Neurologic involvement is not a prominent feature of this group of vasculitides, which include:

- drug induced allergic vasculitis: A number of drugs are associated with the development of cerebral vasculitis. These include methamphetamines (“speed”), cocaine (frank vasculitis occurs but is rare), heroin and ephedrine
- cutaneous vasculitis
- serum sickness: may → encephalopathy, seizures, coma, peripheral neuropathy and brachial plexopathy
- Henoch-Schönlein purpura

11.3.9 Fibromuscular dysplasia

General information

A vasculopathy (angiopathy) affecting primarily branches of the aorta, with renal artery involvement in 85% of cases (the most common site) and commonly associated with hypertension. The disease has an incidence of ≈ 1% and results in multifocal arterial constrictions and intervening regions of aneurysmal dilatation.

The second most commonly involved site is the cervical internal carotid (primarily near C1–2), with fibromuscular dysplasia (FMD) appearing on 1% of carotid angiograms, making FMD the second
most common cause of extracranial carotid stenosis.\textsuperscript{34} Bilateral cervical ICA involvement occurs in \(\approx 80\%\) of cases. 50\% of patients with carotid FMD have renal FMD. Patients with FMD have an increased risk of intracranial aneurysms and neoplasms, and are probably at higher risk of carotid dissection.

Aneurysms and fibromuscular dysplasia: The reported incidence of aneurysms with FMD\textsuperscript{35} ranges from 20–50%.

**Etiology**

The actual etiology remains unknown, although congenital defects of the media (muscular layer) and internal elastic layer of the arteries has been identified which may predispose the arteries to injury from otherwise well-tolerated trauma. A high familial rate of strokes, HTN, and migraine have supported the suggestion that FMD is an autosomal dominant trait with reduced penetrance in males.\textsuperscript{36}

**Presentation**

Most patients have recurrent, multiple symptoms shown in Table 11.4. Up to 50\% of patients present with episodes of transient cerebral ischemia or infarction. However, FMD may also be an incidental finding and some cases have been followed for 5 years without recurrence of ischemic symptoms suggesting that FMD may be a relatively benign condition.

Headaches are commonly unilateral and may be mistaken for typical migraine. Syncope may be caused by involvement of the carotid sinus. Horner’s syndrome occurs in \(\approx 8\%\) of cases. T-wave changes on EKG may be seen in up to one-third of cases, and may be due to involvement of the coronary arteries.

**Diagnosis**

The “gold-standard” for the diagnosis of FMD is the angiogram. The three angiographic types of FMD\textsuperscript{37} are shown in Table 11.5.

**Treatment**

Medical therapy including antiplatelet medication (e.g. aspirin) has been recommended. Direct surgical treatment is problem ridden due to the difficult location (high carotid artery, near the base of the skull), and the friable nature of the vessels making anastomosis or arteriotomy closure difficult. Transluminal angioplasty has achieved some degree of success. Carotid cavernous fistulas and arterial rupture have been reported as complications.

| Table 11.4 Previous symptoms in 37 cases of aortocranial FMD\textsuperscript{36} |
|----------------|----------|
| Symptom        | %        |
| H/A            | 78%      |
| mental distress| 48%      |
| tinnitus       | 38%      |
| vertigo        | 34%      |
| cardiac arrhythmia | 31%    |
| TIA            | 31%      |
| syncope        | 31%      |
| carotidynia    | 21%      |
| epilepsy       | 15%      |
| hearing impairment | 12%  |
| abdominal angina | 8%      |
| angina/MI      | 8%       |
**11.3.10 Miscellaneous vasculopathies**

**CADASIL**

**Key concepts**

- clinical: migraines, dementia, TIAs, psychiatric disturbances
- MRI: white matter abnormalities
- autosomal dominant inheritance
- anticoagulants controversial, generally discouraged

An acronym for Cerebral Autosomal Dominant Arteriopathy with Subcortical Infarcts and Leukoencephalopathy. A familial disease with onset in early adulthood (mean age at onset: 45 ± 11 yrs), mapped to chromosome 19. Clinical and neuroradiologic features are similar to those seen with multiple subcortical infarcts from HTN, except there is no evidence of HTN. The vasculopathy is distinct from that seen in lipohyalinosis, arteriosclerosis and amyloid angiopathy, and causes thickening of the media (by eosinophilic, granular material) of leptomeningeal and perforating arteries measuring 100–400 μm in diameter.

**Clinical involvement**

Recurrent subcortical infarcts (84%), progressive or stepwise dementia (31%), migraine with aura (22%), and depression (20%). All symptomatic and 18% of asymptomatic patients had prominent subcortical white-matter and basal ganglia hyperintensities on T2WI MRI.

**Treatment**

Warfarin (Coumadin®) is used by some.

**11.3.11 Paraneoplastic syndromes affecting the nervous system**

**General information**

Paraneoplastic syndromes (PNS), AKA “remote effects of cancer.” Develop acutely or subacutely. May mimic or be mimicked by metastatic disease. The neurologic disability is usually severe, and may precede other manifestations of the cancer by 6–12 mos. Often one particular neural cell type is predominantly affected. The presence of a PNS may portend a more benign course of the cancer.

16% of patients with lung Ca, and 4% with breast Ca will develop a PNS.

**Types of syndromes**

1. affecting cerebrum or cerebellum
   a) encephalitis
      • diffuse
      • limbic and brainstem: usually due to small-cell lung Ca or testicular Ca as a result of serum antineuronal antibodies
b) “limbic encephalitis” (mesial): dementia (decreased memory, psychiatric symptoms, hallucinations)

c) pan-cerebellar degeneration (PCD) AKA subacute cerebellar degeneration*: (see below)

d) opsoclonus-myoclonus syndrome*: in peds, usually indicates neuroblastoma

2. affecting spinal cord

a) poliomyelitis (anterior horn syndrome): mimics ALS (weakness, hyporeflexia, fasciculations)
b) subacute necrotizing (transverse) myelitis: rapid necrosis of spinal cord
c) ganglionitis* (dorsal root ganglion): chronic or subacute. Pure sensory neuronopathy (not neuropathy)

3. affecting peripheral nervous system

a) chronic sensory-motor: typical neuropathy (as in DM or EtOH abuse)
b) pure sensory (p.1268) 50

c) pure motor: rare. Almost always due to lymphoma (mostly Hodgkin’s)
d) acute inflammatory demyelinating polyradiculopathy, AKA Guillain-Barré (p.184)

e) Eaton-Lambert (EL) myasthenic syndrome*: rare. 66% of patients with this syndrome will have cancer, most common primary is oat cell Ca of lung. Pre-synaptic neuromuscular junction (PSNMJ) blockade due to antibodies against the PSNMJ; NB: true myasthenia gravis (MG) is a post-synaptic block. Worse in AM, improves during day with recruitment (opposite of MG, which is worse at night or with exercise due to depletion). Mostly motor, but often accompanied by paresthesias. MG is affects mostly nicotinic receptors, but EL also affects muscarinic receptors, and therefore autonomic symptoms may occur: dry mouth, males may have impotence. Repetitive nerve stimulation on EMG: for MG use 2–5 Hz stimulation, for EL use >10 Hz, MG: decremental response with low frequency, with EL there is incremental response (more response with repeat stimulation).
f) myasthenia gravis
g) polymyositis: in age >60 yrs, 25% of patients with this have a malignancy*, most often linked to bronchogenic Ca

h) type Ib muscle fiber atrophy: the most common paraneoplastic syndrome; mainly proximal muscle weakness (same as in other endocrine myopathies, e.g. hypothyroid, steroid)

* “classic” neurologic PNS. In a patient without previous cancer history presenting with one of these syndromes with an asterisk, work-up for occult malignancy has high yield.

Pan-cerebellar degeneration

Severe Purkinje cell loss (due to anti-Purkinje cell antibody) → severe pan-cerebellar dysfunction. Presents with vertigo, gait and upper and lower extremity ataxia, dysarthria, N/V, diplopia, oscillopsia, nystagmus, oculomotor dysmetria. Usually not treatable nor remitting even with immune suppression. 20% of patients improve with treatment of the primary cancer. CT is WNL early, late → cerebellar atrophy. In 70% of cases, cerebellar findings precede diagnosis of cancer.

The most common primary malignancies in pan-cerebellar degeneration are shown in Table 11.6.

Evaluation

- LP: CSF for cell count, cytology and IgG. Typically WBCs and IgG are elevated
- Evaluation for primary
  - CT of chest/abdomen/pelvis
  - lymph node exam
  - pelvic exam and mammogram in women

11.4 Neurotoxicology

11.4.1 Ethanol

General information
The acute and chronic effects of ethyl alcohol (ethanol, EtOH) abuse on the nervous system (not to mention the effects of EtOH on other organ systems) are protean, and are beyond the scope of this text. Neuromuscular effects include:

1. acute intoxication: see below
2. effects of chronic alcohol abuse
   a) Wernicke’s encephalopathy (p. 206)
   b) cerebellar degeneration: due to degeneration of Purkinje cells in the cerebellar cortex, predominantly in the anterior superior vermis
   c) central pontine myelinolysis (p. 115)
   d) stroke: increased risk of
      - intracerebral hemorrhage (p. 1330)
      - ischemic stroke
      - possibly aneurysmal SAH
   e) peripheral neuropathy (p. 541)
   f) skeletal myopathy
3. effects of alcohol withdrawal: usually seen in habituated drinkers with cessation or reduction of ethanol intake
   a) alcohol withdrawal syndromes: see below
   b) seizures: up to 33% of patients have a generalized tonic-clonic seizure 7–30 hrs after cessation of drinking – Alcohol withdrawal seizures (p. 464)
   c) delirium tremens (DTs): see below

Acute intoxication
The primary effect of EtOH on the CNS is depression of neuronal excitability, impulse conduction, and neurotransmitter release due to direct effects on the cell membranes. Table 11.7 shows the clinical effects associated with specific EtOH concentrations. Mellanby effect: the severity of intoxication is greater at any given level when blood alcohol levels are rising than when falling.

In most jurisdictions, individuals with blood ethanol levels ≥ 21.7 mmol/l (100 mg/dl) are defined as legally intoxicated, and a number of states have changed this to 80 mg/dl. However, even levels of 10.2 mmol/l (47 mg/dl) are associated with increased risk of involvement in motor vehicle accidents. Chronic alcoholism leads to increased tolerance; in habituated individuals survival with levels exceeding 1000 mg/dl has been reported.

Alcohol withdrawal syndrome

General information
Compensation for the CNS depressant effects of EtOH occurs in chronic alcoholism. Consequently, rebound CNS hyperactivity may result from falling EtOH levels. Clinical signs of EtOH withdrawal are classified as major or minor (the degree of autonomic hyperactivity and the presence/absence of DTs differentiates these), as well as early (24–48 hrs) or late (>48 hrs).

Signs/symptoms include: tremulousness, hyperreflexia, insomnia, N/V, autonomic hyperactivity (tachycardia, systolic HTN), agitation, myalgias, mild confusion. If EtOH withdrawal seizures (p. 464) occur, they tend to be early. Perceptual disturbances or frank hallucinosis may also occur early.

<table>

<tr>
<td>&gt;108.5</td>
<td>usually fatal from respiratory depression</td>
</tr>
</tbody>
</table>
Hallucinosis consists of visual and/or auditory hallucinations with an otherwise clear sensorium (which distinguishes this from the hallucinations of DTs). DTs can occur 3–4 days after cessation of drinking (see below).

Suppressed by benzodiazepines, resumption of drinking, β-adrenergic antagonists, or α2-agonists.

Prevention of and treatment for alcohol withdrawal syndrome

See reference.43

Mild EtOH withdrawal is managed with a quiet, supportive environment, reorientation and one-to-one contact. If symptoms progress, institute pharmacologic treatment.

Benzodiazepines

Benzodiazepines (BDZs) are the mainstay of treatment. They reduce autonomic hyperactivity, and may prevent seizures and/or DTs. All BDZs are effective. Initial doses are shown in Table 11.8 and are higher than those used for treating anxiety. Symptom triggered dosing with repeated evaluation utilizing a standardized protocol (e.g. CIWA-Ar44) may be more efficacious than fixed-dose schedules.45 Avoid IM administration (erratic absorption).

Adjunctive medications

Associated conditions commonly seen in patients experiencing alcohol withdrawal syndrome include dehydration, fluid and electrolyte disturbances, infection, pancreatitis, and alcoholic ketoacidosis, and should be treated accordingly.

Other medications used for EtOH withdrawal itself include:

1. drugs useful for controlling HTN (caution: these agents should not be used alone because they do not prevent progression to more severe levels of withdrawal, and they may mask symptoms of withdrawal)
   a) β-blockers: also treat most associated tachyarrhythmias
      • atenolol (Tenormin®): reduces length of withdrawal and BDZ requirement
      • avoid propranolol (psychotoxic reactions)
   b) α-agonists: do not use together with β-blockers
2. phenobarbital: an alternative to BDZs. Long acting, and helps prophylax against seizures
3. baclofen: a small study47 found 10 mg PO q d X 30 days resulted in rapid reduction of symptoms after the initial dose and continued abstinence
4. “supportive” medications
   a) thiamine: 100 mg IM q d × 3 d (can be given IV if needed, but there is risk of adverse reaction). Rationale: high-concentration glucose may precipitate acute Wernicke’s encephalopathy in patients with thiamine deficiency
   b) folate 1 mg IM, IV or PO q d × 3 d
   c) MgSO4 1 gm × 1 on admission; helpful only if magnesium levels are low, reduces seizure risk. Be sure renal function is normal before administering
   d) vitamin B12 for macrocytic anemia: 100 mcg IM (do not give before folate)
   e) multivitamins: of benefit only if patient is malnourished

</tbody>
</table>

*modify as appropriate based on patient response

Table 11.8 Guidelines for BDZ doses for EtOH withdrawal*
5. seizures: see indications for treatment (p.464)
   a) phenytoin (Dilantin®) (p.446): load with 18 mg/kg = 1200 mg/70 kg
   b) continued seizures may sometimes be effectively treated with paraldehyde if available
6. ethanol drip: not widely used. 5% EtOH in D5 W, start at 20 cc/hr, and titrate to a blood level of 100–150 mg/dl

Delirium tremens (DTs)
When DTs occur, they usually begin within 4 days of the onset of EtOH withdrawal, and typically persist for 1–3 days.
Signs and symptoms include: profound disorientation, agitation, tremor, insomnia, hallucinations, severe autonomic instability (tachycardia, HTN, diaphoresis, hyperthermia). Mortality is 5–10% (higher in elderly), but can be reduced with treatment (including treating associated medical problems and treatment for seizures).
Haloperidol and phenothiazines may control hallucinations, but can lower the seizure threshold. HTN and tachyarrhythmias should be treated as outlined above under alcohol withdrawal syndrome.

Wernicke’s encephalopathy (WE)

General information
AKA Wernicke-Korsakoff encephalopathy (not to be confused with Korsakoff’s syndrome or Korsakoff’s psychosis). Classic triad: encephalopathy (consisting of global confusion), ophthalmoplegia, and ataxia (NB: all 3 are present in only 10–33% of cases).
Due to thiamine deficiency. Body stores of thiamine are adequate only for up to ~18 days. May be seen in:
1. a certain susceptible subset of thiamine deficient alcoholics. Thiamine deficiency here is due to a combination of inadequate intake, reduced absorption, decreased hepatic storage, and impaired utilization
2. hyperemesis (as in some pregnancies)
3. starvation: including anorexia nervosa, rapid weight loss
4. gastroplication (bariatric surgery)
5. hemodialysis
6. cancers
7. AIDS
8. prolonged IV hyperalimentation

Clinical
Oculomotor abnormalities occur in 96% and include: nystagmus (horizontal > vertical), lateral rectus palsy, conjugate-gaze palsies.
Gait ataxia is seen in 87% and results from a combination of polyneuropathy, cerebellar dysfunction, and vestibular impairment.
Systemic symptoms may include: vomiting, fever.

Diagnostic testing
MRI: May show high signal in T2WI and FLAIR images in the paraventricular (medial) thalamus, the floor of the 4th ventricle, and periaqueductal gray of the midbrain. These changes may resolve with treatment. Atrophy of the mammillary bodies may also be seen. Normal MRI does not R/O the diagnosis.

Treatment
Wernicke’s encephalopathy (WE) is a medical emergency. When WE is suspected, 100 mg thiamine should be given IM or IV (oral route is unreliable, see above) daily for 5 days. IV glucose can precipitate acute WE in thiamine deficient patients, give thiamine before glucose.
Thiamine administration improves eye findings within hours to days; ataxia and confusion improve in days to weeks. Many patients that survive are left with horizontal nystagmus, ataxia, and 80% have Korsakoff’s syndrome (AKA Korsakoff’s psychosis), a disabling memory disturbance involving retrograde and anterograde amnesia.

11.4.2 Opioids
Includes heroin (which is usually injected IV, but the powder can be snorted or smoked) as well as prescription drugs. Opioids produce small pupils (miosis).
Overdose may produce:
1. respiratory depression
2. pulmonary edema
3. coma
4. hypotension and bradycardia
5. seizures
6. fatal overdose may occur with any agent, but is more likely with synthetic opioids such as fentanyl (Sublimaze®) among users unfamiliar with their high potency

Reversal of intoxication

A test dose of naloxone (Narcan®) 0.2 mg IV avoids sudden complete reversal of all opioid effects. If no significant reaction occurs, an additional 1.8 mg (for a total dose of 2 mg) will reverse the toxicity of most opioids. If needed, the dose may be repeated q 2–3 minutes up to a total of 10 mg, although even larger doses may be needed with pentazocine or buprenorphine (Buprenex®). Naloxone may precipitate narcotic withdrawal symptoms in opioid dependent patients, with anxiety or agitation, piloerection, yawning, sneezing, rhinorrhea, nausea, vomiting, diarrhea, abdominal cramps, muscle spasms... which are uncomfortable but not life threatening. Clonidine (Catapres®) may be helpful for some narcotic withdrawal symptoms.

With longer acting opioids, especially methadone (Dolophine®), repeat doses of naloxone may be obviated by the use of nalmefene (Revex®), a long-acting narcotic antagonist which is not appropriate for the initial treatment of opioid overdosage.

11.4.3 Cocaine

Cocaine is extracted from Erythroxylon coca leaves (and other Erythroxylon species) and is thus unrelated to opioids. It blocks the re-uptake of nor-epinephrine by presynaptic adrenergic nerve terminals. It is available in 2 forms: cocaine hydrochloride (heat labile and water soluble, it is usually taken PO, IV or by nasal insufflation) and as the highly purified cocaine alkaloid (free base or crack cocaine, which is heat stable but insoluble in water and is usually smoked).

Peak toxicity occurs 60–90 minutes after ingestion (except for “body packers”), 30–60 minutes after snorting, and minutes after IV injection or smoking (freebase or crack).

Acute pharmacologic effects of cocaine

Effects on body systems outside the nervous system include: tachycardia, acute myocardial infarction, arrhythmias, rupture of ascending aorta (aortic dissection), abruptio placenta, hyperthermia, intestinal ischemia, and sudden death.

Acute pharmacologic effects pertinent to the nervous system include:
1. mental status: initial CNS stimulation that first manifests as a sense of well-being and euphoria. Sometimes dysphoric agitation results, occasionally with delirium. Stimulation is followed by depression. Paranoia and toxic psychosis may occur with overdosage or chronic use. Addiction may occur
2. pupillary dilatation (mydriasis)
3. hypertension: from adrenergic stimulation

Non-pharmacologic effects related to the nervous system
1. pituitary degeneration: from chronic intranasal use
2. cerebral vasculitis: less common than with amphetamines
3. seizures: possibly related to the local anesthetic properties of cocaine
4. stroke
   a) intracerebral hemorrhage: see Intracerebral hemorrhage, Etiologies (p. 1332)
   b) subarachnoid hemorrhage: possibly as a result of HTN in the presence of aneurysms or AVMs, however, sometimes no lesion is demonstrated on angiography. May possibly be due to cerebral vasculitis
   c) ischemic stroke: may result from vasoconstriction
   d) thrombotic stroke
   e) TIA
5. anterior spinal artery syndrome
6. effects of maternal cocaine use on the fetal nervous system include: microcephaly, disorders of neuronal migration, neuronal differentiation and myelination, cerebral infarction, subarachnoid and intracerebral hemorrhage, and sudden infant death syndrome (SIDS) in the postnatal period
Treatment of toxicity
Most cocaine toxicity is too short-lived to be treated. Anxiety, agitation or seizures may be treated with IV benzodiazepines, e.g. lorazepam (p.471). Refractory HTN may be treated with nicardipine (p.126) or phentolamine (Regitine®) (p.655). IV lidocaine used to treat cardiac arrhythmias may cause seizures.50

11.4.4 Amphetamines
Toxicity is similar to that of cocaine (see above), but longer in duration (may last up to several hours). Cerebral vasculitis may occur with prolonged abuse which may lead to cerebral infarction.
Elimination of amphetamines requires adequate urine output. Antipsychotic drugs such as haloperidol (Haldol®) should not be used because of risk of seizures.

11.4.5 Carbon monoxide
General information
Carbon monoxide (CO) is the largest source of death from poisoning in the U.S.A.
Normal cellular function requires \( \approx 5 \text{ ml } \text{O}_2/100 \text{ ml blood} \). Blood normally contains \( \approx 20 \text{ ml } \text{O}_2/100 \text{ ml} \).
CO binds to hemoglobin (Hb) with an affinity \( \approx 250 \) times that of \( \text{O}_2 \), and it causes a left shift of the Hb/O\(_2\) dissociation curve. It also binds to intracellular myoglobin.
Only \( \approx 6\% \) of patients show the classic “cherry-red” color of blood.

Clinical findings
Clinical findings related to CO-Hb levels are shown in Table 11.9.

Diagnostic studies
EKG changes are common, usually non-specific ST-T wave changes.
In cases of severe intoxication, CT may show symmetrical low attenuation in the globus pallidus; see differential diagnosis (p.1386).

Outcome
Prognosticators
1. outcome is more closely correlated with hypotension than with actual CO-Hb level
2. coma
3. metabolic acidosis
4. EEG
5. CT/MRI changes: in one study, the presence of MRI lesions after 1 month did not accurately predict subsequent outcome
6. CO-Hb level
7. other factors probably have an effect, including: age, severity of exposure

Approximately 40% of patients exposed to significant levels of CO die. 30–40% have transient symptoms but make a full recovery. 10–30% have persistent neurological sequelae including CO-encephalopathy (may be delayed in onset) – impaired memory, irritability, parietal lobe symptoms including various agnosias.
Brain lesions:
1. white matter lesions:
   a) multifocal small necrotic lesions in deep hemispheres
   b) extensive necrotic zones along lateral ventricles
   c) Grinker’s myelinopathy (not necrosis)
2. grey matter lesions:
   a) bilateral necrosis of globus pallidus
   b) lesions of hippocampal formation and focal cortical necrosis

12.1 C-Spine x-rays

12.1.1 Normal findings

For radiographic signs of cervical spine trauma, see Table 63.2, and for guidelines for diagnosing clinical instability, see Table 65.4.

Contour lines

On a lateral C-spine x-ray, there are 4 contour lines (AKA arcuate lines). Normally each should form a smooth, gentle curve (Fig. 12.1):

1. posterior marginal line (PML): along posterior cortical surfaces of vertebral bodies (VB). Marks the anterior margin of spinal canal
2. anterior marginal line (AML): along anterior cortical surfaces of VBs

* See discussion of the basilar lines (p. 218)
3. spinolaminar line (SL L): along base of spinous processes. The posterior margin of the spinal canal
4. posterior spinous line (PSL): along tips of spinous processes

Relation of atlas to occiput
See also criteria for atlantooccipital dislocation (AOD) (p. 965).

Relation of atlas to axis
These measurements are useful for atlantoaxial subluxation/dislocation (p. 968) e.g. in trauma, rheumatoid arthritis (p. 1134) or Down syndrome (p. 1138).

12.1.2 Rule of Spence
On AP or open-mouth odontoid x-ray, if the sum total overhang of both C1 lateral masses on C2 is \( \geq 7 \) mm (x + y in Fig. 12.7), the transverse atlantal ligament (TAL) is probably disrupted\(^1,2\) (when corrected for an 18% magnification factor, it has been suggested that the criteria be increased to \( \geq 8.2 \) mm\(^3\))

12.1.3 (Anterior) atlantodental interval (ADI)

Note: the term ADI usually refers to the anterior atlantodental interval (there is also a posterior ADI (p. 213) and a lateral ADI which can be seen on AP radiographs).

AKA pre-dental space. The distance between the anterior margin of the dens and the closest point of the anterior arch of C1 (“c1 button”) on a lateral C-spine x-ray (Fig. 12.2). The normal maximal ADI is variously given in the range of 2 to 4 mm.\(^4,5\) Commonly accepted upper limits are shown in Table 12.1. An abnormally increased ADI is a surrogate marker for TAL disruption\(^6\)

12.1.4 Posterior atlantodental interval (PADI)

AKA the neural canal width (NCW).\(^5\) The PADI is the AP diameter of the bony canal at C1 and is measured from the back of the odontoid to the anterior aspect of the posterior C1 ring (Fig. 12.2). It is more useful than the ADI for some conditions, e.g. AAS in rheumatoid arthritis (p. 1134) or Down syndrome (p. 1138).

Fig. 12.2 The atlantodental interval (ADI) (p. 213) and posterior atlantodental interval (PADI) on a lateral C-spine x-ray
**Canal diameter**

Normal canal diameter on lateral C-spine x-ray (from spinolaminar line (SLL) to posterior vertebral body with 6 foot tube to film distance): 17 ± 5 mm. In the presence of osteophytic spurs, measure from the back of the spur to the SLL.

Cervical spinal stenosis: various cutoffs for the normal minimum AP diameter have been suggested. On a plain lateral C-spine x-ray this is usually measured from the posterior vertebral body (or the posterior aspect of an osteophyte) to the spinolaminar line. Some use 15 mm. Most agree that stenosis is present when the AP diameter is <12 mm in an adult. This measurement is less critical than it once was, it is a surrogate marker for stenosis severe enough to compress the spinal cord, which now may be demonstrated directly with MRI (or myelography).

**Prevertebral soft tissue**

Abnormally increased prevertebral soft tissue (PVST) may indicate the presence of a vertebral fracture, dislocation, or ligamentous disruption. Normal values for lateral C-spine x-ray and CT scan are shown in Table 12.2. Plain films are subject to errors due to magnification and rotation. Multi-detector CT (MDCT) eliminates these shortcomings.

Increased PVST is more likely with anterior than posterior injuries. NB: the sensitivity of these measurements is only ≈ 60% at C3 and 5% at C6. False positives may occur with basal skull/facial fractures, especially with fracture of the pterygoid plates. An ET-tube may allow fluid to accumulate in the posterior oropharynx which can obscure this measurement. In this setting, one can look for a thin fat layer between the prevertebral muscles and the posterior pharynx on cervical CT; the prevertebral tissue (posterior to this line) will be thickened (no measurements available at this time). MRI can also demonstrate abnormal signal within the prevertebral tissue.

**Interspinous distances**

C-spine AP: a fracture/dislocation or ligament disruption may be diagnosed if the interspinous distance is 1.5 times that at both adjacent levels (measured from center of spinous processes). Also look for a malalignment of spinous processes below a certain level which may be evidence of rotation due to a unilaterally locked facet.

C-spine lateral: look for “fanning” or “flaring” which is an abnormal spread of one pair of spinous processes that may also indicate ligament disruption.

### 12.1.5 Pediatric C-spine

**Cl (atlas)**

Ossification centers: usually 3 (Fig. 12.3)

- 1 (sometimes 2) for body (not ossified at birth; appears on x-ray during 1st yr)
- 1 for each neural arch (appear bilaterally ≈ 7th fetal week)

Synchondroses:

- Synchondrosis of the spinous process: fuses by ≈ 3 yrs age
- 2 neurocentral synchondroses: fuse by ≈ age 7 yrs
The ossification centers of C1 fail to completely close in 5% of adults (usually posteriorly). When present, the rare anterior defect is usually associated with a posterior defect.

C2 (axis)

Developmentally there are 5 ossification centers. The two halves of the odontoid fuse together in the midline (dashed line in Fig. 12.4) at 7 months development, so that at birth there are 4 primary ossification centers (Fig. 12.4):
- odontoid process
- vertebral body
- 2 neural arches

The posterior arches fuse together by 2-3 years of age. The anterior synchondroses normally fuse between 3-6 years of age. However, the dentocentral synchondrosis (AKA subdental synchondrosis) may be visible on x-ray until ≈11 years of age. A secondary ossification center (os terminale) appears at the summit of the dens between 3–6 years of age, and fuses with the dens by age 12 years.15

C3–7
3 ossification centers at birth16 (see Fig. 12.5).
- vertebral body
- 2 neural arches
The 2 neural arches fuse together posteriorly by 2-3 years age.
The neural arches each fuse to the body by 3-6 years age.
Cervical bodies are normally slightly wedge shaped in pediatric population (narrower anteriorly).
Wedging decreases with age.

12.2 Lumbosacral (LS) spine x-rays
L4–5 is normally the lumbar disc space with the greatest vertical height. Also see Normal LS spine measurements (p.1102).
AP view: look for defect or non-visualization of the “owl’s eyes” which is due to pedicle erosion which may occur with lytic tumors (common with metastatic disease).
Oblique views: look for discontinuity in neck of “Scotty dog” for defect in pars interarticularis.
Butterfly vertebra: An uncommon congenital anomaly thought to arise from failure of fusion of the lateral halves of the VB due to persistent notochord tissue, producing a “butterfly” appearance on AP x-rays or coronal CT scan reconstructions. The involved VB is widened, and adjacent vertebrae may show a compensatory deformity as if to fill in some of the gap. May be associated with other spinal and rib malformations. On lateral views may simulate compression fracture. In severe cases, there may be significant kyphosis and/or scoliosis. Often asymptomatic, requiring no treatment. May be associated with lipomyelomeningocele (p.269).

12.3 Skull x-rays
Water’s view: AKA submental vertex view. X-ray tube angled up 45° (perpendicular to clivus).
Towne’s view: x-ray tube angled down 45°, to view occiput.

12.3.1 Sella turcica
Normal adult dimensions on skull x-ray
Technique: true lateral, 91 cm target to film distance, central ray 2.5 cm anterior and 1.9 cm superior to EAM. Table 12.3 shows normal values (Fig. 12.6 shows how measurements are made).
Depth (D): defined as the greatest measurement from floor to diaphragma sellae.
Length (L): defined as the greatest AP diameter.

Abnormal findings
Pituitary adenomas tend to enlarge the sella, in contrast to craniopharyngiomas which erode the posterior clinoids. Empty sella syndrome tends to balloon the sella symmetrically, and also does not erode the clinoids. Tuberculum meningiomas usually do not enlarge the sella, and may be associated with enlargement of the sphenoid sinus; see sphenoid pneumosinus dilatans (p.1372).
"T" shaped sella suggests optic nerve glioma. It can also occur congenitally in Hurler syndrome (a mucopolysaccharidosis).

12.3.2 Basilar invagination and basilar impression (BI)

Terminology

The terms basilar impression and basilar invagination are often used interchangeably in the literature: historically, basilar invagination (AKA cranial settling) denoted upward indentation of skull base usually due to acquired softening of bone (see below), often associated with atlanto-occipital fusion, while basilar impression implied normal bone. Making a distinction seems pointless (the abbreviation (BI) will be used for either). Common feature: upward displacement of the upper cervical spine (including odontoid process, AKA cranial migration of the odontoid) through the foramen magnum into the p-fossa.

Platybasia: flattening of the skull base. Originally assessed on plain x-rays (which are subject to error due to skull rotation or difficulty identifying landmarks), now more commonly evaluated on CT or MRI. May or may not be associated with BI, and may occur in association with craniofacial abnormalities, Chiari malformation, Paget’s disease…

Quantitated by measuring the basal angle, which on plain x-rays, measured the angle between lines drawn from the nasion to center of sella and then to the anterior foramen magnum, but on MRI was felt to be better represented by the angle between a line drawn along the floor of the anterior fossa to the dorsum sellae and a second line drawn along the posterior clivus. Normal mean basal angle: 130°. Platybasia: >145° (abnormally obtuse basal angle).

Two subtypes of BI

See reference.

Type I: BI without Chiari malformation. Tip of odontoid tends to be above CI, McR, and WCCL in Fig. 12.7. Brainstem compression is due to odontoid process invagination. 85% can be reduced with traction. Treatment: transoral surgery is recommended, usually accompanied by posterior fusion.

Type II: BI+Chiari malformation. Odontoid tip tends to be above CI, but not McR or WCCL Brainstem compression is due to reduced p-fossa volume. Only 15% can be reduced with traction. Foramen magnum decompression is appropriate.

Fig. 12.6 Measurements of the sella turcica (lateral view)
Measurements used in BI

1. McRae’s line (“McR” in Fig. 12.1): drawn across foramen magnum (tip of clivus (basion) to opisthion). The mean position of the odontoid tip below the line is 5 mm (± 1.8 mm SD) on CT and 4.6 mm (± 2.6 mm SD) on MRI. No part of odontoid should be above this line (the most accurate measure for BI).

2. Chamberlain’s line (“CL” in Fig. 12.1): posterior hard palate to posterior margin of foramen magnum (opisthion). Less than 3 mm or half of dens should be above this line, with 6 mm being definitely pathologic. Seldom used because the opisthion is often hard to see on plain film and may also be invaginated. On CT and MRI the normal odontoid tip is 1.4 mm (± 2.4) below the line.

3. McGregor’s baseline (“McG” in Fig. 12.1): posterior margin of hard palate to most caudal point of occiput. No more than 4.5 mm of dens should be above this. On CT and MRI the normal odontoid tip is 0.8 mm (± 2.4) above the line.

4. Wackenheim’s clivus-canal line (“WCCCL” in Fig. 12.1): the odontoid should be tangential to or below the line that extends the course of the clivus (the clivus baseline). If the clivus is concave or convex, this baseline is drawn to connect the basion to the base of the posterior clinoids on the clivus.

5. Fischgold’s digastic line (“FDGL” in Fig. 12.7): joins the digastic notches. The normal distance from this line to the middle of the atlanto-occipital joint is 10 mm (decreased in BI). No part of odontoid should be above this line. More accurate than the bimastoid line (FBML).

6. Fischgold’s bimastoid line (“FBML” in Fig. 12.7): joins tips of mastoid processes. The odontoid tip averages 2 mm above this line (range: 3 mm below to 10 mm above) and this line should cross the atlanto-occipital joint.

Conditions associated with BI

1. Congenital conditions (BI is the most common congenital anomaly of the craniocervical junction, it is often accompanied by other anomalies):
   a) Down syndrome
   b) Klippel-Feil syndrome (p. 271)
   c) Chiari malformation (p. 277): in a series of 100 patients, 92 had BI
   d) Syringomyelia

2. Acquired conditions
   a) Rheumatoid arthritis (in part due to incompetence of transverse ligament, see Basilar impression in rheumatoid arthritis (p. 1137)
   b) Post-traumatic

3. Conditions with BI associated with softening of bone include:
   a) Paget’s disease
b) osteogenesis imperfecta: patients have blue discolored sclera and early hearing loss and due to a genetic defect that causes defective Type 1 collagen. Bones are weak ("brittle-bone disease"). Autosomal dominant inheritance. There are 4 common types of OI and some uncommon ones.
c) osteomalacia
d) rickets
e) hyperparathyroidism

12.4 Contrast agents in neuroradiology

Also see Intraoperative dyes (p. 1426) for visible dyes useful in the operating room.

12.4.1 Iodinated contrast agents

General precautions

Water-soluble contrast agents have superseded non-water-soluble ones such as Pantopaque® (ethyl iophendylate meglumine).

Caution: iodinated contrast (IV or intra-arterial) may delay excretion of metformin (Glucophage®, Avandamet®), an oral hypoglycemic agent used in diabetes type II, and can be associated with lactic acidosis and renal failure (particularly in patients with CHF or those consuming alcohol). The manufacturer recommends withholding metformin 48 hrs prior to and following contrast administration (or longer if there is evidence of declining renal function following use of contrast). Metformin should also be held ≥ 48 hours before any surgery, and should not be restarted post-op until the patient has fully recovered and is eating and drinking normally.

Maximum dose of iodine with normal renal function is ≈ 86 gm in a 24 hour period.

Intrathecal contrast agents

Inadvertent intrathecal injection of unapproved contrast agents

Caution: serious reactions can occur with inadvertent intrathecal injection (e.g. for myelography, cisternography, ventriculography...) of iodinated contrast media that are not specifically indicated for intrathecal use (including ionic contrast agents as well as some non-ionic agents (e.g. Optiray®, Reno-60...)). This can cause uncontrollable seizures, intracerebral hemorrhage, cerebral edema, coma, paralysis, arachnoiditis, myoclonus (tonic-clonic muscle spasms), rhabdomyolysis with subsequent renal failure, hyperthermia, and respiratory compromise, with a significant fatality rate. Management suggestions for inadvertent intrathecal injection include:

1. immediately remove CSF+contrast if the error is recognized when the opportunity is available (e.g. withdraw fluid through myelography needle)
2. elevate head of bed ≈ 45° (to keep contrast out of head)
3. if there is a question about what may have occurred (i.e. it is not certain if an inappropriate contrast agent was used) send blood and CSF with contrast for high-performance liquid chromatography for identification of agent
4. antihistamines: e.g. diphenhydramine (Benadryl®) 50 mg deep IM
5. respiration: supplemental oxygen, and if needed, intubation
6. control HTN
7. IV hydration
8. IV steroids
9. sedation if patient is agitated
10. treat fever with acetaminophen and if needed with a cooling blanket
11. pharmacologic paralysis if necessary to manage muscle activity
12. anticonvulsant medication: more than one agent may be required (e.g. phenytoin + phenobarbital + a benzodiazepine)
13. consider unenhanced brain CT scan: may help assess if contrast has diffused intracranially, but this requires placing patient flat and may not be advisable
14. insert lumbar subarachnoid drain with CSF drainage (e.g. 10 cc q hr)
15. monitor: electrolytes, anticonvulsant levels, creatine kinase (CK)
16. repeat EEGs to assess seizure activity while sedated/paralyzed

Iohexol (Omnipaque®)
The primary approved agent employed for intrathecal use today is iohexol (Omnipaque®).
A non-ionic triiodinated compound. Concentration is expressed as follows: e.g. Omnipaque 300 contains the equivalent of 300 mg of organic iodine per ml of media (300 mgI/ml).

Used for myelography, cisternography as well as IV contrasted CT. Uses and concentrations are shown in Table 12.4.

Intrathecal use

NB: only Omnipaque 180, 210, 240 and 300 are labeled for intrathecal use. 140 and 350 are not FDA approved for intrathecal use, however, some neuroradiologists will use Omnipaque 140 or diluted 180 e.g. for CT ventriculography (off-label usage).

Consider discontinuing neuroleptic drugs (including: phenothiazines, e.g. chlorpromazine, prochlorperazine, and promethazine) at least 48 hours prior to procedure. Elevate HOB ≥ 30° for the first few hours after the procedure. Hydrate orally or IV.

Use with caution in patients with seizure history, severe cardiovascular disease, chronic alcoholism or multiple sclerosis.

Iohexol undergoes slow diffusion from the intrathecal space to the systemic circulation and is eliminated by renal excretion with no significant metabolism or deiodination.

Maximum dosage: a total dose of 3060 mg iodine should not be exceeded in an adult during a single myelogram (some say up to 4500 mg is OK) (e.g. 15 cc of Omnipaque 300 = 15 ml × 300 mgI/ml = 4500 mg of iodine).

Iopamidol (e.g. Isovue 300, Isovue 370®)
Triiodinated, non-ionic, water-soluble. Used for intravascular and intrathecal radiographic contrast. Isovue 300 and 370 contains 300 and 270 mg iodine/ml, respectively.

*a most centers use Optiray®, see text

*b follow with 250 ml bolus of 0.45%NS to rehydrate patient

*180 will be very dense on CT, and some use 1–3 ml of 140 or diluted 180%(dilute approximately 2 parts contrast to 1 part preservative-free normal saline)
Non-intrathecal contrast agents
For inadvertent intrathecal injection of contrast agents not intended for intrathecal use, see above.

Ioversol (Optiray®)
Not for intrathecal use (see above).
Uses and concentrations include:
• arteriography: Optiray 300 (ioversol 64%) or Optiray 320 (ioversol 68%). Total procedural dose should not usually exceed 200 ml
• IV contrast enhanced CT scan of brain:
  a) adult: 50–150 ml of Optiray 300, 320, or 100–250 ml of Optiray 240.
  Typically: 100 ml of Optiray 320
  b) pediatrics: 1–3 ml/kg of Optiray 320

Iopromide (Ultravist®)
Not for intrathecal use (see above). Available in 150, 240, 300 & 370 mg iodine/ml. Osmolality of Ultravist 300 is 607.
Cerebral angiography (300 mg/ml): maximum dose is 150 ml per procedure.
Contrast enhanced CT (CECT) (300 mg/ml). Pediatrics (>2 years age): typical dose in is 1–2 ml/kg IV, maximum dose is 3 ml/kg per procedure. Adult: typical dose is 50–200 ml, maximum dose is 200 ml.

Iodixanol (Visipaque®)
Not for intrathecal use (see above). Triiodinated, non-ionic, isosmolar to blood. For intravascular use. FDA approved for CECT, some angiographers use Visipaque 270 for cerebral angiography (slightly lower opacification, but also slightly lower iodine dose). Available in 270 and 320 mg iodine/ml.

Iodinated contrast with allergies or renal insufficiency
Allergy prep
Indicated for patients with previous history of reaction to IV iodinated contrast material. Minor previous reactions such as hives and itching merit preparation with this regimen whenever possible. Patients with anaphylactic shock or severe edema causing compromise of the airway should probably not receive IV iodine even with this prep, unless absolutely necessary. Caution: in spite of this regimen, the patient may still have serious reaction (modified\textsuperscript{13}). This prep has also been used for the rare gadolinium allergy.
1. utilize non-ionic contrast medium (e.g. iohexol) whenever possible
2. have emergency equipment available during study
3. medications:
   a) steroid ( Table 8.1 for further details of steroid dosing)
      • prednisone 50 mg PO: 20–24 hrs, 8–12 hrs & 2 hrs before study
      • equivalent dose of IV Solumedrol® (methylprednisolone): $\approx 25$ mg
   b) diphenhydramine (Benadryl®) 50 mg, EITHER IM 1 hr before, OR IV 5 min before study
   c) optional: H2 antagonist, e.g. cimetidine 300 mg PO or IV 1 hr before study

Medications for an emergency scan when 24 hour prep is not possible:
• hydrocortisone 100 mg IV then scan within 2 hours

Prep for renal insufficiency or patients with DM
For patients with DM or mild renal insufficiency (e.g. slight serum creatinine elevation, >1.2 mg/dl (U.S.) which is >100 mcmol/L) 1 mg/dl of creatinine (used in the U.S.)=$88.4$ mcmol/L, to mitigate against iodine contrast-induced nephropathy:
• N-acetyl cysteine (Mucomyst; the actual efficacy of NAC has not been proven, and may be no better than hydration alone): regimens all accompany hydration and include:
  a) 800 mg PO q 8 hrs for 24 hours before the study,\textsuperscript{14} followed by 600 mg PO BID for 24 hours after the study
  b) 600 mg PO BID X 2 days before the study, 600 mg PO BID for 24 hours after
  c) 600-mg IV bolus before the study, and 600 mg PO BID for 48 hours after\textsuperscript{15}
• hydration: 1 L of sterile water with 3 amps of sodium bicarbonate IV at 100 ml/hr, start 1 hour prior to the study, and continue until entire L given

12.4.2 Reactions to intravascular contrast media

General information
See also treatment of inadvertent intrathecal injection of ionic contrast agents (p. 219)

Beta blockers
Beta blockers can increase the risk of contrast media reactions, and may mask some manifestations of an anaphylactoid reaction. They also make use of epinephrine undesirable since the alpha effects of epinephrine will predominate (bronchospasm, vasoconstriction, increased vagal tone). If treatment is required for hypotension after beta-blocker administration, may try glucagon 2–3 mg IV bolus, followed by 5 mg IV drip over 1 hour (glucagon has positive inotropic and chronotropic effect that is not mediated through adrenergic pathways).

Idiosyncratic reactions and treatment

Hypotension with tachycardia (anaphylactoid reaction)
1. mild: Trendelenburg position. IV fluids
2. if no response but remains mild:
   epinephrine (use with caution in patients with coronary artery disease, limited cardiac reserve, hypertension, or unclipped cerebral aneurysm)
   a) 0.3–0.5 ml of 1:1000 SQ (0.3–0.5 mg) q 15–20 mins (peds: 0.01 mg/kg)
   b) or, ASEP recommendations (especially for elderly or patients in shock): 10 ml of 1:100,000 IV over 5 to 10 min (put 0.1 ml of 1:1000 in 10 ml of NS, or dilute 1 amp of 1:10,000 to 10 ml with NS)
3. moderate to severe or worsening (anaphylaxis): add:
   a) IV colloidal fluids, e.g. hetastarch (Hespan®) 6% (colloids are required since there is extravascular shift of fluids due to see page, these agents also carry a small risk of allergic reaction)
   b) epinephrine (see above). May repeat × 1
   c) O₂ 2–6 L/min per NC. Intubate if necessary
   d) EKG to R/O ischemic changes
4. if shock develops: add dopamine (p. 128), start at 5 mcg/kg/min

Hypotension with bradycardia (vasovagal reaction)
1. mild:
   a) Trendelenburg position
   b) IV fluids
2. if no response, add:
   a) atropine 0.75 mg IV, may repeat up to 2–3 mg over 15 mins PRN. Use with caution in patients with underlying heart disease
   b) EKG and/or cardiac monitor: especially if atropine or dopamine are used
3. if no response: add dopamine (p. 128), start at 5 mcg/kg/min

Urticaria
1. mild: self limited. No treatment necessary
2. moderate:
   a) diphenhydramine (Benadryl®) 50 mg PO or deep IM (avoid IV, can cause anaphylaxis itself)
   b) cimetidine (Tagamet®) 300 mg PO or IV diluted to 20 ml and given over 20 mins. H₂ receptors contribute to wheal and flare of reaction
3. severe: treat as above for moderate reaction, and add:
   a) epinephrine (see above)
   b) maintain IV line

Facial or laryngeal angioedema
1. epinephrine: see above. May repeat up to 1 mg
2. if respiratory distress: O₂ 2–6 L/min. Intubate if necessary (orotracheal may be very difficult due to swelling of tongue, nasotracheal intubation or emergency cricothyrotomy may be required)
3. diphenhydramine: see above
4. cimetidine: see above
5. if angioedema is accessible, add ice pack
6. maintain IV line
7. steroids are usually effective only for chronic angioedema

**Bronchospasm**
1. mild to moderate:
   a) epinephrine: see above. May repeat up to 1 ml
   b) if respiratory distress: O₂ 2–6 L/min. Intubate if necessary
   c) maintain IV line
   d) inhalational therapy with a β-adrenergic agonist, e.g. albuterol (Proventil®) if respiratory therapy is available, otherwise, metered dose inhaler e.g. pirbuterol (Maxair®) or metaproterenol (Metaprel®), 2 puffs
2. severe: treat as above for moderate reaction, and add:
   a) aminophylline 250–500 mg in 10–20 cc NS slow IV over 15–30 mins. Monitor for hypotension and arrhythmias
   b) intubate
3. prolonged: add the following (will not have immediate effect):
   a) hydrocortisone 250 mg IV
   b) diphenhydramine: see above
   c) cimetidine: see above

**Pulmonary edema**
1. O₂ 2–6 L/min per NC. Intubate if necessary
2. raise head and body
3. furosemide (Lasix®) 40 mg IV
4. EKG
5. if hypoxia develops (may manifest as agitation or combativeness), add:
   a) morphine 8–15 mg IV. May cause respiratory depression, be prepared to intubate
   b) epinephrine: see above. CAUTION: use only if MI can be R/O as cause of the pulmonary edema. Patients with acute intracranial pathology may be at risk of neurogenic pulmonary edema (p.1178)

Seizures
If seizure is not self limited, start with lorazepam (Ativan®) 2–4 mg IV for an adult. Take precautions for status epilepticus (p.470) and proceed to other drugs as indicated (p.471).

**12.5 Radiation safety for neurosurgeons**

12.5.1 General information
Radiation exposure has both a deterministic component (exposure over a certain threshold will cause a specific injury) as well as a stochastic component (any dose increases the chances of an adverse event, and the higher the cumulative dose, the higher the chances).

12.5.2 Units
See reference.³⁶
Absorbed dose: the amount of energy absorbed per unit mass. Expressed in Gray or rads.
Gray (Gy): the SI unit. 1 Gy = 100 cGy = 100 rads = an absorbed dose of 1 joule/kg.
Rad: 1 rad = an absorbed dose of 100 ergs/gram = 0.01 joule/kg = 0.01 Gy = 1 cGy.
The biological effect (dose equivalent) of radiation: can be expressed in rem or Sieverts.
Sievert (Sv): the SI unit. The dose equivalent in sieverts is equal to the absorbed dose in grays multiplied by a “quality factor” (Q) which differs for different sources of radiation, e.g. high-energy protons have a Q of 10, x-rays have a Q of 1. 1 Sv =100 rems.
Roentgen-equivalent man (rem): the absorbed dose in rads multiplied by Q. 1 rem is estimated to cause ≈ 300 additional cases of cancer per million persons (one third of which are fatal). 1 rem = 0.01 sievert.
12.5.3 Typical radiation exposure

The average annual exposure to radiation is 360 mrem (about 30 mrem are due to background cosmic radiation, ≈ 20% of the total dose is due to radioactive potassium-40 which is in every cell). Exposure from a transcontinental airline flight is ≈ 5 mrem.

CXR: causes about 0.01–0.04 rem of exposure to the chest.

Spine x-ray with obliques: 5 rem.

CAT scan (brain, noncontrast): median effective dose to the head = 0.2 rem, but the range varied 13 fold within and across institutions.\(^{37}\)

Spine CT: 5 rem.

Cerebral arteriogram: ≈ 10–20 rem (including fluoroscopy).\(^{38}\)

Cerebral embolization: 34 rem.

Bone scan: 4 rem.

C-arm fluoroscopy\(^{39}\): exposure is shown in Table 12.5.

Doses during a minimally invasive TLIF\(^{40}\):

- Patient exposure: mean 60 mGy to the skin in the AP plane (range: 8–250 mGy), 79 mGy in the lateral plane.
- Surgeon exposure: 76 mrem to dominant hand, 27 mrem at the waist under a lead apron, and 32 mrem to an unprotected thyroid level detector.

12.5.4 Occupational exposure

The U.S. Nuclear Regulatory Commission (NRC) maximal recommended annual occupational dose limits for radiation are shown in Table 12.6.\(^{41}\) The 1990 recommendations of the International Commission on Radiological Protection (ICRP) was to keep exposure ≤ 2 rem/year averaged over 5 years.\(^{42}\)

ALARA: an acronym for “As Low As Reasonably Achievable” by which the NRC means making every reasonable effort to keep radiation dose as far below the limits as possible consistent with the purpose for which the licensed activity is undertaken.\(^{43}\)

Steps to reduce occupational radiation dose (to staff) during surgery:

1. increase the distance from the radiation source: radiation exposure is proportional to the inverse square of the distance. Conventional wisdom is to try to keep 6 feet away. In a AANS publication, 3 m (10 ft) was recommended.\(^{44}\)

- Lead aprons/shields may or may not work. Distance ALWAYS works (inverse square law – double the distance and get 1/4 the radiation).

2. shielding: shielding is less effective at higher kV (used with larger patients). Portable lead “doors” are more effective than aprons. Wrap-around 2-piece aprons are better than front side aprons. With front aprons the wearer must always face the x-ray source, otherwise the apron can actually reflect some radiation back onto the wearer. Non-lead aprons may not provide the rated protection at levels >100 keV.\(^{45}\)

3. don’t overuse magnification: most fluoro systems increase the radiation emitted × 4 to compensate for the associated reduction in image brightness

4. “boost” mode can double the radiation output. Use should be kept to a minimum

5. use live fluoro only when absolutely necessary

6. for lateral imaging, when possible stand on the “downstream” (image intensifier (ImI)) side of the C-arm: scatter is the most significant cause of exposure here and is higher on the source side\(^{47}\) (this asymmetry is not as significant for C-spine\(^{48}\)).

7. keep the ImI as close to the patient as possible (reduces patient & staff exposure and improves image quality)

8. on AP images (with the patient prone or supine): position the x-ray tube under the table with the ImI over the patient (lowers scatter exposure to staff)\(^{49}\)

9. collimate the beam as much as possible: reduces radiation to patient and to staff, and results in less image degradation

10. keep hands, arms, etc. out of the primary beam at all times (consider using leaded gloves if hands need to be within the beam or nearby for an extended time)

11. minimize number of images: plan your shot, avoid frequent “checks” or peeks

12. use image guided navigation when possible and practical

13. leaded glasses are recommended only for personnel with very high fluoro times: cataracts can be induced by single doses of 200 rads (very high), cumulative doses of 750 rads have not been associated with cataracts.

13 Imaging and Angiography

13.1 CAT scan (AKA CT scan)

13.1.1 General information

CAT scans employ ionizing radiation (x-rays) with the attendant risks; see Radiation safety for neurosurgeons (p.223).

Attenuation of the x-ray beam on a CT scan is defined in Hounsfield units. These units are not absolute, and vary between CT scanner models. Some sample values are shown in Table 13.1.

13.1.2 Noncontrast vs. IV contrast enhanced CT scan (CECT)

Noncontrast CT scans are often employed in emergency situations (to quickly rule out most acute abnormalities), to evaluate bone in great detail, or as a screening test. It excels in demonstrating acute blood (EDH, SDH, IPH, SAH), fractures, foreign bodies, pneumocephalus and hydrocephalus. It is weak in demonstrating acute stroke (DWI MRI is preferred), and often has poor signal quality in the posterior fossa (due to bone artifact).

IV enhanced CT scans are used primarily for imaging neoplasms or vascular malformations, especially in patients with contraindications to MRI. All CT contrast agents contain iodine.

Typical IV dose of contrast: 60–65 ml of e.g. Isovue 300® (p.220) which delivers 18–19.5 grams of iodine.

13.1.3 CT angiography (CTA)

Employs rapid injection of iodinated contrast at 3–4 cc/sec, typically 65–75 ml of e.g. Isovue 300®. Optimal results in patients who can hold their breath for 30–40 seconds (for spiral CT).

<sup>a</sup>Hct < 23% will cause an acute SDH to be isodense with brain
Various methods may be used to determine timing of CT after injection: may be based on time to peak in aorta after a small test injection, or can be based empirically on time, or give injection and look for peak in the region of interest.

Accuracy is diminished for vessels that are perpendicular to the axial CT plane. Also in the vicinity of dense clot, CTA has trouble resolving the adjacent vessels.

**13.1.4 CT perfusion (CTP)**

Requires use of iodinated contrast. Areas of interest are selected from an unenhanced CT scan in the 3 supratentorial vascular territories. Contrast is given at a standard rate (e.g. 40 ml IV at 5 ml/sec). Scans through the regions of interest are repeated at intervals, e.g. every 2 seconds for 1 minute.

Acetazolamide (ACZ) (Diamox®) challenge: after the above, a bolus of 1000 mg of IV ACZ is given, and scans are repeated at intervals for approximately 10 minutes, with a final scan usually at 15 minutes.

Parameters then calculated from the images: cerebral blood volume (CBV), CBF, mean transit times (MTT), and time to peak (TTP). In ischemic stroke, MTT is almost always increased and CBF is decreased.

Abnormalities that can be demonstrated:
1. flow significant stenosis: decreased CBV & CBF, increased MTT and TTP
2. steal: after ACZ challenge (see above), CBV & CBF decrease, often with increases in the corresponding contralateral territory; MTT increases

In comparison to perfusion weighted MRI (PWI) (p. 232):
1. PWI acquires multiple slices of the whole brain over and over. CTP is limited to a given slice or several slices (usually 10–20 mm thick), and one has to choose where to place that slice
2. PWI has more artifact than CTP

**13.2.2 T1 weighted image (T1WI)**

Short $T_1 \rightarrow$ high signal (bright). “Anatomic image”, somewhat resembles CT. Shorter acquisition time than T2WI. Proton rich tissue (e.g. H$_2$O) has long T1.

<table>
<thead>
<tr>
<th>Table 13.2 Range of acquisition data</th>

</tr>
</thead>
<tbody>
<tr>
<td>fat (including bone marrow), blood &gt;48 hrs old, melanin</td>
</tr>
</tbody>
</table>

(note: grey-bar illustrates direction of intensity change and does not show actual grey on MRI)
Clues to recognizing T1WI: CSF is black, subcutaneous fat is white, TR and TE are short (hundreds and double digits, respectively).

The only objects that appear white on T1WI are: fat, melanin, Onyx® (p. 1589), and subacute blood (>48 hrs old). White matter is higher signal than grey matter (myelin has a high fat content). Most pathology is low signal on T1WI.

13.2.3 T2 weighted image (T2WI)
Long $T_2 \rightarrow$ high signal (bright). “Pathological image.” Most pathology shows up as high signal, including surrounding edema.

Clues to recognizing T2WI: CSF is white, TR & TE are long (thousands and hundreds, respectively).

13.2.4 Spin density image
AKA balanced image, AKA proton density image. Part way between T1WI and T2WI. CSF = grey, approximately isodense with brain. Becoming less commonly used.

13.2.5 FLAIR
Acronym: FLuid-Attenuated Inversion Recovery. Long TR and TE. Resembles a T2WI except the CSF is nulled out (appears dark). The grey/white intensity pattern is reversed from T1WI and is more prominent. Most abnormalities including MS plaques, other white matter lesions, tumors, edema, encephalomalacia, gliosis and acute infarcts appear bright. Periventricular lesions such as MS plaques become more conspicuous. Also good for demonstrating abnormalities in CSF.

Differential diagnosis of increased signal in subarachnoid spaces on FLAIR:
1. subarachnoid hemorrhage (SAH): the best sequence for detecting acute SAH on MRI
2. meningitis: occurs in some cases
3. meningeal carcinomatosis
4. superior sagittal sinus thrombosis
5. stroke
6. adjacent tumor: if related to higher protein
7. previous administration of gadolinium
8. high levels of FIO$_2$ especially at levels nearing 100% as may be used in patients getting MRI under general anesthesia. Shows up in basal cisterns and in sulci over the convexity, but not in ventricles

13.2.6 Echo train (AKA fast spin echo (FSE))
t$R$ is held constant, t$E$ is progressively increased utilizing multiple echoes (8–16) rather than one. Image approaches T2WI but with substantially reduced acquisition time (fat is brighter on FSE, which may be rectified by fat suppression techniques).

13.2.7 Gradient echo
AKA T2* (called T2-star), and some manufacturers have trademarked names for this, e.g. “GRASS” (a GE trademarked acronym for Gradient Recalled Acquisition in a Steady State) or FISP. A “fast” T2WI utilizing a partial flip angle. CSF and flowing vessels appear white. Bone, calcium and heavy metals are dark. Typical acquisition data: TR = 22, TE = 11, angle 8°. Used e.g. in cervical spine to produce a “myelographic” image, improves MRI’s ability to delineate bony spurs. Also shows small old cerebral hemorrhages (seen in 60% of patients presenting with hemorrhagic infarction, and in 18% with ischemic infarcts); these patients may be at increased risk of hemorrhage from anticoagulation.

Gradient-echo T2WI MRI is the 3–4× more sensitive test than FLAIR for demonstrating intraparenchymal blood (which appears dark) due to high sensitivity to paramagnetic artifact. It is not as sensitive as the more recently introduced SWI.

13.2.8 “STIR” image

Acronym for “Short Tau Inversion Recovery.” Summates T1 & T2 signals. Causes fat to drop out – sometimes also called fat suppression or “fat sat” (for fat saturation), allows gadolinium enhancement to show up better in areas of fat. Useful primarily in spine and orbit. Very good for showing bone edema (can help in dating spine fractures). The dorsal root ganglion may enhance on fat suppression images.

13.2.9 Contraindications to MRI

General information

An extensive reference details safety issues. Web sites for MRI safety include: www.MRI safety.com and www.IMRSER.org. Some issues that come up frequently in neurosurgical patients follows.

Pregnancy and MRI

During the first trimester, MRI can cause reabsorption of products of conception (miscarriage). There are no studies to determine the long term effects of MRI on a fetus after the first trimester (the low risk of MRI in this situation is probably preferable to the known dangers of ionizing radiation of x-rays (including CT)). Gadolinium contrast is contraindicated during all of pregnancy, and is not approved for use in age <2 years. Breast-feeding must be interrupted for 2 days after administration of gadolinium to the mother.

Common contraindications to MRI

1. cardiac pacemakers/defibrillator, implanted neurostimulators, cochlear implants, infusion pumps: may cause temporary or permanent malfunction
2. ferromagnetic aneurysm clips (see below): some centers exclude all patients with any type of aneurysm clip
3. metallic implants or foreign bodies with large component of iron or cobalt (may move in field, or may heat up)
4. Swann-Ganz catheter (pulmonary artery catheter)
5. metallic fragments within the eye
6. placement of a vascular stent, coil or filter within the past 6 weeks
7. shrapnel: BB’s (some bullets are OK)
8. relative contraindications:
   a) claustrophobic patients: may be able to sedate adequately to perform study
   b) critically ill patients: ability to monitor and access to patient are impaired. Specially designed non-magnetic ventilator may be required. Cannot use most brands of electronic IV pumps/regulators
   c) obese patients: may not physically fit into many closed bore MRI scanners. Open bore scanners may circumvent this but many utilize lower field strength magnets and generally produce inferior quality images in large patients
   d) non-MRI compatible metal implants in the region of interest (or previous surgery with high speed drills which may leave metal filings): may produce susceptibility artifact which can distort the image in that area
   e) programmable shunt valve (p.418): most will tolerate up to a 3 T MRI without permanent damage, however, the pressure setting may be altered and therefore should be rechecked after having an MRI for any reason

Aneurysm clips and MRI

MRI concerns in patients with a cerebral aneurysm clip:
1. the danger of the MRI magnetic field causing the aneurysm clip to be pulled or torqued off of the aneurysm or to tear the neck
2. the artifact produced by the metal of the clip in the magnetic field
3. heat generated in the region of the clip: not clinically significant

The more ferromagnetic the clip, the larger the force exerted on it by the magnetic field and the greater the image distortion near the clip.

Stainless steel (SS) is classified as martensitic (ferromagnetic) or austenitic (non-ferromagnetic). Cobalt-based superalloys are non-ferromagnetic and include Elgiloy (Sugita clips), Phynox (Yasargil),
and Vari-Angle (McFadden). Essentially all modern aneurysm clips are MRI compatible, but patients clipped before the 1990s may have ferromagnetic clips.

Table 13.5 shows the magnetic remanence of various clips which is related to their ferromagnetic properties. If in doubt at the time of aneurysm surgery, apply the following simple test: non-ferromagnetic clips cannot be lifted or dragged with a small magnet.

13.2.10 Hemorrhage on MRI

Because its signal characteristics change with time (and location), blood is one of the most complex entities to interpret on MRI. A mnemonic for the changes in appearance of blood on MRI with time is shown in Table 13.6. See also intracerebral hemorrhage (p.1330). Blood, hemosiderin and calcium are dark on GRASS images. FLAIR (p.229) is the best sequence for detecting SAH on MRI (p.229).

13.2.11 MRI contrast

Current agents are mostly based on gadolinium (a rare earth metal which is paramagnetic in solutions) include: gadopentatate dimeglumine (Magnevist®), gadodiamide (Omniscan®), gadoversetamide (OptiMARK®), gadobenate dimeglumine (MultiHance®) and gadoteridol (ProHance®).

Adverse reactions:
1. anaphylactic reactions: rare (prevalence: 0.03–0.1%)
2. nephrotoxicity: incidence is lower than with iodinated agents used with angiograms or CT and x-ray contrast
3. nephrogenic systemic fibrosis (NSF): a rare, but serious illness characterized by fibrosis of skin, joints and other organs, which is associated with certain gadolinium containing agents given to patients with severe renal failure (most were on dialysis). Gadolinium is now relatively contraindicated with a GFR of 30–60 ml/min, and is contraindicated with GFR<30. Safest agents: Dotarem, Gadovist and ProHance. Contrast agents with a linear structure appear to be associated with a higher risk of NSF and include: Omniscan, Multihance, Magnevist and OptiMARK. In patients with end-stage renal disease, the risk is ≈ 2.4% per gadolinium study.
4. gadolinium allergy: use the same allergy prep as for iodine allergy (p.221)
5. as of the time of publication of this book, the FDA is investigating the risk of accumulation of gadolinium in brain tissue after repeated MRI scans using gadolinium based contrast agents (GBCAs). In the meantime, the FDA is recommending that health-care professionals consider
limiting the use of GBCAs to situations where the additional information provided by the contrast is absolutely necessary.

6. see also issues related to pregnancy (p.230)

### 13.2.12 Magnetic resonance angiography (MRA)

There are 2 ways to obtain an MRA:
- Gadolinium enhanced: usually for extracranial vessels (e.g. carotids)
- Noncontrast images using flow related enhancement techniques (most common: 2D time of flight (2D TOF)). Usually for intracranial vessels. Anything that appears bright on T1WI will also show up on MRA, but doesn’t necessarily represent blood flow. This includes fat and fat-laden macrophages in an area of old stroke. Using fat-sat T1WI can mitigate this. Has some utility in screening for aneurysms (p.1161), and for angiographically occult vascular malformations (p.1246). High-flow AVMs are hard to resolve because arterialized veins can appear similar to arteries.

### 13.2.13 Diffusion-weighted imaging (DWI) and perfusion-imaging (PWI)

#### Diffusion-weighted imaging

Primary uses: early detection of ischemia (stroke) and differentiating active MS plaques from old ones. DWI is sensitive to random Brownian motion of water molecules.

Two images are generated, an apparent diffusion coefficient (ADC) map (based on a number of variables (time, slice orientation…)), and a trace image (the actual DWI). Freely diffusing water (e. g. in CSF) appears dark on DWI.

The DWI is based on a T2WI, and anything that is bright on T2WI can also be bright on DWI (so-called “shine-through”). Since bright areas on DWI can represent either restricted diffusion or T2 “shine-through,” check the ADC map: if the area is black on the ADC map, then this likely represents true restricted diffusion (recent infarct is the most common etiology).

Intraparenchymal areas of bright signal on DWI that are not bright on the ADC map are abnormal and represent regions of restricted diffusion such as acute stroke.

#### Differential diagnosis of areas of increased signal (bright) on DWI:

1. ischemic brain: acute stroke and areas with hypoperfusion (penumbra). While restricted diffusion usually indicates irreversible cell injury (death), it can sometimes indicate tissue that is just near cell death (penumbra). Acute brain ischemia can light up within minutes. The DWI abnormality will persist for ≈ 1 month. The ADC map usually normalizes after ≈ 1 week.
2. cerebral abscess (p.323): DWI= bright, ADC= dark
3. active MS plaque (old plaques will not be bright)
4. some tumors: most tumors are dark on DWI, but highly cellular tumors may have decreased diffusion (bright on DWI) (e.g. epidermoids, some meningiomas…)

Other possible uses of DWI:
- TIAs: some, but not all, are associated with DWI abnormalities. However, factors other than focal ischemia (e.g. global ischemia, hypoglycemia, status epilepticus…) can produce ADC decline and the DWI images must therefore be interpreted in relation to the clinical setting.
- DWI may also be able to distinguish cytotoxic from vasogenic edema (p.90).

---

---
**Perfusion-weighted MRI**

Provides information related to the perfusion status of the microcirculation. PWI is the most sensitive study for ischemia of the brain (more sensitive than DWI and FLAIR which primarily show infarcted tissue). There are several methods currently in use; the bolus-contrast approach is the most widely employed. Ultrafast gradient imaging is used to follow the gradual reduction to normal following administration of contrast (usually gadolinium). A signal wash-out curve is derived and is compared to contrast in an artery. In practical terms, PWI is not widely used because of technical challenges. Time-to-peak and mean-transit-time are 2 common parameters that are displayed (higher signal=longer times beyond normal).

**DWI and PWI mismatch**

DWI and PWI may be combined to locate areas of diffusion-perfusion mismatch (deficit on PWI that exceeds the zone of diffusion deficit on DWI), thus identifying salvageable brain tissue at risk of infarction – “penumbra” (p.1202) – e.g. to screen for potential candidates for thrombolytic therapy.

**13.2.14 Magnetic resonance spectroscopy (MRS)**

**General information**

This section specifically covers proton (H+) MRS which can be performed on almost any MRI scanner (especially units ≥1.5 T) with the appropriate software. Spectroscopy of other nuclei (e.g. phosphorous) can be evaluated only with specialized equipment.

**Single voxel MRS**

**General information**

A small area is selected on the “scout” MRI and the spectroscopic peaks for that region are displayed in resonance as a function of parts-per-million (ppm). Since only small regions are selected, may be subject to “sampling” error.

Clinically important characteristic peaks are delineated in Table 13.7.

<table>
<thead>
<tr>
<th>Moiety</th>
<th>Resonance (ppm)</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>lipid</td>
<td>0.5–1.5</td>
<td>slightly overlaps lactate peak at TE ≈ 35</td>
</tr>
<tr>
<td>lactate</td>
<td>1.3</td>
<td>a couplet peak. Not present in normal brain. End product of anaerobic glycolysis, a marker of hypoxia. Present in: ischemia, infection, demyelinating disease, inborn errors of metabolism… At higher TE (e.g. TE = 144), the peak inverts which can help distinguish it from the lipid peak</td>
</tr>
<tr>
<td>N-acetyl aspartate (NAA)</td>
<td>2</td>
<td>a neuronal marker. Normally the tallest peak (higher than Cr or Cho). ↓ in all focal and regional brain abnormalities (tumor, MS, epilepsy, Alzheimer’s disease, abscess, brain injury…)</td>
</tr>
<tr>
<td>creatine (Cr)</td>
<td>3</td>
<td>useful primarily as a reference for choline. Higher in grey matter than white matter</td>
</tr>
<tr>
<td>choline (Cho)</td>
<td>3.2</td>
<td>marker of membrane synthesis. ↑ in neoplasms and some rare conditions of increased cell growth &amp; in the developing brain. Stroke is low in choline</td>
</tr>
</tbody>
</table>

*Cr has another less important peak*
Illustrative patterns

Normal brain: See Fig. 13.1.

Tumor: See Fig. 13.1. ↓ NAA, ↑ lactate, ↑ lipid, ↑ choline (rule of thumb: with gliomas, the higher the choline, the higher the grade up to grade 3, thereafter necrosis reduces relative choline levels and the lipid peak may be utilized).

Stroke: ↑ lactate peak predominates. Choline is characteristically low.

Abscess\(^1^\): Reduced NAA, Cr & choline peaks, and “atypical peaks” (succinate, acetate...) from bacterial synthesis is pathognomonic for abscess (not always present). Lactate may be elevated.

Multiple sclerosis: Bland pattern. NAA slightly reduced. Lactate and lipid slightly elevated. Choline not elevated.

Possible uses of MRS
1. differentiating abscess from neoplasm
2. post-op enhancement vs. recurrence of tumor
3. distinguishing tumor from MS plaques: occasionally cannot be differentiated
4. in AIDS: may be able to help differentiate toxo from lymphoma from PML (PML: ↓ NAA, no significant increase in choline, lactate or lipid)
5. the promise of differentiating tumor infiltration from edema has not materialized
6. some utility in distinguishing tumor from radiation necrosis (p.1560)
7. large inositol peak may distinguish hemangiopericytoma from meningioma\(^1^8\)

Multi-voxel MRS

Color coded scan with selected overlay for NAA, choline... one at a time. May reduce risk of sampling error.

13.2.15 Diffusion tensor imaging (DTI) MRI and white matter tracts

AKA diffusion tensor tractography (DTT) MRI. An MRI technique that demonstrates white matter tracts by exploiting the difference in diffusion parallel to the nerve axons that comprise white matter tracts from diffusion perpendicular to their course.

Available only with specialized software for specific MRI scanners.

Contraindications are same as for MRI in general (p.230).

Probably most useful to permit planning surgical approaches that minimize disruption of critical white matter tracts during intraparenchymal brain surgery for deep lesions, especially when a lesion (e.g. tumor, AVM, cerebral hemorrhage...) may displace these tracts from their expected position.

The major divisions of white matter tracts demonstrable by DTT MRI are (Fig. 13.2):

- Projection fibers: tend to be oriented rostro-caudally
  - Corticospinal tract coalesces as corona radiata funnels into internal capsule and forms pyramidal tract

![Fig. 13.1 Proton MRS of (A) normal brain, and (B) high grade glioma](image)
• Commissural fibers: medio-laterally oriented, connecting the cerebral hemispheres
  ○ Corpus callosum
  ○ Anterior commissure
  ○ Posterior commissure
• Association fibers: connect regions within the same hemisphere
  ○ U-fibers: connect adjacent gyri
  ○ Long association fibers: connect more distant areas
    – Optic radiations: connect lateral geniculate bodies to visual cortex. Pass lateral to the body of the lateral ventricles.
    – Uncinate fasciculus: connects the anterior temporal lobe to the inferior frontal gyrus. Damage can cause language deficits.
    – Superior longitudinal fasciculus (SLF): connects regions of frontal lobe to temporal and occipital lobes. Injury can cause language deficits.
    – Arcuate fasciculus: part of SLF. Classic neuroanatomy teaching: connects the superior and middle frontal gyri (Broca’s area (motor speech)) to the superior temporal gyrus (Wernicke’s area (language comprehension)). DTI has suggested broader connections, including premotor cortex. Injury causes conduction aphasia
    – Inferior longitudinal fasciculus (ILF): connects temporal and occipital lobes at the level of the optic radiation. Injury can cause deficits in object recognition, visual agnosias, prosopagnosia (face blindness)
  – Cingulum: project from cingulate gyrus to the entorhinal cortex as part of the limbic system
The convention for color coding tracts on DTI images:\footnote{19}
• Blue: superior-inferior tracts
• Red: mediolateral (horizontal) tracts
• Green: anterior-posterior tracts

Owing to a number of technical considerations, DTI is somewhat more operator-dependent than conventional MRI.

For surgical planning, the goal is to keep the surgical trajectory roughly parallel (at <30°angle) to the long axis of the white matter tract that one is trying to preserve (unproven hypothesis\footnote{20}).

Surgical “corridors” have been described taking into consideration preservation of white matter tracts:
• Anterior corridor: parallel to association fibers, between the SLF and the cingulum
• Posterior corridor: enters at the parieto-occipital sulcus, passes adjacent to the optic radiations
• Lateral corridor

Fig. 13.2 White matter tracts (color conventions for DTI are not used in this anatomic diagram)
13.3 Angiography

See Endovascular Neurosurgery section (p. 1575).

13.4 Myelography

Contraindications:
1. anticoagulation
2. allergy to iodinated contrast: requires iodine allergy prep (p. 221). NB: risk of adverse reaction still persists
3. infection at the desired puncture site
4. extensive midline lumbar spinal fusion may preclude needle access to the subarachnoid space

Lumbar myelogram

Using iohexol (Omnipaque® 140 or 180) as shown in Table 12.4.

Cervical myelogram with water soluble contrast via LP

Use iohexol (Omnipaque® 300 or 240) as shown in Table 12.4. Insert spinal needle into lumbar subarachnoid space, tilt the head of the myelogram table down with the patient’s neck extended and then inject dye. If a complete cervical block is seen, have patient flex neck. If the block cannot be traversed, patient may need C1–2 puncture or MRI (first obtain a CT which may show dye above the block that cannot be appreciated on myelography alone).

Post myelographic CT

Increases sensitivity and specificity of myelography (p. 1031). In cases of complete block on myelogram, CT will often show dye distal to the apparent site of the block.

13.5 Radionuclide scanning

13.5.1 Three phase bone scan

Technetium-99 (99mTc) pertechnetate is a radioisotope that may be attached to various substrates for use in bone scanning. It may be used to label polyphosphate (rarely used today), diphosphonate (MDP), or phosphorous (HDP) (the most widely agent used currently). Accumulates in areas of osteoblastic activity.

With technetium 99m-HDP, images are obtained immediately after injection (flow phase), at 15 min (blood pooling) and in 4 hours (bone imaging). Cellulitis shows up as increased activity in the first 2 phases, and there is little or diffuse increased activity in the 3rd. Osteomyelitis causes increased uptake in all 3 phases.

Used in evaluation of acute osteomyelitis with sensitivity and specificity of $\approx 95\%$ each, and is usually positive within 2–3 days. False positives can occur in conditions involving increased bone turnover, e.g. fracture, septic arthritis, tumors. False negative can occur in cases with associated bone infarction.

Applications for bone scans include:
1. infection
   a) osteomyelitis of the spine – vertebral osteomyelitis (p. 355) – or skull
   b) discitis (p. 356)
2. tumor
   a) spine metastases (p. 818)
   b) primary bone tumors of the spine (p. 792)
   c) skull tumors (p. 775)
3. diseases involving abnormal bone metabolism
   a) Paget’s disease: of the skull or spine (p. 1120)
   b) hyperostosis frontalis interna (p. 780)
4. craniosynostosis (p. 252)
5. fractures: spine or skull
6. “low back problems” (p. 1032): to help identify some of the above conditions

13.5.2 Gallium scan

Nuclear medicine scan with 67Ga citrate which accumulates in areas of inflammation and some malignancies. Utility in neurosurgery for: sarcoidosis (p. 189), chronic vertebral osteomyelitis; see also comparison to bone scan (p. 355).
References

14 Electrodiagnostics

14.1 Electroencephalogram (EEG)

14.1.1 General information

The primary use of EEG is in the diagnosis and management of seizure disorders. Non-convulsive use of EEG is essentially limited to monitoring for burst suppression (see below) (e.g. induced barbiturate coma) or for differential diagnosis of diffuse encephalopathy, including:

1. differentiating psychogenic unresponsiveness from organic: a normal EEG indicates either psychiatric unresponsiveness or locked-in syndrome
2. non-convulsive status epilepticus (seizures): absence or complex partial status
3. subclinical focal abnormalities: e.g. PLEDs (see below), focal slowing...
4. specific patterns diagnostic for certain pathologies: e.g.:
   a) periodic lateralizing epileptiform discharges (PLEDs): may occur with any acute focal cerebral insult (e.g. herpes simplex encephalitis (HSE), abscess, tumor, embolic infarct): seen in 85% of cases of HSE (onset 2–5 d after presentation), if bilateral is ≈ diagnostic of HSE
   b) subacute sclerosing panencephalitis (SSPE) (pathognomonic pattern): periodic high voltage with 4–15 secs separation with accompanying body jerks, no change with painful stimulation (differential diagnosis includes PCP overdose)
   c) Creutzfeldt-Jakob disease (p.367): myoclonic jerks. EEG → bilateral sharp wave 1.5–2 per second (early → slowing; later → triphasic). May resemble PLEDs, but are reactive to painful stimulation (most PLEDs are not)
   d) triphasic waves: not really specific. May be seen in hepatic encephalopathy, post-anoxia, and hyponatremia
5. objective measure of severity of encephalopathy: usually used for anoxic encephalopathy (e.g. periodic spikes with seizures indicates <5% chance of normal neurologic outcome, with high mortality). Alpha coma, burst suppression, and electrocerebral silence are all poor prognosticators
6. differentiating hydranencephaly (p.288) from severe hydrocephalus
7. as a clinical confirmatory test in the determination of brain death (p.310)

14.1.2 Common EEG rhythms

Common EEG rhythms are shown in Table 14.1.

14.1.3 Burst suppression

Isoelectric intervals interrupted by bursts of 8–12 Hz electrical activity that diminish to 1–4 Hz prior to electrical silence. Often used as an endpoint for titrating neuroprotective drugs such as barbiturates, propofol...

14.2 Evoked potentials

14.2.1 General information

Evoked potentials are averaged EEG waveforms recorded following repetitive stimulation. The process of averaging nulls-out EEG activity that is not time-locked to the stimulus. Resultant waveforms contain peaks that are named N (negative – upward deflection) or P (positive – downward deflection) followed by the latency in milliseconds to the onset of the peak.

14.2.2 Sensory evoked potentials (SEP)

General information

May use electrical stimulation of peripheral nerves (somatosensory or (SSEP)), auditory clicks through earphones (auditory or AEP, AKA BAER (brainstem auditory evoked response)) or flashing lights through goggles (visual EP or VEP).

Evoked potentials are most commonly used by neurosurgeons for intraoperative monitoring purposes. SSEP (especially from median nerve stimulation) also has prognostic significance in cervical spondylotic myelopathy although use for this purpose is limited.

Typical waveforms

Abbreviations

Abbreviations used below: BAER = brain stem auditory evoked response; UE/LE SSEP = upper/lower extremity somatosensory evoked potential; PR VER = pattern reversal visual evoked response which requires patient cooperation and visual attention as opposed to flash VER which may even be done through closed eyelids. See also references.3,4

14.2.3 Intra-operative evoked potentials

General information

EPs may be used for intra-operative monitoring (e.g. monitoring hearing during resection of vestibular schwannomas, or monitoring SSEPs during some spine surgery), however, their delayed nature often makes them of limited usefulness in avoiding acute intra-operative injury. A 10% increased latency of

aM= mastoid ("i" is ipsilateral to stimulus, and “c” is contralateral)
a major EP peak, or a drop in amplitude of ≥ 50% is significant and should cause the surgeon to assess all variables (retractors, instruments, blood pressure...). Intra-operative SSEPs may also be used to localize primary sensory cortex in anesthetized patients (as opposed to using brain mapping techniques in awake patients) by looking for phase reversal potentials across the central sulcus.5,6

**Brainstem auditory evoked responses (BAER)**

AKA auditory brainstem response (ABR), AKA auditory evoked potential (AEP). Auditory clicks are delivered to the patient by earphones. Peaks (Table 14.4). Once used for assistance in diagnosing vestibular schwannomas, their use for intraoperative monitoring is limited and has been largely replaced by direct eighth cranial nerve monitoring which provides more rapid information for the surgeon.

**SSEP monitoring during spine surgery**

Paralytics actually improve SSEP recordings by reducing muscle artifact, but will abolish the visible twitch that confirms that the stimulus is being received. Typical stimulus sites: median, ulnar, and tibial nerves. Impulses ascend in the ipsilateral posterior column. UE SSEPs travel primarily in the dorsal columns, but LE SSEPs are carried mostly in the dorsolateral fasciculus (p. 72) which is supplied by the anterior spinal artery. Thus, UE and LE SSEPs are more sensitive to direct mechanical effects primarily on the posterior spinal cord (sensory) and may remain unchanged with some injuries to the anterior cord (motor), however, LE SSEPs can detect ischemic effects on the anterior cord by virtue of involvement of the anterior spinal artery.

In a personal series of 809 patients,7 17 had SSEP degradation, 14 of these (82%) responded to intra-op interventions (see below), and in 13 of these 14 (93%) there were no new deficits. In the 3 that did not respond, 2 had significant new neurologic deficits.

Transcranial motor evoked potentials (TCMEPs)

Anesthetic requirements: In addition to EP anesthetic requirements, neuromuscular blockade must be minimized to permit ≥2 out of 4 twitches.

AKA motor evoked potentials (MEP): transcranial electrical or magnetic stimulation of motor cortex and descending motor axons with recording of motor potentials from distal spinal cord or muscle groups. Using direct electrical stimulation is limited in awake patients by local pain. Due to the large potentials, the acquisition time is shorter and feedback to the surgeon is almost immediate. However, due to patient movement from the muscle contractions, continuous recording is usually not possible (except with monitoring the response over the spinal cord). Useful for surgery involving the spinal cord (cervical or thoracic), no utility for lumbar spine surgery. Seizures occur rarely, usually in patients with increased seizure risk and with high-rate stimulation frequency.

Contraindications to MEP:
1. history of epilepsy/seizures
2. past surgical skull defects
3. metal in head or neck
4. use special care with implanted electronic devices

Descending evoked potentials (DEP)

(Formerly referred to by the misleading term “neurogenic motor evoked potentials”). Rostral stimulation of the spinal cord with recording of a caudal neurogenic response from the spinal cord or peripheral nerve, or a myogenic response from a distal muscle. DEPs can be mediated primarily by sensory nerves and therefore do not represent true motor potentials. However, shown to be sensitive to spinal cord changes and may be useful when TCMEPs cannot be obtained.
14.2.4 Electrophysiologic monitoring criteria to trigger notification of surgeon

Any of the following:
1. SSEP:
   a) 50% decrease in peak signal amplitude from baseline
   b) increase in peak latency >10%
   c) complete loss of a waveform
2. TCMEP: sustained 50% decrease in signal amplitude
3. DEP: decrease in signal of >60%

Interventions for loss or degradation of monitoring signal during spine surgery

When compression is the culprit, the prognosis may be good. Vascular injuries generally do not fare as well.

Options/suggestions include (adapted/excerpted from the ‘Vitale checklist’):

1. verify that the change is real (check connections, equipment…)
2. place OR on alert status
   a) announce intraoperative pause and stop the case
   b) eliminate possible distractions (music, unnecessary conversations…)
   c) “muster the troops”: the attending anesthesiologist, senior neurologist or neurophysiologist and experienced nurse are called to the room. Consult a surgical colleague if necessary
3. anesthetic/metabolic considerations
   a) optimize mean arterial pressure (MAP usually >85 mm Hg preferred)
   b) check hematocrit for anemia (could contribute to cord ischemia)
   c) optimize blood pH (rule out acidemia) and pCO2
   d) normalize patient body temperature
   e) check anesthetic technical factors: assess extent of paralytics
   f) discuss possibility of “Stagnara wake up test” (see below) with attending anesthesiologist and scrub nurse
4. technical/neurophysiologic considerations
   a) rule-out 60 Hz. interference from other equipment (OR table, C-arm, microscope… anything with a plug)
   b) verify that stimulating electrodes recording leads are making good contact

14.3 NCS/EMG

14.3.1 General information

Electrodiagnostic studies of peripheral nerves consist of two parts:
1. conduction measurements: typically referred to as “NCV” (nerve conduction velocity) but technically should be called NCS (nerve conduction studies) since amplitude, latency and duration of motor & sensory nerves are also evaluated
2. electromyogram (EMG) AKA “needle exam” (see below)

14.3.2 Electromyography

General information

There are 3 phases of an EMG exam:

Phase 1 – insertional activity: the electric response of the muscle to mechanical irritation caused by small movements of the needle

Phase 2 – spontaneous activity: in muscle at rest

1. normal: silent with stationary needle once insertional activity has subsided
   a) after denervation (secondary to a nerve injury) or muscle injury:
      • positive sharp waves (PSW)
      • fibrillation potentials (AKA fibrillations or fibs): action potentials arising from single muscle fibers. Detectable on EMG; not visible to the naked eye, c.f. fasciculations (p.505). Earliest onset 7–10 days after denervation, sometimes not for 3–4 weeks. If the nerve recovers, it
may reinnervate the muscle, but with larger motor units resulting in longer duration and decreased numbers

b) myotonic discharges (“dive bomber” sound on speaker monitor)

c) complex repetitive discharge (CRD): ephaptic conduction of groups of adjacent muscle fibers. Occurs in neuropathic or myopathic disorders

d) fasciculation potentials: nonspecific, but typically associated with motor neuron disease (ALS) (p.183)

e) other less common spontaneous activity includes: myokymic, neuromyotonic and cramp discharges

Phase 3 – volitional activity: evaluated with minimal volitional effort and maximal effort

1. motor unit action potential (MUAP) analysis: includes evaluation of motor unit amplitude, duration, polyphasia and stability. Generally increase amplitude and duration suggest a disorder of the LMN, and reduction of amplitude and duration suggests a primary myopathic disorder

2. with minimal volitional effort. Two possible abnormal findings
   a) reduced recruitment (or fast firing) is always indicative of a neuropathic process
   b) early or increased recruitment: indicative of a myopathic process

3. with maximal effort

Definitions

SNAP: sensory nerve action potential. Key concept: since the ganglion of the sensory nerves lies within the neural foramen, preganglionic lesions (injury to the nerve root proximal to the neural foramen, e.g. root compression by herniated disc or root avulsion) does not affect the cell body, and therefore the distal SNAP is unaffected. Postganglionic lesions (distal to the neural foramen, e.g. peripheral nerve injury) reduces SNAP amplitudes and/or slows the sensory conduction velocity.

F-wave: stimulation of a nerve causes orthodromic and antidromic conduction. Some anterior horn cells that are stimulated antidromically will fire orthodromically producing the F-wave. F-wave latency may be prolonged in multilevel radiculopathy (not sensitive). Most helpful in evaluating proximal root slowing, e.g. GBS (p.184).

H-reflex: practical only in S1 nerve root, similar information to the ankle jerk. Stimulation of la afferent fibers passes through a monosynaptic connection causing an orthodromic alpha-motor action potential that can be measured in the triceps surae.

Volitional activity: the motor unit action potential (MUAP) can be assessed only with voluntary muscle contraction by the patient. Components of the MUAP measured include: amplitude, rise time, duration, and number of phases (crossings of the baseline).

Polyphasic potentials: MUAPs with > 4 phases. Normally comprise < 15% of MUAPs. Following a nerve injury, abnormally increased polyphasic potentials can be seen 6–8 weeks after reinnervation begins, gradually increase over several months, and then begin to wane (as firing becomes more synchronous).

Myotonia: there are a number of myotonic conditions, including myotonic dystrophy in which there is sustained contraction of the muscle. Classic EMG finding: “dive bomber” sound due to myotonic discharges.

EMG for radiculopathy

EMG pearls for the neurosurgeon

General principles:

- EMG – if a reliable motor exam can be done, the EMG will not likely add any information. A normal motor exam will usually be associated with a normal EMG
- EMG is not extremely sensitive for radiculopathy (e.g. irritative radiculopathy might not be picked up), this is more likely in the cervical region than lumbar. However, when abnormal, EMG is very specific
- EMG is best reserved for cases with documented weakness where additional localizing/prognostic information is needed, or when the patient’s strength cannot be reliably assessed (inability to cooperate, functional overlay…)
- Timing
  - It takes about 3 weeks after onset of radiculopathy for the EMG to reliably show any findings
  - “Acute changes” begin at about 3 weeks and can last up to about 6 months
  - Chronic changes can be seen starting at about 6 months, and may persist indefinitely
Cervical EMG:
- EMG is most helpful for nerve roots C5-T1. There are no good muscles to reliably test C3-4, and compression here may cause findings in lower nerve roots.

Lumbar EMG:
- If lumbar MRI is normal in a patient with evidence of motor weakness (e.g. foot drop), do an EMG to look for peripheral neuropathy (again, a good motor exam can give the same info). If the EMG is negative for peripheral neuropathy (e.g. peroneal nerve palsy) then do an MRI (or CT) of abdomen and pelvis to look for pelvic floor tumor.

Findings
Include spontaneous activity (fibs & PSWs, see above).
The earliest possible finding (within 2–3 d) is reduced recruitment with volitional activity, but this occurs only with significant compression of motor fibers.
EMG is useful if there is a concern about possible overlapping peripheral neuropathy (e.g. carpal tunnel syndrome vs. C6 radiculopathy).

EMG criteria for radiculopathy
1. fibrillations and/or positive sharp waves in at least 2 muscles innervated by a single nerve root in question, but by 2 different peripheral nerves
2. abnormal paraspinals: this supports the diagnosis, but is not required since paraspinals will be normal in ~50%

Lumbar radiculopathy from herniated disc
With radiculopathy, SNAP is usually normal (see above). Paraspinal muscle fibrillations may occur. Accuracy in predicting level of involvement is ~84%.
Foot drop: the short head of the biceps femoris in the LE is the first muscle innervated by the peroneal division of the sciatic nerve at or just above the popliteal fossa just after the nerve splits off from the sciatic nerve. In cases e.g. of foot drop it is a good muscle to test to determine if there is a peroneal neuropathy vs. a more proximal lesion (i.e. above the popliteal fossa).
Findings with healing radiculopathy (e.g. following discectomy or spontaneous healing):
- motor potentials return first (if nerve injury were “complete”, it would take a month to return)
- if lost, sensory potentials return last or may not return
- following laminectomy, paraspinal potentials may no longer be useful for EMG because cutting the muscles during surgery alters their electrical signals resulting in effective denervation due to muscle injury. Fibs and PSWs decrease in amplitude over time but may remain present indefinitely

EMG in plexopathy
Reduction of SNAP with no paraspinal muscle fibrillations (the dorsal rami exit proximally to innervate the paraspinals, and are involved ~ only with root lesions).

EMG in nerve root avulsion
Produces muscles weakness and sensory loss with normal SNAP since the lesion is proximal to the dorsal root ganglion (where the cell bodies for the sensory nerves are located).

Developmental Anomalies

15 Primary Intracranial Anomalies 248

16 Primary Spinal Anomalies 265

17 Primary Craniospinal Anomalies 277
15 Primary Intracranial Anomalies

15.1 Arachnoid cysts, intracranial

15.1.1 General information

Key concepts

- a congenital abnormality, most common in middle fossa, cerebellopontine angle (CPA), suprasellar region, and posterior fossa
- most are asymptomatic (i.e. an incidental finding) except in the suprasellar region
- imaging often shows remodeling of bone; imaging characteristics exactly mimic CSF on CT or MRI in most cases
- recommendation for incidentally discovered arachnoid cyst in adults: a single follow-up imaging study in 6–8 months is usually adequate to rule-out any increase in size. Subsequent studies only if concerning symptoms develop

AKA leptomeningeal cysts, distinct from posttraumatic leptomeningeal cysts (AKA growing skull fractures) (p.915), and unrelated to infection. Arachnoid cysts (AC) are congenital lesions that arise during development from splitting of arachnoid membrane (thus they are technically intra-arachnoid cysts) and contain fluid that is usually identical to CSF. They do not communicate with the ventricles or subarachnoid space. May be uniloculated or may have septations. Typically lined with meningotheial cells positive for epithelial membrane antigen (EMA) and negative for carcinoembryonic antigen (CEA). AC may also occur in the spinal canal.

“Temporol lobe agenesis syndrome” is a label that had been used to describe the findings with middle cranial fossa ACs. This term is now obsolete since brain volumes on each side are actually the same, bone expansion and shift of brain matter account for the parenchyma that appears to be replaced by the AC.

Two types of histological findings:
1. “simple arachnoid cysts”: arachnoid lining with cells that appear to be capable of active CSF secretion. Middle fossa cysts seem to be exclusively of this type
2. cysts with more complex lining which may also contain neuroglia, ependyma, and other tissue types

15.1.2 Epidemiology of intracranial arachnoid cysts

Incidence: 5 per 1000 in autopsy series. Comprise ≈1% of intracranial masses.

Male:female ratio is 4:1. More common on the left side.

Bilateral arachnoid cysts may occur in Hurler syndrome (a mucopolysaccharidosis).

15.1.3 Distribution

Almost all occur in relation to an arachnoid cistern (exception: intrasellar, the only one that is extradural, Table 15.1).

Epidermoid cysts in the cerebellopontine angle (CPA) may mimic an arachnoid cyst, but are high signal on DWI MRI.

See also differential diagnosis of midline posterior fossa arachnoid cysts (p.256).

15.1.4 Presentation

Most ACs are asymptomatic. Those that become symptomatic usually do so in early childhood. The presentation varies with location of the cyst, and oftentimes appear mild considering the large size of some.

Typical presentations are shown in Table 15.2 and include:
1. symptoms of intracranial hypertension (elevated ICP): H/A, N/V, lethargy
2. seizures
3. sudden deterioration:

15.1.5 Evaluation

General information

Routine evaluation with CT or MRI is usually satisfactory. Further evaluation with CSF contrast or flow studies (cisternograms, ventriculograms...) are only occasionally necessary for the diagnosis of midline suprasellar and posterior fossa lesions; for Differential diagnosis, see Intracranial cysts (p. 1374); see Fig. 15.1 for the classification scheme of Galassi et al for middle fossa cysts.

CT scan

Smooth bordered non-calcified extraparenchymal cystic mass with density similar to CSF and no enhancement with IV contrast. Expansion of nearby bone by remodelling is usually seen, confirming their chronic nature. Often associated with ventriculomegaly (in 64% of supratentorial and 80% of infratentorial cysts).

Convexity or middle fossa cysts exert mass effect on adjacent brain and may compress ipsilateral lateral ventricle and cause midline shift. Suprasellar, quadrigeminal plate, and midline posterior-fossa cysts may compress the third and fourth ventricle and cause hydrocephalus by obstructing the foramina of Monro or the Sylvian aqueduct.
MRI
Better than CT in differentiating the CSF contained in arachnoid cysts from the fluid of neoplastic cysts. May also show cyst walls.

Cisternograms and/or ventriculograms
Using either iodinated contrast or radionuclide tracers. Variable rate of opacification has resulted in difficulty correlating results with operative findings. Some cysts are actually diverticula, and may fill with radiotracer or contrast.

15.1.6 Treatment

General information
Many (but not all) authors recommend not treating arachnoid cysts that do not cause mass effect or symptoms, regardless of their size and location. For incidentally discovered arachnoid cyst in an adult not considered for surgery: a single follow-up imaging study in 6–8 months is usually adequate to rule-out any changes (since they may grow in size). Subsequent studies may be done if concerning symptoms develop. Pediatric patients may need to be followed until adulthood.

Treatment considerations for cysts (excluding suprasellar cysts)
Surgical treatment options are summarized in Table 15.3.

Cyst shunting
Probably the best overall treatment. For shunting into peritoneum, use a low pressure valve. If there is concurrent ventriculomegaly, one may simultaneously place a ventricular shunt (e.g. through a “Y” connector). Ultrasound, ventriculoscope, or image guidance may assist in locating suprasellar cysts. Shunting of middle fossa ACs may also be accomplished through the lateral ventricle, thus shunting both compartments.9

NB: in running the distal shunt tubing from the middle fossa, it should be routed behind the ear (do not tunnel in front of ear to avoid injury to facial nerve – if this anterior route is unavoidable, it may help to solicit the services of a plastic surgeon to help avoid the facial nerve).

Treatment of Suprasellar cysts
These cysts present with some unique treatments options which include:
- transcallosal cystectomy10
percutaneous ventriculo-cystostomy: procedure of choice of Pierre-Kahn et al.\textsuperscript{5} Performed via a paramedian coronal burr hole through the lateral ventricle and foramen of Monro (may be facilitated by using a ventriculoscope\textsuperscript{8})

subfrontal approach (for fenestration or removal): dangerous and ineffective\textsuperscript{5}

ventricular drainage is ineffective (actually promotes cyst enlargement) and should not be routinely considered

15.1.7 Outcome
Even following successful treatment a portion of the cyst may remain due to the remodeling of the bone and chronic shift of brain contents. Hydrocephalus may develop following treatment. Endocrinopathies tend to persist even after successful treatment of suprasellar cysts.

15.2 Craniofacial development
15.2.1 Normal development

Fontanelles
Anterior fontanelle: the largest fontanelle. Diamond shaped, 4 cm (AP) × 2.5 cm (transverse) at birth. Normally closes by age 2.5 yrs.

Sphenoid and mastoid fontanelles: small, irregular. Normally, former closes by age 2–3 mos, latter by age 1 yr.

Cranial vault
Growth: largely determined by growth of brain. 90% of adult head size is achieved by age 1 yr; 95% by age 6 yrs. Growth essentially ceases at age 7 yrs. By end of 2nd yr, bones have interlocked at sutures and further growth occurs by accretion and absorption.

Skull is unilaminar at birth. Dípl•œ appear by 4th yr and reach a maximum by age 35 yrs (when diploic veins form).

Mastoid process: formation commences by age 2 yrs, air cell formation occurs during 6th yr.
15.2.2 Craniosynostosis

General

Originally called craniostenosis. Incidence: $\approx 0.6/1000$ live births.

Primarily a prenatal deformity, postnatal craniosynostosis (CSO) occurs uncommonly (postnatal causes consist primarily of positional alterations which may not represent true synostosis). CSO is rarely associated with hydrocephalus (HCP). The assertion that CSO may follow CSF shunting for HCP is unproven. Other causes for failure of normal skull growth include lack of brain growth due to any of the causes of arrested development of the cerebral hemispheres (lissencephaly, micropolygyria, some cases of hydranencephaly...).

Treatment is usually surgical. In most instances, the indication for surgery is for cosmesis and to prevent the severe psychological effects of having a disfiguring deformity. However, with multiple CSO, brain growth may be impeded by the unyielding skull. Also, ICP may be pathologically elevated, and although this is more common in multiple CSO, elevated ICP occurs in $\approx 11\%$ of cases with a single stenotic suture. Coronal synostosis can cause amblyopia. Most cases of single suture involvement can be treated with linear excision of the suture. Involvement of multiple sutures or the skull base usually requires the combined efforts of a neurosurgeon and craniofacial surgeon, and may need to be staged in some cases. Risks of surgery include: blood loss, seizures, stroke.

Diagnosis

Many cases of “synostosis” are really due to positional flattening (e.g. “lazy lambdoid”, see below). If this is suspected, instruct parents to keep head off of flattened area and recheck patient in 6–8 weeks: if it was positional, it should be improved, if it was CSO then it usually declares itself. The diagnosis of CSO may be aided by:

1. palpation of a bony prominence over the suspected synostotic suture (exception: lambdoidal synostosis, see below)
2. gentle firm pressure with the thumbs fails to cause relative movement of the bones on either side of the suture
3. plain skull x-rays:
   a) lack of normal lucency in center of suture. Some cases with normal x-ray appearance of the suture (even on CT) may be due to focal bony spicule formation
   b) beaten copper calvaria (p.254), sutural diastasis and erosion of the sella may be seen in cases of increased ICP
4. CT scan:
   a) helps demonstrate cranial contour
   b) may show thickening and/or ridging at the site of synostosis
   c) will demonstrate hydrocephalus if present
   d) may show expansion of the frontal subarachnoid space
   e) three-dimensional CT may help better visualize abnormalities
5. in questionable cases, a technetium bone scan can be performed:
   a) there is little isotope uptake by any of the cranial sutures in the first weeks of life
   b) in prematurely closing sutures, increased activity compared to the other (normal) sutures will be demonstrated
   c) in completely closed sutures, no uptake will be demonstrated
6. MRI: usually reserved for cases with associated intracranial abnormalities. Often not as helpful as CT
7. measurements, such as occipito-frontal-circumference may not be abnormal even in the face of a deformed skull shape

Increased ICP

Evidence of increased ICP in the newborn with craniosynostosis include:

1. radiographic signs (on plain skull x-ray or CT, see above)
2. failure of calvarial growth (unlike the non-synostotic skull where increased ICP causes macrocra-nia in the newborn, here it is the synostosis that causes the increased ICP and lack of skull growth)
3. papilledema
4. developmental delay
Types of craniosynostosis

Sagittal synostosis
General information
The most common CSO affecting a single suture; 80% male. Results in dolichocephaly or scaphocephaly (boat shaped skull) with frontal bossing, prominent occiput, palpable keel-like sagittal ridge. OFC remains close to normal, but the biparietal diameter is markedly reduced. As many as 44% of patients with nonsyndromic sagittal synostosis have elevated ICP.17

Surgical treatment
Skin incision may be longitudinal or transverse. A linear "strip" craniectomy is performed, excising the sagittal suture from the coronal to the lambdoid suture, preferably within the first 3–6 months of life. The width of the strip should be at least 3 cm, no proof exists that interposing artificial substances (e.g. silastic sheeting over the exposed edges of the parietal bone) retards the recurrence of synostosis. Great care is taken to avoid dural laceration with potential injury to the underlying superior sagittal sinus. The child is followed and reoperated if fusion recurs before 6 months age. After ≈ 1 yr age, more extensive cranial remodelling is usually required.

Coronal synostosis
General information
Accounts for 18% of CSO, more common in females. In Crouzon’s syndrome this is accompanied by abnormalities of sphenoid, orbital and facial bones (hypoplasia of midface), and in Apert’s syndrome is accompanied by syndactyly.18 Unilaterial coronal CSO → plagiocephaly with forehead on affected side flattened or concave above eye (normal side falsely appears to bulge abnormally), supra-orbital margin higher than normal side (on skull x-ray → harlequin eye sign). The orbit rotates out on the abnormal side, and can produce amblyopia. Without treatment, flattened cheeks develop and the nose deviates to the normal side (root of nose tends to rotate towards deformity).

Bilateral coronal CSO (usually in craniofacial dysmorphism with multiple suture CSO, e.g. Apert’s) → brachycephaly with broad, flattened forehead (acrocephaly). When combined with premature closure of frontosphenoidal and frontoethmoidal sutures, results in foreshortened anterior fossa with maxillary hypoplasia, shallow orbits, progressive proptosis.

Surgical treatment
Simple strip craniectomy of the involved suture has been used, often with excellent cosmetic result. However, some argument that this may not be adequate has been presented. Therefore, a more current recommendation is to do frontal craniotomy (uni- or bi-lateral) with lateral canthal advancement by taking off orbital bar.

Metopic synostosis
At birth, the frontal bone consists of two halves separated by the frontal or metopic suture. Abnormal closure results in a pointed forehead with a midline ridge (trigonocephaly). Many of these have a 19p chromosome abnormality and are retarded.

Lambdoid synostosis
Epidemiology
Long considered a clinical rarity with a reported incidence range 1–9% of CSO,19 recent reports suggest a higher incidence of 10–20%20 which may be due to an actual increased incidence, or simply to increased awareness or changing diagnostic criteria. More common in males (male:female = 4:1), and the right side is involved in 70% of cases. Usually presents between 3–18 months of age, but may be seen as early as 1–2 months of age.

Controversy exists regarding the actual criteria for this condition, and some authors differentiate between those cases which appear to have a primary abnormality of the lambdoid suture from those which may be due to positional flattening, the so-called “lazy lambdoid.” Others do not make this distinction, and sometimes refer to the condition as occipital plagiocéphaly to avoid the need to implicate abnormalities of the lambdoid suture.

Positional flattening (or molding) may be produced by:
1. decreased mobility: patients who constantly lie supine with the head to the same side, e.g. cerebral palsy, mental retardation, prematurity, chronic illness
2. abnormal postures: congenital torticollis,21 congenital disorders of the cervical spine
3. intentional positioning: trend since 1992 to place newborns in a supine sleeping position to reduce the risk of sudden infant death syndrome (SIDS), sometimes with a foam wedge to tilt the child to one side to reduce the risk of aspiration

4. intrauterine etiologies: intrauterine crowding (e.g. from multiparous births or large fetal size), uterine anomalies

Clinical findings
Flattening of the occiput. May be unilateral or bilateral. If unilateral, it is sometimes termed lambdoid plagiocephaly which when severe also produces bulging of the ipsilateral forehead resulting in a “rhomboid” skull with the ipsilateral ear located anterior and inferior to the contralateral ear. The contralateral orbit and forehead may also be flattened. This may be confused with hemifacial microsomia or with plagiocephaly seen in unilateral coronal craniosynostosis. Bilateral lambdoid synostosis produces brachycephaly with both ears displaced anteriorly and inferiorly. Unlike the palpable ridge of sagittal or coronal synostosis, an indentation may be palpated along the synostotic lambdoid suture (although a periosteal ridge may be found in some).

Diagnostic evaluation
The physical exam is the most important aspect of diagnosis. Skull x-ray may help differentiate (see below). If the skull x-ray is equivocal, prevent the infant from laying on the affected side for several weeks. A bone scan should be obtained if no improvement occurs (see below). In definite cases of synostosis, and for some cases of refractory positional flattening (which usually corrects with time, but may take up to 2 years) surgical treatment may be indicated.

Skull x-ray: Shows a sclerotic margin along one edge of the lambdoid suture in 70% of cases. Local “beaten copper cranium” (BCC) occasionally may be seen due to indentations in the bone from underlying gyri which may be due to locally increased ICP. BCC produces a characteristic mottled appearance of the bone with lucencies of varying depth having round and poorly marginated edges. BCC correlates with generalized ↑ ICP only when it is seen with sellar erosion and sutural diastasis.

CT scan: Bone windows may show eroded or thinned inner table in the occipital region in 15–20% of cases, >95% are on the side of the involvement. The suture may appear closed. Brain windows show parenchymal brain abnormalities in <2% heterotopias, hydrocephalus, agenesis of the corpus callosum; but ≤70% will have significant expansion of the frontal subarachnoid space (may be seen in synostosis of other sutures, see above).

Bone scan: Isotope uptake in the lambdoid suture increases during the first year, with a peak at 3 months of age (following the usual inactivity of the first weeks of life). The findings with synostosis are those typical for CSO (p.252).

Treatment
Early surgical treatment is indicated in cases with severe craniofacial disfigurement or those with evidence of increased ICP. Otherwise, children may be managed nonsurgically for 3–6 months. The majority of cases will remain static or will improve with time and simple nonsurgical intervention. Approximately 15% will continue to develop a significant cosmetic deformity.

Nonsurgical management:
Although improvement can usually be attained, some degree of permanent disfigurement is frequent.

Repositioning will be effective in ~85% of cases. Patients are placed on the unaffected side or on the abdomen. Infants with occipital flattening from torticollis should have aggressive physical therapy and resolution should be observed within 3–6 months.

More severe involvement may be treated with a trial of molding helmets (however, no controlled study has proven the efficacy).

Surgical treatment:
Required in only ~20% of cases. The ideal age for surgery is between 6 and 18 months. The patient is positioned prone on a well-padded cerebellar headrest (the face should be lifted and gently massaged every ≈30 minutes by the anesthesiologist to prevent pressure injuries).

Surgical options range from simple unilateral craniectomy of the suture to elaborate reconstruction by a craniofacial team.

Linear craniectomy extends from the sagittal suture to the asterion is often adequate for patients ≤12 weeks of age without severe disfigurement. Great care is taken to avoid dural laceration near the asterion which is in the region of the transverse sinus. The excised suture demonstrates an internal ridge. Better results are obtained with earlier surgery, more radical surgery may be necessary after the age of 6 months.

Average blood loss for uncomplicated cases is 100–200 ml and therefore transfusion is often required.
Multiple synostoses
Fusion of many or all cranial sutures → oxycephaly (tower skull with undeveloped sinuses and shallow orbits). These patients have elevated ICP.

Craniofacial dysmorphic syndromes
Over 50 syndromes have been described, Table 15.4, shows a few selected ones.
A number of craniosynostosis syndromes are due to mutations in the FGFR (fibroblast growth factor receptor) genes. FGFR gene-related craniosynostosis syndromes include some classic syndromes (Apert, Crouzon, Pfeiffer…) as well as several newer entities (Beare-Stevenson, Muenke, Jackson-Weiss syndromes). All exhibit autosomal dominant inheritance.

15.2.3 Encephalocele
General information
Cranium bifidum is a defect in the fusion of the cranial bone, it occurs in the midline, and is most common in the occipital region. If meninges and CSF herniate through the defect, it is called a meningocele. If meninges and cerebral tissue protrude, it is called an encephalocele.

Encephalocele AKA cephalocele is an extension of intracranial structures outside of the normal confines of the skull. One case was seen for every five cases of spinal myelomeningoceles. A nasal polypoid mass in a newborn should be considered an encephalocele until proven otherwise. See also Differential diagnosis (p.1388).

Classification
System based on Suwanwela and Suwanwela:
1. occipital: often involves vascular structures
2. cranial vault: comprises ≥ 80% of encephaloceles in Western hemisphere
   a) interfrontal
   b) anterior fontanelle
   c) interparietal: often involves vascular structures
   d) temporal
   e) posterior fontanelle
3. fronto-ethmoidal: AKA sincipital; 15% of encephaloceles; external opening into face in one of the following 3 regions:
   a) nasofrontal: external defect in the nasion
   b) naso-ethmoidal: defect between nasal bone and nasal cartilage
   c) naso-orbital: defect in the antero-inferior portion of medial orbital wall
4. basal: 1.5% of encephaloceles; (see below)
   a) transethmoidal: protrudes into nasal cavity through defect in cribriform plate
   b) sphenoid-ethmoidal: protrudes into posterior nasal cavity

c) transsphenoidal: protrudes into sphenoid sinus or nasopharynx through patent cranioopharyngeal canal (foramen cecum)
d) fronto-sphenoidal or sphenoorbital: protrudes into orbit through superior orbital fissure

5. posterior fossa: usually contains cerebellar tissue and ventricular component

Basal encephalocele

The only group that does not produce a visible soft tissue mass. May present as CSF leak or recurrent meningitis. May be associated with other craniofacial deformities, including: cleft lip, bifid nose, optic-nerve dysplasia, coloboma and microphthalmia, hypothalamic-pituitary dysfunction.

Iniencephaly is characterized by defects around the foramen magnum, rachischisis and retrocollis. Most are stillborn, some survive up to age 17.

Etiology

Two main theories:
1. arrested closure of normal confining tissue allows herniation through persistent defect
2. early outgrowth of neural tissue prevents normal closure of cranial coverings

Treatment

Occipital encephalocele

Surgical excision of the sac and its contents with water-tight dural closure. It must be kept in mind that vascular structures are often included in the sac. Hydrocephalus is often present and may need to be treated separately.

Basal encephalocele

Caution: a transnasal approach to a basal encephalocele (even for biopsy alone) may be fraught with intracranial hemorrhage, meningitis, or persistent CSF leak. Usually a combined intracranial approach (with amputation of the extracranial mass) and transnasal approach is used.

Outcome

Occipital encephalocele

The prognosis is better in occipital meningocele than in encephalocele. The prognosis is worse if a significant amount cerebral tissue is present in the sac, if the ventricles extend into the sac, or if there is hydrocephalus. Less than \( \approx 5\% \) of infants with encephalocele develop normally.

15.3 Dandy Walker malformation

15.3.1 General information

Definition: an enlarged posterior fossa with complete or partial agenesis of the cerebellar vermis and cystic dilatation of the fourth ventricle which is distorted and encased in a membrane. The anomaly was first described by Dandy & Blackfan in 1914, and was named Dandy Walker malformation forty years later by Benda to acknowledge Taggart and Walker’s contributions in 1942.

15.3.2 Differential diagnosis

Disorders with posterior fossa CSF collections include:
1. Dandy Walker malformation (DWM)
2. Dandy Walker variant (DWV): vermian hypoplasia and cystic dilatation of the fourth ventricle, without enlargement of the posterior fossa
3. persistent Blake’s pouch cyst (BPC): tetraventricular hydrocephalus, communicating 4th ventricle and posterior fossa cyst, with or without hypoplasia of both the cerebellar vermis and the medial aspects of the cerebellar hemispheres
4. retrocerebellar arachnoid cyst: anteriorly displaces the 4th ventricle and cerebellum, which can produce significant mass effect
5. Joubert’s syndrome: absence or underdevelopment of the cerebellar vermis
6. mega cisterna magna: enlarged posterior fossa secondary to an enlarged cisterna magna with a normal vermis and fourth ventricle)
Differentiating features: DWM and DWV are difficult to distinguish, and may represent a continuum of developmental anomalies that are grouped together as Dandy Walker complex.\^32

Retrocerebellar arachnoid cysts and BPCs may mimic DWM, but these do not have vermian agenesis and the cyst does not open into the 4th ventricle. The position of the choroid plexus of the fourth ventricle is normal in arachnoid cysts, absent in Dandy Walker malformations, and displaced into the superior cyst wall in BPC. An intrathecal enhanced CT scan (performed after instilling iodinated contrast into a ventricular catheter) would identify a mega cisterna magna which communicates with the ventricles, while DWM and most but not all arachnoid cysts do not.

### 15.3.3 Pathophysiology

The etiology of DWM is unknown. Multiple unsatisfactory theories have been abandoned. DWM is likely due to dysembryogenesis, secondary to insults of varying severity to the cerebellum and 4th ventricle. This results in agenesis of the cerebellar vermis with a large posterior fossa cyst communicating with an enlarged 4th ventricle.\^32,30

Hydrocephalus occurs in 70–90% of cases, and Dandy Walker malformation is present in 2–4% of all cases of hydrocephalus.

### 15.3.4 Risk factors and epidemiology

Gestational exposure to rubella, CMV, toxoplasmosis, warfarin, alcohol, and isotretinoin are thought to be predisposing factors. Autosomal recessive inheritance has been identified in a few cases, but a genetic basis is lacking in most. Incidence: 1 per 25,000–35,000 live births.\^30 Male:female=1:3.

### 15.3.5 Associated abnormalities

CNS abnormalities include agenesis of the corpus callosum in 17%\(^{33}\) and occipital encephalocele in 7%. Other findings include heterotopias, spina bifida, syringomyelia, microcephaly, dermoid cysts, porencephaly, and Klippel-Feil deformity. Most have an enlarged posterior fossa with elevation of the torcular herophili. Atresia of the foramina of Magendie and Luschka may occur.\(^{34}\)

Systemic abnormalities include\(^{35}\): facial abnormalities (e.g. angiomias, cleft palates, macroglossia, facial dysmorphia), ocular abnormalities (e.g. coloboma, retinal dysgenesis, microphthalmia), and cardiovascular anomalies (e.g. septal defects, patent ductus arteriosus, aortic coarctation, dextrocardia). Note: be aware of the possibility of a cardiac abnormality when considering surgery on these patients.

### 15.3.6 Treatment

Early decompression of ventriculomegaly is recommended to achieve maximum cognitive development. In the absence of hydrocephalus, DWM may be followed. When treatment is necessary, the posterior fossa cyst must be shunted. Shunting the lateral ventricles alone is contraindicated because of the risk of upward herniation.\(^{35}\) However, it is important to confirm patency of the cerebral aqueduct, otherwise the supratentorial ventricles need to be shunted concomitantly. Varying reports exist regarding rates of associated aqueductal stenosis, although it is widely believed to be rare.

Another option once used commonly is excision of the obstructing membrane. This has fallen out of favor due to its associated risks of morbidity and mortality. However, it remains an option for patients with frequent shunt malfunctions.

Newer treatments include endoscopic third ventriculostomy in cases where the aqueduct is patent, however further study is necessary.\(^{36,37}\)

### 15.3.7 Prognosis

Prognosis ranges widely as there are various levels of severity of the malformation. Some pediatric neurosurgical literature quotes 12–50% mortality rates, although this is improving with modern shunting techniques. Only 50% have normal IQ. Ataxia, spasticity, and poor fine motor control are common. Seizures occur in 15%.
15.4 Aqueductal stenosis

15.4.1 General information
Aqueductal stenosis (AqS) produces what is sometimes called triventricular hydrocephalus, characterized by a normal sized 4th ventricle and enlarged third and lateral ventricles on MRI or CT. Most cases occur in children, however some present for the first time in adulthood.

15.4.2 Etiologies
1. a congenital malformation: may be associated with Chiari malformation or neurofibromatosis
2. acquired
   a) due to inflammation (following hemorrhage or infection, e.g. syphilis, T.B.)
   b) neoplasm: especially brainstem astrocytomas— including tectal gliomas (p. 634), lipomas
   c) quadrigeminal plate arachnoid cysts

15.4.3 Aqueductal stenosis in infancy
AqS is a frequent cause of congenital hydrocephalus (HCP) (up to 70% of cases\textsuperscript{27}), but occasionally may be the result of HCP. Patients with congenital AqS usually have HCP at birth or develop it within \( \approx 2–3 \) mos. Congenital AqS may be due to an X-linked recessive gene.\textsuperscript{28} Four types of congenital AqS described by Russell (summarized\textsuperscript{38}):  
1. forking: multiple channels (often narrowed) with normal epithelial lining that do not meet, separated by normal nervous tissue. Usually associated with other congenital abnormalities (spina bifida, myelomeningocele)
2. periaqueductal gliosis: luminal narrowing due to subependymal astrocytic proliferation
3. true stenosis: aqueduct histologically normal
4. septum

15.4.4 Aqueductal stenosis in adulthood

General information
AqS may be an overlooked cause of “normal pressure hydrocephalus” in the adult.\textsuperscript{39} It is unknown why some cases of AqS would remain occult, and manifest only in adulthood. In one series of 55 cases,\textsuperscript{40} 35% had duration of symptoms <1 year, 47% for 1–5 years; the longest was 40 yrs. Although most follow this longstanding benign course, there are reports of elevated ICP and sudden death.

Symptoms
See Table 15.5. Headache was the most common symptom, and had characteristics of H/A associated with elevated ICP. Visual changes were next, and usually consisted of blurring or loss of acuity. Endocrine changes included menstrual irregularities, hypothyroidism, and hirsutism.

Signs
Papilledema was the most common finding (53%). Visual fields were normal in 78% the remainder having reduced peripheral vision, increased blind spots, quadrantic or hemianopic field cuts, or scotomata. Intellectual impairment was present in at least 36% Other signs included: ataxia (29%), “pyramidal tract signs” in 44% (mild hemi- or para-paresis (22%), spasticity (22%), or Babinski’s (20%), anosmia (9%).

Evaluation
MRI is the test of choice. MRI will show the absence of the normal flow void in the Sylvian aqueduct. Contrast should be given to rule-out tumor.

Treatment (of non-tumoral AqS)
Although treatments of the primary lesion have been attempted (e.g. lysis of aqueductal septum), this has fallen into disfavor with the improved efficacy of CSF shunting and endoscopic third ventriculostomy (ETV).
1. shunting: CSF is usually shunted to the peritoneum or the vascular system, however shunting to subarachnoid space is also feasible (once obstruction at the level of the arachnoid granulations has been ruled out)

2. a Torkildsen shunt (shunting a lateral ventricle to the cisterna magna) may work in adult cases, however pediatric patients with obstructive hydrocephalus may not have an adequately developed subarachnoid space for this to function properly

3. endoscopic third ventriculostomy (p.415)

Follow-up of at least two years to rule out tumor is recommended.

### 15.5 Agenesis of the corpus callosum

#### 15.5.1 General information

A failure of commissuration occurring $\approx 2$ weeks after conception. Results in expansion of the third ventricle and separation of the lateral ventricles (which develop dilated occipital horns and atria, and concave medial borders).

The corpus callosum (CC) forms from rostrum (genu) to splenium, in agenesis there may be an anterior portion with absence of the posterior segment (the converse occurs infrequently). Absence of the anterior CC with presence of some posterior CC is indicative of some form of holoprosencephaly.

#### 15.5.2 Incidence

1 in 2,000–3,000 neuroradiological examinations.

#### 15.5.3 Associated neuropathologic findings

See reference.  
- porencephaly

Table 15.5 Symptoms of aqueductal stenosis presenting in adulthood (55 patients $> 16$ years age$^{40}$)
- microgyria
- interhemispheric lipomas and lipomas of the corpus callosum (p.260)
- arhinencephaly
- optic atrophy
- colobomas
- hypoplasia of the limbic system
- bundles of Probst: aborted beginnings of corpus callosum, bulge into lateral ventricles
- loss of horizontal orientation of cingulate gyrus
- schizencephaly (p.288)
- anterior and hippocampal commissures may be totally or partially absent
- hydrocephalus
- cysts in the region of the corpus callosum
- spina bifida with or without myelomeningocele
- absence of the septum pellucidum (p.260)

15.5.4 Possible presentation
- hydrocephalus
- microcephaly
- seizures (rare)
- precocious puberty
- disconnection syndrome: more likely with acquired CC defect than in congenital

May be an incidental finding, and by itself may have no clinical significance. However, may be occur as part of a more complex clinical syndrome or chromosomal abnormality (e.g. Aicardi syndrome: agenesis of CC, seizures, retardation, patches of retinal pigmentation).

15.6 Absence of the septum pellucidum

Etiologies
1. holoprosencephaly (p.289)
2. schizencephaly (p.288)
3. agenesis of the corpus callosum (p.259)
4. Chiari type 2 malformation (p.284)
5. basal encephalocele
6. porencephaly/hydranencephaly
7. may occur in severe hydrocephalus: thought to be due to necrosis with resorption of the septum
8. septo-optic dysplasia: see below

Septo-optic dysplasia

AKA de Morsier syndrome. Incomplete early morphogenesis of anterior midline structures produces hypoplasia of the optic nerves and possibly optic chiasm (affected patients are blind) and pituitary infundibulum. The septum pellucidum is absent in about half the cases. About half the cases also have schizencephaly (p.288).

Presentation may be due to secondary hypopituitarism manifesting as dwarfism, isolated growth hormone deficiency, or panhypopituitarism. Occasionally hypersecretion of growth hormone, corticotropin or prolactin may occur, and precocious puberty may occur. Most patients are of normal intelligence although retardation may occur. Septo-optic dysplasia may be a less severe form of holoprosencephaly (p.289), and occasionally may occur as part of this anomaly (with its attendant poorer prognosis for function or survival). The ventricles may be normal or dilated. May be seen by the neurosurgeon because of concerns of possible hydrocephalus.

15.7 Intracranial lipomas

15.7.1 General information

Intracranial and intraspinal lipomas are felt to be of maldevelopmental origin (p.706) and may arise from failure of involution of the primitive meninges.
15.7.2 Epidemiology of intracranial lipomas

Incidence: 8 in 10,000 autopsies. Usually found in or near the midsagittal plane, particularly over the corpus callosum; lipomas in this region are frequently associated with agenesis of the corpus callosum (p. 259). The tuber cinereum and quadrigeminal plate are less frequently affected. Rarely, the CP angle or cerebellar vermis may be involved. May occur in isolation, but also has been described in association with a number of congenital anomalies, including: trisomy 21, Pallister-Hall syndrome, frontal encephalocele, facial anomalies, etc. Other midline abnormalities may also be found: agenesis of the corpus callosum, myelomeningocele, and spina bifida.

15.7.3 Evaluation

May be diagnosed by CT, MRI (study of choice), and by ultrasound in infants.

CT: Low density, may have peripheral calcification (difficult to appreciate on MRI). Differential diagnosis on CT: primarily between dermoid cyst, teratoma, and germinoma.

MRI: Characteristic finding is a midline lesion with signal characteristics of fat (high intensity on T1WI, low intensity on T2WI).

15.7.4 Presentation

Often discovered incidentally. Large lipomas may be associated with seizures, hypothalamic dysfunction, or hydrocephalus (possibly from compression of the aqueduct). Associated findings that may or may not be directly related: mental retardation, behavioral disorders and headache.

15.7.5 Treatment

Direct surgical approach is seldom necessary for intracranial lipomas. Shunting may be required for cases where hydrocephalus results from obstruction of CSF circulation.

15.8 Hypothalamic hamartomas

15.8.1 General information

**Key concepts**

- rare, non-neoplastic congenital malformation, usually occurs in tuber cinereum
- may be parahypothalamic (pedunculated) or intrahypothalamic (sessile)
- presentation: precocious puberty, seizures (usually starting with gelastic seizures (brief unprovoked laughter)), developmental delay
- treatment: GnRH analogs for precocious puberty. Latero-basal craniotomy for pedunculated lesions, transcallosal interforniceal approach for intrahypothalamic lesions, option of endoscopic approach for lesions ≤1.5 cm dia, stereotactic radiosurgery may be an alternative

Hypothalamic hamartomas (HH; hamartoma: an abnormal conglomeration of cells normally found in the same area) AKA diencephalic hamartomas or hamartomas of the tuber cinereum. Rare, non-neoplastic congenital malformations arising from inferior hypothalamus or tuber cinereum (floor of the third ventricle between the infundibular stalk and the mammillary bodies). May occur as part of Pallister-Hall syndrome (genetics: AD inherited defect in GL13 gene resulting in abnormally short GL13 protein which participates in normal shaping of many organs).

15.8.2 Clinical findings

1. specific types of seizures:
   a) gelastic seizures (brief episodes of unprovoked laughter) are the most characteristic type and are the earliest seizure manifestation. Present in up to 92% of patients. They are resistant to medical management and can lead to cognitive and behavioral deficits. Not pathognomonic. A neocortical origin has been described.
b) epileptic encephalopathy: gelastic fits gradually increase in frequency and other seizure types accrue: complex partial seizures, drop attacks, tonic seizures, tonic-clonic seizures, and secondarily generalized seizures. This phase is associated with marked deterioration of cognitive and behavioral abilities. Develops in 52% by a mean age of 7 years.

2. precocious puberty: believed to be due to release of gonadotropin-releasing hormone (GnRH) found within hamartoma cells. $^{54}$ HH are the most common CNS tumor to cause precocious puberty, other causes include: other CNS tumors – astrocytoma, ependymoma, pineal tumors (p.658), optic/hypothalamic gliomas (especially in NFT patients) –, CNS XRT, hydrocephalus, CNS inflammation, septo-optic dysplasia (p.260), and chronic hypothyroidism

3. developmental delay: primarily in patients with seizure disorder (severity correlates with duration of seizures). 46% of patients have borderline intellectual function (mental retardation)

4. behavioral disturbances: aggressive behavior, rage attacks...

15.8.3 Imaging

MRI: nonenhancing, isointense on T1WI, slightly hyperintense or isointense on T2WI.$^{56}$

15.8.4 Pathology

Two subtypes of hypothalamic hamartomas$^{56,51}$:
1. pedunculated or para-hypothalamic: narrower base attached to the floor of the hypothalamus (not arising within hypothalamus). No distortion of 3rd ventricle. Generally associated with precocious puberty more than seizures
2. intrathalamic or sessile: within hypothalamus (distorting the 3rd ventricle) or broad attachment to hypothalamus. More often associated with seizures. 66% have developmental delay, 50% have precocious puberty

Microscopic pathology: Clusters of disorganized small neurons surrounded by large pyramidal like neurons in an astrocyte-rich neuropil$^{57}$ (in contrast to the usual ganglion cells surrounded by oligodendrocytes found in the hypothalamus).

15.8.5 Treatment

Precocious puberty usually responds well to GnRH analogs.$^{58}$

Indications for surgery:
1. precocious puberty that fails to respond to medical therapy (GnRH analogs)
2. seizures that cannot be adequately controlled medically. Post-op seizure control is related to completeness of resection
3. neurologic deficit from mass effect of the tumor

Options:
1. surgical resection
   a) pedunculated lesions: approaches include$^{59}$ subtemporal, subfrontal, pterional, orbitozygomatic (most commonly recommended). Risks: cranial neuropathy, stroke.$^{59}$
   b) sessile lesions with intraventricular component: transcallosal anterior interforniceal approach.$^{60,61,62}$ Risks: memory impairment (fornical injury), endocrine disturbances, weight gain.$^{60,62}$
   c) neuroendoscopic approach: considered for HH $\leq 1.5$ cm diameter.$^{63}$ Risks: 25% incidence of thalamic cerebrovascular injury
2. stereotactic radiosurgery: especially for small sessile lesions, subtotal resection, or patients refusing or not candidates for surgery. In small series, 3-year outcome showed improvement similar to surgical resection with less neurologic and endocrinologic morbidity.$^{64,65}$

References

16 Primary Spinal Anomalies

16.1 Spinal arachnoid cysts

16.1.1 General information
Almost always dorsal, most common in thoracic spine. With a ventral cyst, consider a neurenteric cyst (see below). Most are actually extradural and these are sometimes referred to as arachnoid diverticula – these may be associated with kyphoscoliosis in juveniles or with spinal dysraphism. Intradural arachnoid cysts may be congenital or may follow infection or trauma.

Usually asymptomatic, even if large.

16.1.2 Treatment
When indicated, treatment options include:

1. percutaneous procedures: may be done under MRI or CT guidance. CT guidance usually requires use of intrathecal contrast to delineate the cyst
   a) needle aspiration
   b) needle fenestration
2. open surgical resection or fenestration

16.2 Spinal dysraphism (spina bifida)

16.2.1 Definitions
See reference. 

Spina bifida occulta. Congenital absence of a spinous process and variable amounts of lamina. No visible exposure of meninges or neural tissue.

The following two entities are grouped together under the term spina bifida aperta (aperta from the Latin for “open”) or spina bifida cystica.

Meningocele. Congenital defect in vertebral arches with cystic distension of meninges, but no abnormality of neural tissue. One third have some neurologic deficit.

Myelomeningocele. Congenital defect in vertebral arches with cystic dilatation of meninges and structural or functional abnormality of spinal cord or cauda equina.

16.2.2 Spina bifida occulta (SBO)
Reported prevalence range of SBO: 5–30% of North Americans (5–10% is probably more realistic). The defect may be palpable, and there may be overlying cutaneous manifestations (in Table 16.3).

Often an incidental finding, usually of no clinical importance when it occurs alone. Numerous reviews have shown no statistical association of SBO with nonspecific LBP. An increased incidence of disc herniation was shown in one study.

SBO may occasionally be associated with diastematomyelia, tethered cord, lipoma, or dermoid tumor. When symptomatic from one of these associated conditions, the presentation is usually that of tethered cord; gait disturbance, leg weakness and atrophy, urinary disturbance, foot deformities..., see Tethered cord syndrome (p. 272).

16.2.3 Myelomeningocele

Embryology
The anterior neuropore closes at gestation day 25. The caudal neuropore closes at day 28.

Epidemiology/genetics
Incidence of spina bifida with meningocele or myelomeningocele (MM) is 1–2/1000 live births (0.1–0.2%). Risk increases to 2–3% if there is one previous birth with MM, and 6–8% after two affected children. The risk is also increased in families where close relatives (e.g. siblings) have given birth to
MM children, especially when on the mother’s side of the family. Incidence may increase in times of war, famine or economic disasters, but it may be gradually declining overall. Transmission follows non-Mendelian genetics, and is probably multifactorial. Prenatal folic acid (in the form of folic acid) lowers the incidence of MM (p.290).

Hydrocephalus in myelomeningocele
Hydrocephalus (HCP) develops in 65–85% of patients with MM, and 5–10% of MM patients have clinically overt HCP at birth. Over 80% of MM patients who will develop HCP do so before age 6 mos. Most MM patients will have an associated Chiari type 2 malformation (p.284). Closure of the MM defect may convert a latent HCP to active HCP by eliminating a route of egress of CSF.

Latex allergy in myelomeningocele
Up to 73% of MM patients are allergic to proteins present in latex (the milky sap from the rubber tree Hevea brasiliensis), found only in naturally occurring rubber products (and which are not present in synthetics such as: silicone, vinyl, plastic, neoprene, nitrile...). The allergy is thought to arise from early and frequent exposure to latex products during medical care for these patients, and there is a suggestion that latex-free surgery on these infants may reduce the risk of the development of latex allergy.

Prenatal diagnosis
See Prenatal detection of neural tube defects (p.290).

Intrauterine closure of MM defect
Controversial. Does reduce incidence of Chiari II defect, but it has not been determined if this is clinically significant. Argued whether this reduces incidence of hydrocephalus. Does not improve distal neurologic function.

General management
Assessment and management of lesion
- measure size of defect
- assess whether lesion is ruptured or unruptured
  - ruptured: start antibiotics (e.g. nafcillin and gentamicin; D/C 6 hrs after MM closure, or continue if shunt anticipated in next 5 or 6 days)
  - unruptured: no antibiotics necessary
- cover lesion with telfa, then sponges soaked in lactated ringers or normal saline (form a sterile gauze ring around the lesion if it is cystic and protruding) to prevent desiccation
- Trendelenburg position, patient on stomach (keeps pressure off lesion)
- perform surgical closure within 36 hrs unless there is a contraindication to surgery (simultaneous shunt is not usually done except if overt hydrocephalus (HCP) at birth): see below

Neurological assessment and management
- items related to spinal lesion
  - watch for spontaneous movement of the LEs (good spontaneous movement correlates with better later functional outcome)
  - assess lowest level of neurologic function (Table 16.1) by checking response of LEs to painful stimulus: although some infants will have a clear demarcation between normal and abnormal levels, at least 50% show some mixture of normal, reflex, and autonomous activity (arising from uninhibited anterior horn motor neurons)
    - differentiating reflex movement from voluntary may be difficult. In general, voluntary movement is not stereotyped with repetitive stimulus and reflex movement usually only persists as long as the noxious stimulus is applied
- items related to the commonly associated Chiari type 2 malformation:
  - measure OFC: risk of developing hydrocephalus (see above). Use OFC graphs (p.395), and also look for abnormal rate of growth (e.g. >1 cm/day)
  - head U/S within ≈ 24 hrs
  - check for inspiratory stridor, apneic episodes
Ancillary assessment and management

- evaluation by neonatologist to assess for other abnormalities, especially those that may preclude surgery (e.g. pulmonary immaturity). There is an average incidence of 2–2.5 additional anomalies in MM patients
- bladder: start patient on regular urinary catheterizations, obtain urological consultation (non-emergent)
- AP & lat spine films: assess scoliosis (baseline)
- orthopedic consultation for severe kyphotic or scoliotic spine deformities and for hip or knee deformities

Surgical management

Timing of MM closure

Early closure of MM defect is not associated with improvement of neurologic function, but evidence supports lower infection rate with early closure. MM should be closed within 24 hrs whether or not membrane is intact (after ≈ 36 hrs the back lesion is colonized and there is increased risk of postoperative infection).

Simultaneous MM defect closure and VP shunting

In patients without hydrocephalus, most surgeons wait at least ≈ 3 days after MM repair before shunting. In MM patients with clinically overt HCP at birth (ventriculomegaly with enlarged OFC and/or symptoms), MM repair and shunting may be performed in the same sitting without increased incidence of infection, and with shorter hospitalization. It may also reduce the risk of MM repair breakdown previously seen during the interval before shunting. Patient is positioned prone, head turned to right (to expose the right occiput), right knee and thigh flexed to expose right flank (consider using left flank to prevent confusion with appendectomy scar later in life).

Surgical technique of myelomeningocele repair

Key concepts

- critical goals: 1) free placode from dura (to avoid tethering), 2) watertight dural closure, 3) skin closure (can be accomplished in essentially all cases). Closure does not restore any neurologic function
- timing goal: surgical closure with latex-free setup ideally ≤ 36 hours after birth
- helpful tips: start at normal dura, open as wide as the defect, trim placode if necessary to close dura, undermine skin to achieve closure (avoid trapping skin → dermoid tumor)
- post-op CSF leak usually means a shunt is required
General principles: prevent desiccation – keep the exposed neural tissue moist. Use latex-free environment (reduces development of latex allergy, as well as attack by maternal antibodies that may have crossed through the placenta). Do not allow scrub solutions or chemical antimicrobials to contact neural placode. Do not use monopolar cautery. At every point during the closure, avoid placing tension on the neural placode.

Multiple layer closure is advocated, 5 layers should be attempted, although occasionally only 2 or so layers may be closed. There is no evidence that multiple layer closure either improves neurologic function or prevents later tethering, but there is a suggestion that when tethering does occur, it may be easier to release when a previous multilayered closure was performed. Silastic does not prevent adherence in series with long follow-up (>6 yrs), and may even render untethering procedures more difficult.

Begin by dividing the abnormal epithelial covering from the normal skin. The pia-arachnoid may be separated from the neural tissue. The placode is folded into a tube and the pia-arachnoid is then approximated around it with 7–0 suture (absorbable suture, e.g. PDS, may make future re-operation easier). It often helps to start with normal dura above, and then work down. The dura can then be isolated around the periphery and followed deep to the spinal canal superiorly. The dura is then also formed into a tube and approximated in a watertight closure. If the dura cannot be closed, the placode may be judiciously trimmed. The filum terminale should be divided if it can be located. The skin is then mobilized and closed. Dermoid tumors may result from retained skin during the closure, but alternatively dermoids may also be present congenitally.

If there is a kyphotic deformity, it is repaired at the same sitting as the MM defect closure. The kyphotic bone is rongeured, and 2–0 Vicryl is used to suture the adjacent bones. Some surgeons use a brace post-op, some do not.

Post-op management of MM repair
1. keep patient off all incisions
2. bladder catheterization regimen
3. daily OFC measurements
4. avoid narcotics (midbrain malformation renders these patient more sensitive to respiratory depression from narcotics)
5. if not shunted
   a) regular head U/S (twice weekly to weekly)
   b) keep patient flat to ↓ CSF pressure on incision
6. if a kyphectomy was done, use of a brace is optional (surgeon preference)

Late problems/issues
Include:
1. hydrocephalus: may mimic ≈ anything listed below. ALWAYS RULE OUT SHUNT MALFUNCTION when a MM patient deteriorates
2. syringomyelia (and/or syringobulbia) (p.1144):
3. Tethered cord syndrome (p.272) as many as 70% of MM patients have a tethered cord radiographically (some quote 10–20%), but only a minority are symptomatic. Unfortunately there is no good test to check for symptomatic retethering (SSEPs may deteriorate, myelography may help)
   a) scoliosis: early untethering of cord may improve scoliosis; see Scoliosis in tethered cord (p.272)
   b) symptomatic tethering may manifest as delayed neurological deterioration
4. dermoid tumor at the MM site (p.784); incidence ≈ 16%
5. medullary compression at foramen magnum, see symptomatic Chiari II malformation (p.284)
6. use of growth hormone to increase stature is controversial

Outcome
Without any treatment, only 14–30% of MM infants survive infancy; these usually represent the least severely involved; 70% will have normal IQ’s, 50% are ambulatory.

With modern treatment, ≈ 85% of MM infants survive. The most common cause of early mortality are complications from the Chiari malformation (respiratory arrest, aspiration ...), where late mortality is usually due to shunt malfunction. 80% will have normal IQ. Mental retardation is most closely linked to shunt infection. 40–85% are ambulatory with bracing, however, most choose to use wheelchairs for ease. 3–10% have normal urinary continence, but most may be able to remain dry with intermittent catheterization.
16.2.4 Lipomyeloschisis

General information
Dorsal spinal dysraphism with lipoma. Six forms are described,\(^{18}\) the following 3 are clinically important as possible causes of progressive neurologic dysfunction via tethering (p.272) and/or compression:
1. (intra)dural lipoma
2. lipomyelomeningocele (see below)
3. fibrolipoma of the filum terminale

Lipomyelomeningocele
General information
A subcutaneous lipoma that passes through a midline defect in the lumbodorsal fascia, vertebral neural arch, and dura, and merges with an abnormally low tethered cord.\(^{18}\) These may be terminal, dorsal, or transitional (between the two).

The intradural fatty tumor may also be known as lipoma of the cauda equina. In addition to being abnormally low, the conus medullaris is split in the midline dorsally usually at the same level as the bifid spine, and this dorsal myeloschisis may extend superiorly under intact spinal arches.\(^{19}\) There is a thick fibrovascular band that joins the lamina of the most cephalic vertebrae with the bifid lamina. This band constricts the meningocele sac and neural tissue, causing a kink in the superior surface of the meningocele. Asymptomatic lipomas of the filum terminale occur in 0.2–4%\(^{20,21}\) of MRIs.

The dura is dehiscent at the level of the dorsal myeloschisis, and reflects onto the placode. The lipoma passes through this dehiscence to become attached to the dorsal surface of the placode, and may continue cephalad under intact arches with the possibility of extension into the central canal superiorly to levels without dorsal myeloschisis. The lipoma is distinct from the normal epidural fat which is looser and more areolar. The subarachnoid space typically bulges to the side contralateral to the lipoma. These lipomas account for 20% of covered lumbosacral masses.

Presentation
In a pediatric series, 56% presented with a back mass, 32% with bladder problems, and 10% because of foot deformities, paralysis or leg pain.\(^{22}\)

Physical examination
Almost all patients have cutaneous stigmata of the associated spina bifida: fatty subcutaneous pads (located over the midline and usually extends asymmetrically to one side) with or without dimples, port-wine stains, abnormal hair, dermal sinus opening, or skin appendages.\(^{23}\) Clubbing of the feet (talipes equinovarus) may occur.

The neurologic exam may be normal in up to 50% of patients (most presenting with skin lesion only). The most common neurologic abnormality was sensory loss in the sacral dermatomes.

Evaluation
Plain LS spine x-rays will show spina bifida in most cases. Present in almost all by definition, but some may have segmentation anomalies instead such as butterfly vertebra (p.216). Abnormalities of fusion and sacral defects may also be seen.

The abnormally low conus can be demonstrated on myelogram/CT or on MRI. MRI also demonstrates the lipomatous mass (high signal on T1 WI, low signal on T2WI).

All patients should have pre-op urological evaluation to document any deficit.

Treatment
Since symptoms are due to (1) tethering of the spinal cord, especially during growth spurts, and (2) compression due to progressive deposition of fat, especially during periods of rapid weight gain; the goals of surgery are to release the tethering and reduce the bulk of fatty tumor. Simple cosmetic treatment of the subcutaneous fat pad does not prevent neurologic deficit, and may make later definitive repair more difficult or impossible.

Surgical treatment is indicated when the patient reaches 2 months of age, or at the time of diagnosis if the patient presents later in life. Adjuncts to surgical treatment include evoked potential monitoring and laser. Overall, with surgery, 19% will improve, 75% will be unchanged, and 6% will worsen. Foot deformities often progress regardless.
Surgical technique (modified)
See reference.19
1. mobilize the subcutaneous mass, it funnels down through the deep fascia
2. open last intact vertebral arch (work from normal dura)
3. identify the fibrovascular band that crosses the most cephalic widely bifid lamina
4. sectioning the fibrovascular band frees the dural tube and releases the sharp kink in the superi-
or surface of the meningocoele
5. taking care to preserve dorsal nerve roots, the dura is incised anterior to the dura-lipoma
   junction
6. similar procedure is carried out with arachnoid membrane
7. dural/arachnoid incisions are continued around entire extent of tethered conus
8. cord and placode are untethered; monitoring techniques described in Tethered cord syndrome
   (p.272) are an option
9. subtotal removal of lipoma: lipoma is then trimmed as completely as possible, intentionally
   leaving some fat behind to avoid injury to dorsal surface of placode. Superior extension along
dorsal surface of cord or into central canal is debulked as much as is safely possible
10. the placode is reformed into a closed neural tube
11. close the pial margins
12. the dura is closed (primarily if possible, or using fascia lata graft if too much tension is placed on
   folded placode)

16.2.5 Dermal sinus

General information
A tract beginning at the skin surface, lined with epithelium. Usually located at either end of neural
tube: cephalic or caudal. Most common location is lumbosacral. Probably results from failure of the
cutaneous ectoderm to separate from the neuro-ectoderm at the time of closure of the neural
groove.2

Spinal dermal sinus

General information
May appear as a dimple or as a sinus, with or without hairs, usually very close to midline, with an
opening of only 1–2 mm. Surrounding skin may be normal, pigmented (“port wine” discoloration),
or distorted by an underlying mass.

The sinus may terminate superficially, may connect with the coccyx, or may traverse between
normal vertebrae or through bifid spines to the dural tube. It may widen at any point along its path
to form a cyst; called an epidermoid cyst if lined with stratified squamous epithelium and contain-
ing only keratin from desquamated epithelium, or called a dermoid cyst if also lined with dermis
(containing skin appendages, such as hair follicles and sebaceous glands) and also containing sebum
and hair.

Although innocuous in appearance, they are a potential pathway for intradural infection which
may result in meningitis (sometimes recurrent) and/or intrathecal abscess. Less serious, a local infec-
tion may occur. The lining dermis contains normal skin appendages which may result in hair, sebum,
desquamated epithelium and cholesterol, within the tract. As a result, the contents of the sinus tract
are irritating and can cause a sterile (chemical) meningitis with possible delayed arachnoiditis if it
enters the dural space.

Incidence of a presumed sacral sinus (a dimple whose bottom could not be seen on skin retrac-
tion): 1.2% of neonates.24

Dermal sinuses are similar but distinct from pilonidal cysts which may also be congenital
(although some authors say they are acquired), contain hair, are located superficial to the postsa-
cral fascia, and may become infected.

If the tract expands intradurally to form a cyst, the mass may present as a tethered cord or as an
intradural tumor. Bladder dysfunction is usually the first manifestation.
The tract from a spinal dermal sinus always courses cephalad as it dives inward from the surface.
An occipital sinus may penetrate the skull and can communicate with dermoid cysts as deep as the
cerebellum or fourth ventricle.

Evaluation
These tracts are NOT to be probed or injected with contrast as this can precipitate infection or sterile
meningitis.
Exam is directed towards detecting abnormalities in sphincter function (anal and urinary), lumbosacral reflexes, and lower extremity sensation and function.

Radiologic evaluation
When seen at birth, ultrasound is the best means to evaluate for spina bifida and a possible mass inside the canal.
If seen initially following birth, an MRI should be obtained. Sagittal images may demonstrate the tract and its point of attachment. MRI also optimally demonstrates masses (lipomas, epidermoids...) within the canal.
Plain x-rays and CT are unable to demonstrate the fine tract which may exist between the skin and the dura.
Plain x-rays must be done when embarking on surgery as part of operative planning, as preparation for the possibility of a complete laminectomy.

Treatment
Sinuses above the lumbosacral region should be surgically removed. More caudally located sinuses are slightly controversial. Although ≈ 25% of presumed sacral sinuses seen at birth will regress to a deep dimple on follow-up (time not specified), it is recommended that all dermal sinuses should be surgically explored and fully excised prior to the development of neurologic deficit or signs of infection. The results following intradural infection are never as good as when undertaken prior to infection. Surgery within the week of diagnosis is appropriate. Sinuses that terminate on the tip of the coccyx rarely penetrate the dura, and may not need to be treated unless local infection occurs.

Surgical technique
An ellipse is cut around the opening, and the sinus is followed deep until the termination of the tract is encountered. Careful insertion of a lacrimal duct probe under direct vision may facilitate excision without violating the tract. If the tracts penetrate the spine, laminectomy must be performed and the tract followed to its full extent (even if necessary to extend the laminectomy to T12). An extradural cyst may be present. If the tract enters the dura, it usually does so in the midline, and in these cases the dura should be opened and inspected. Extreme care is taken to prevent spilling the contents into the subdural space.

Cranial dermal sinus
General information
Stalk begins with a dimple in the occipital or nasal region. Cutaneous stigmata of hemangioma, subcutaneous dermoid cyst, or abnormal hair formation may occur. Occipital sinuses extend caudally, and if they enter the skull, they do so caudal to the torcular herophili. Presentation may include recurrent bacterial (usually S. aureus) or aseptic meningitis. Evaluation should include MRI to look for intracranial extension and associated anomalies, including an intracranial dermoid cyst.

Treatment
When operating on a cranial dermal sinus, use a sagittally based incision to permit deep exploration. The tract must be followed completely. Be prepared to enter the posterior fossa.

16.3 Klippel-Feil syndrome
16.3.1 General information
Congenital fusion of two or more cervical vertebrae. Ranges from fusion of only the bodies (congenital block vertebrae) to fusion of the entire vertebrae (including posterior elements). Results from failure of normal segmentation of cervical somites between 3–8 weeks gestation. Involved vertebral bodies are often flattened and associated disc spaces are absent or hypoplastic. Hemivertebrae may also occur. Neural foramina are smaller than normal and oval. Cervical stenosis is rare. Complete absence of the posterior elements with an enlarged foramen magnum and fixed hyperextension posture is called iniencephaly and is rare. Incidence of Klippel-Feil is unknown due to its rarity and the fact that it is frequently asymptomatic.
May occur in conjunction with other congenital cervical spine anomalies such as basilar impression and atlanto-occipital fusion.
16.3.2 Presentation

Classic clinical triad (all 3 are present in <50%):
1. low posterior hairline
2. shortened neck (brevicollis)
3. limitation of neck motion (may not be evident if <3 vertebrae are fused, if fusion is limited only to the lower cervical levels, or if hypermobility of nonfused segments compensates). Limitation of movement is more common in rotation than flexion-extension or lateral bending.

Other clinical associations include scoliosis in 60% facial asymmetry, torticollis, webbing of the neck (called pterygium colli when severe), Sprengel’s deformity in 25–35% (raised scapula due to failure of the scapula to properly descend from its region of formation high in the neck to its normal position about the same time as the Klippel-Feil lesion occurs), synkinesis (mirror motions, primarily of hands but occasionally arms also) and less commonly facial nerve palsy, ptosis, cleft or high arched palate. Systemic congenital abnormalities may also occur including: genitourinary (the most frequent being unilateral absence of a kidney), cardiopulmonary, CNS, and in ≈ 30% deafness (due to defective development of the osseous inner ear).

No neurologic symptoms have ever been directly attributed to the fused vertebrae, however symptoms may occur from nonfused segments (less common in short-segment fusions) which may be hypermobile possibly leading to instability or degenerative arthritic changes.

16.3.3 Treatment

Usually directed at detecting and managing the associated systemic anomalies. Patients should have cardiac evaluation (EKG), CXR, and a renal ultrasound. Serial examinations with lateral flexion-extension lateral C-spine x-rays to monitor for instability. Occasionally, judicious fusion of an unstable nonfused segment may be needed at the risk of further loss of mobility. See also recommendations regarding athletic competition (p.937).

16.4 Tethered cord syndrome

16.4.1 General information

Abnormally low conus medullaris. Usually associated with a short, thickened filum terminale, or with an intradural lipoma (other lesions, e.g. lipoma extending through dura, or diastematomyelia are considered as separate entities). Most common in myelomeningocele (MM). Diagnosis must be made clinically in MM, as almost all of these patients will have tethering radiographically.

16.4.2 Presentation

Presenting signs and symptoms in patients with tethered cord are shown in Table 16.2.

16.4.3 Myelomeningocele patients

If a MM patient has increasing scoliosis, increasing spasticity, worsening gait (in those previously ambulatory), or deteriorating urodynamics:
- always make sure that there is a working shunt with normal ICP
- if painful, should be considered tethered cord until proven otherwise
- if painless, should be considered syringomyelia until proven otherwise
- may be due to brainstem compression – see symptomatic Chiari II malformation (p.284) – requiring posterior fossa decompression

16.4.4 Scoliosis in tethered cord

Progressive scoliosis may be seen in conjunction with tethered cord. Early untethering of the cord may result in improvement of scoliosis, however, untethering must be done when the scoliosis is mild. When cases of ≤10° scoliosis were untethered, 68% had neurologic improvement and the remaining 32% were stabilized, whereas when scoliosis is severe (≥50°) ≈ 16% deteriorated.
16.4.5 Tethered cord in adults

General information

Although most cases of tethered cord present in childhood, cases of adult tethered cord also occur (≈ 50 published cases as of 1982). For comparison of adult and childhood forms, Table 16.3

Evaluation

Radiographically: low conus medullaris (below L2) and thickened filum terminale (definition of thickened filum: normal diameter <1 mm; diameters >2 mm are pathological). NB: apparent filum diameter on CT-myelogram may vary with concentration of contrast material.

It is difficult to differentiate a tethered cord from a congenitally low lying conus (filum diameter is generally normal in the latter).

16.4.6 Pre-op evaluation

Pre-operative cystometrogram is strongly recommended, especially if the patient seems continent (postoperative changes in bladder function are not uncommon, possibly due to stretching of the lower fibers of the cauda equina).

Surgical treatment

If the only abnormality is a thickened, shortened filum, then a limited lumbosacral laminectomy may suffice, with division of the filum once identified.

If a lipoma is found, it may be removed with the filum if it separates easily from neural tissues.

Distinguishing features of the filum terminale intraoperatively

The filum is differentiated from nerve roots by presence of characteristic squiggly vessel on surface of filum. Also, under the microscope, the filum has a distinctively whiter appearance than the nerve roots, and ligamentous-like strands can be seen running through it. NB: intra-op electrical stimulation and recording of anal sphincter EMG are more definitive.
In MM, it is usually impossible to permanently untether a cord, however, in a growing MM child, it may be that after 2–4 untetherings that the child will be finished growing and tethering may cease to be a problem. Cases that are untethered early in childhood may recur later, especially during the adolescent growth-spurt. Incidence of post-op CSF leak: 15%.

Adult form: surgical release is usually good for pain relief. However, it is poor for return of bladder function.

### 16.5 Split cord malformation

#### 16.5.1 General information

There is no uniformly accepted nomenclature for malformations characterized by duplicate or split spinal cords. Pang et al. have proposed the following.

The term split cord malformation (SCM) should be used for all double spinal cords, all of which appear to have a common embryologic etiology.

#### 16.5.2 Type I SCM

Defined as two hemicords, each with its own central canal and surrounding pia, each within a separate dural tube separated by a dural-sheathed rigid osseocartilaginous (bony) median septum. This has often (but not consistently) been referred to as diastematomyelia. There are abnormalities of the spine at the level of the split (absent disc, dorsal hypertrophic bone where the median “spike” attaches). Two-thirds have overlying skin abnormalities including: nevi, hypertrichosis (tuft of hair), lipomas, dimples or hemangiomas. These patients often have an orthopedic foot deformity (neurogenic high arches).

Treatment: symptoms are most commonly due to tethering of the cord; and are usually improved by untethering. In addition to untethering, the bony septum must be removed and the dura reconstituted as a single tube (these spines are often very distorted and rotated, therefore start at normal anatomy and work towards defect). **DO NOT cut the tethered filum until after the median septum is removed to avoid having the cord retract up against septum.**

---

</tbody>
</table>

16.5.3 Type II SCM

Consists of two hemicords within a single dural tube, separated by a nonrigid fibrous median septum. This has sometimes been referred to as diplomyelia. Each hemicord has nerve roots arising from it. There is usually no spine abnormality at the level of the split, but there is usually spina bifida occulta in the lumbosacral region.

Treatment: consists of untethering the cord at the level of the spina bifida occulta, and occasionally at the level of the split.31

16.6 Lumbosacral nerve root anomalies

Congenital anomalies of nerve roots are rare. This possibility should be considered in cases of failed back surgery for herniated disc.

Classification system of Cannon et al.32

1. Type 1 anomalies: include conjoined nerve root (2 nerve roots arise from a common dural sheath). They separate at various distances from the thecal sac, and exit through the same or separate neural foramina. Neurosurgeons need to be aware of this anomaly to avoid inadvertent injury e.g. during surgery for herniated disc

2. Type 2 anomalies: 2 nerve roots exit through one foramen. Variants33:
   a) leaves an unoccupied neural foramen
   b) all foramina occupied, but one foramen has 2 nerve roots

3. Type 3 anomalies: adjacent nerve roots are connected by an anastomosis

17 Primary Craniospinal Anomalies

17.1 Chiari malformations

17.1.1 General information

The term “Chiari malformation” (after pathologist, Hans Chiari) is preferred for type 1 malformations, with the commonly used term “Arnold-Chiari malformation” reserved for type 2 malformation.

The Chiari malformations consist of four types of hindbrain abnormalities, probably unrelated to each other. The majority of Chiari malformations are types 1 or 2 (Table 17.1), a very limited number of cases comprise the remaining types. Chiari zero is a novel condition (p.286).

17.1.2 Type 1 Chiari malformation

General information

Key concepts

- a heterogeneous entity with the common feature of impaired CSF circulation through the foramen magnum
- may be congenital or acquired
- evaluation: MRI of brain and cervical spine (to R/O syringomyelia). Cine MRI to evaluate CSF flow through foramen magnum in uncertain cases
- cerebellar tonsillar herniation on MRI: criteria vary, >5 mm below the foramen magnum is often cited, but is neither essential nor diagnostic of the condition
- treatment, when indicated, is surgical, but aspects of what that surgery should entail are controversial (enlargement of foramen magnum is usually involved)
- associated with syringomyelia in 30–70% which almost always improves with treatment of the Chiari malformation

AKA primary cerebellar ectopia; AKA adult Chiari malformation (since it tends to be diagnosed in the 2nd or 3rd decade of life). A heterogeneous group of conditions, with the underlying commonality of disruption of normal CSF flow through the foramen magnum (FM). Some cases are congenital, but others are acquired (this section is kept here under developmental for historical and organizational reasons).

</tbody>
</table>
Classically described as a rare abnormality restricted to caudal displacement of cerebellum with tonsillar herniation below the foramen magnum (below for criteria) and "peg-like elongation of tonsils." Unlike Chiari type 2, the medulla is not caudally displaced (some authors disagree on this point3), the brainstem is not involved, lower cranial nerves are not elongated, and upper cervical nerves do not course cephalad. Syringomyelia of the spinal cord is present in 30–70%4 True hydromyelia probably doesn’t occur; CSF flow has not been documented in man, and it is generally not possible to find communication between the syrinx and the central canal in Chiari 1 patients. Hydrocephalus occurs in 7–9% of patients with Chiari type 1 malformation and syringomyelia.4

Cerebellar tonsil descent below FM with impaction, while common, is no longer a sine qua non of diagnosis.

**Associations**

May be associated with

1. a small posterior fossa
   a) underdevelopment of the occipital bone due to a defect in the occipital somites originating from the para-axial mesoderm
   b) low lying tentorium (the roof of the p-fossa)
   c) thickened or elevated occipital bone (the floor of the p-fossa)
   d) space occupying lesion in p-fossa: arachnoid cyst (retrocerebellar or supracerebellar), tumor (e.g. FM meningioma or cerebellar astrocytoma), hypervascular dura
2. has been described with just about anything that takes up intracranial space
   a) chronic subdural hematomas
   b) hydrocephalus
3. following lumboperitoneal shunt (p. 418) or multiple (traumatic) LPs6: acquired Chiari 1 malformation (may be asymptomatic)
4. arachnoid web or scar or fibrosis around brainstem and tonsils near FM
5. abnormalities of the upper cervical spine
   a) hypermobility of the craniovertebral junction
   b) Klippel-Feil syndrome
   c) occipitalization of the atlas
   d) anterior indentation at foramen magnum: e.g. basilar invagination or retroversion of the odontoid process
6. Ehlers-Danlos syndrome
7. craniosynostosis: especially cases involving all sutures
8. retained rhomboid roof: rare

**Epidemiology**

Average age at presentation is 41 years (range: 12–73 yrs). Slight female preponderance (female: male = 1.3:1). Average duration of symptoms clearly related to Chiari malformation is 3.1 yrs (range: 1 month-20 yrs); if nonspecific complaints, e.g. H/A, are included, this becomes 7.3 years.7 This latency is probably lower in the MRI era.

**Clinical**

**Clinical correlates**

Patients with Chiari type 1 malformation may present due to any or all of the following:

1. compression of brain stem at the level of the foramen magnum
2. hydrocephalus
3. syringomyelia
4. isolation of the intracranial pressure compartment from the spinal compartment causing transient elevations of ICP intracranial pressure
5. 15–30% of patients with adult Chiari malformation are asymptomatic8

**Symptoms**

The most common symptom is pain (69%, especially headache which is usually felt in the suboccipital region Table 17.2). H/A are often brought on by neck extension or valsala maneuver. Weakness is also prominent, especially unilateral grasp. Hermitte’s sign may also occur. Lower extremity involvement usually consists of bilateral spasticity.
Signs
Downbeat nystagmus is considered a characteristic of this condition. 10% will have a normal neurologic exam with occipital H/A as their only complaint. Some patients may present primarily with spasticity.

See Table 17.3. Three main patterns of clustering of signs:

1. foramen magnum compression syndrome (22%): ataxia, corticospinal and sensory deficits, cerebellar signs, lower cranial nerve palsies. 37% have severe H/A
2. central cord syndrome (65%): dissociated sensory loss (loss of pain & temperature sensation with preserved touch & JPS), occasional segmental weakness, and long tract signs (syringomyelic syndrome). 11% have lower cranial nerve palsies
3. cerebellar syndrome (11%): truncal and limb ataxia, nystagmus, dysarthria

Natural history
The natural history is not known with certainty (only 2 reports on “natural history”). A patient may remain stable for years, with intermittent periods of deterioration. Rarely, spontaneous improvement may occur (debated).

*Classically: downbeat nystagmus on vertical movement, and rotatory nystagmus on horizontal movement; also includes oscillopsia.

Evaluation

Of 70 skull x-rays, only 36% were abnormal (26% showed basilar impression, 7% platybasia, and 1 patient each with Paget’s and concave clivus); in 60 C-spine x-rays, 35% were abnormal (including assimilation of atlas, widened canal, cervical fusions, agenesis of posterior arch of atlas).

MRI
MRI of brain and C-spine is the diagnostic test of choice. Easily shows many of the classic abnormalities described earlier, including tonsillar herniation, as well as hydrocephalus, empty sella.

Tonsillar herniation: Criteria for the descent of the tonsillar tips below the foramen magnum (FM) to diagnose Chiari type 1 malformation have gone through a number of reconsiderations.

Initially, >5 mm was defined as clearly pathologic (with 3–5 mm being borderline). Barkovich found tonsillar positions as shown in Table 17.4, and Table 17.5 shows the effect of utilizing 2 vs. 3 mm as the lowest normal position.

The tonsils normally ascend with age as shown in Table 17.6.
Patients with syringohydromyelia without hindbrain herniation that responded to p-fossa decompression have been described (so-called “Chiari zero malformation”). Conversely, 14% of patients with tonsillar herniation >5 mm are asymptomatic (average extent of ectopia in this group was 11.4 ± 4.86 mm).

Potentially more significant than the absolute tonsillar descent is the amount of compression of the brainstem at the FM, best appreciated on axial T2WI MRI through the FM. Complete obliteration of CSF signal and compression of the brainstem at the FM by impacted tonsils is a common significant finding.

Cine MRI
AKA CSF flow study. May demonstrate blockage of CSF flow at FM. Not widely available. Accuracy is not high, therefore usually does not alter management.

<sup>a</sup>negative number indicates distance below FM
<sup>b</sup>S.D. = standard deviation. Descent > 2 S.D. beyond normal is suggested as a criteria for tonsillar ectopia
Myelography
Generally used only when MRI cannot be obtained. Only 6% false negative. It is critical to run the intrathecal contrast (dye) all the way up to the foramen magnum. Usually combined with CT scan.

CT
Unenhanced CT is poor for evaluating the foramen magnum region due to bony artifact. It is very good at demonstrating hydrocephalus (as is MRI). When combined with intrathecal iodinated contrast (myelogram), reliability improves. Findings: tonsillar descent with possible complete blockage of dye at foramen magnum.

Treatment
Indications for surgery
Since patients respond best when operated on within 2 years of the onset of symptoms (below), early surgery is recommended for symptomatic patients. Asymptomatic patients may be followed and operated upon if and when they become symptomatic. Patients who have been asymptomatic and stable for years may be considered for observation, with surgery indicated for signs of deterioration.

Surgical techniques
The most frequently performed operation is posterior fossa decompression (suboccipital craniectomy), with or without other procedures (usually combined with dural patch grafting and cervical laminectomy of C1, sometimes to C2 or C3). Options for grafts: same incision (pericranium), separate incision (e.g. or fascia lata), and allograft (avoided by many authors because of dissatisfaction with ability to provide water-tight closure and because of infectious risks).

Goals of surgery: decompress the brain stem and reestablish normal flow of CSF at the cranio cervical junction.

The patient is positioned prone on chest rolls with the head in a Mayfield head-holder or in a horseshoe headrest. Flex the neck to open the interspace between the occiput and posterior arch of C1. The shoulders are retracted inferiorly with adhesive tape. If a fascia lata graft is to be taken, elevate one thigh on a sandbag. A midline incision from inion to ≈ C2 spinous process is made. The removal of bone above the foramen magnum should be ≈ 3 cm high by ≈ 3 cm wide (keep the posterior fossa part of these operations small, the main thrust is to open the foramen magnum to decom press the tonsils and an upper cervical laminectomy; the compression is not in the p-fossa). Excessive removal of occipital bone may allow the cerebellar hemispheres to herniate through the opening (“cerebellar ptosis”), and create additional problems. If a pericranial graft is to be taken, it should be harvested at this time to reduce the amount of blood entering the subsequent dural opening.\textsuperscript{16} Pericranial graft can be procured without extending the incision about the inion using the technique of Dr. Robert Ojemann\textsuperscript{16} with subgaleal dissection and using a monopolar cautery with a bent tip to incise the periosteum and then a Penfield #1 dissector to free it from the bone surface.

Open the dura in a “Y” shaped incision, and excise the triangular top flap. CAUTION: the transverse sinuses are usually abnormally low in Chiari malformations. Suture the patch graft to provide more room for the contents (tonsils + medulla).

An option that is sometimes used in pediatrics is to not initially open the dura but to lyse constricting bands over the dura at the foramen magnum and then use intraoperative ultrasound to determine if there is adequate room for CSF flow, the dura is then opened only if there is not.

Historical procedures that have been appended to the above: plugging the obex (with muscle or teflon), drainage of syrinx if present (fenestration, usually through dorsal root entry zone, with or without stent or shunt), 4th ventricular shunting, terminal ventriculostomy, and opening foramen of Magendie if obstructed (see reference for illustrations\textsuperscript{9}). Current recommendations are that these or other additional procedures beyond dural patch grafting are usually not warranted.

Some authors repeatedly admonish not to attempt to remove adhesions binding the tonsils together (to avoid injuring vital structures, including PICAs). Others recommend cautiously separating the tonsils and even shrinking them down with bipolar cautery. In cases with ventral brain-stem compression, some authors advocate performing a transoral clivus-odontoid resection as they feel these patients may potentially deteriorate with posterior fossa decompression alone.\textsuperscript{17} Since this deterioration was reversible with odontoidectomy, it may be reasonable to perform this procedure on patients who show signs of deterioration or progression of basilar impression on serial MRIs after posterior fossa decompression.
Booking the case: Chiari malformation

Also see defaults & disclaimers (p. 27).
1. position: prone
2. equipment:
   a) optional microscope
   b) intra-op Doppler, if used
3. consent:
   a) procedure: surgery through the back of the neck to open the bone at the base of the skull and to insert a “patch” to make more room for the brainstem
   b) alternatives: non-surgical management is usually not effective
   c) complications: CSF leak, brainstem injury/stroke, apnea, failure to improve syrinx (if present)

Operative findings
See Table 17.7.
Tonsillar herniation is present in all cases (by definition); the most common position being at Cl (62%). Fibrous adhesions between dura, arachnoid and tonsils with occlusion of foramina of Luschka and Magendie in 41%. The tonsils separated easily in 40%.

Surgical complications
After suboccipital craniectomy plus Cl–3 laminectomy in 71 patients, with dural patch grafting in 69, one death due to sleep apnea occurred 36 hrs post-op. Respiratory depression was the most common post-op complication (in 10 patients), usually within 5 days, mostly at night. Close respiratory

*vascular abnormalities: PICA dilated or abnormal course in 8 patients (PICA often descends to lower margin of tonsils); large dural venous lakes in 3
monitoring is therefore recommended.3 Other risks of the procedure include: CSF leak, herniation of cerebellar hemispheres, vascular injuries (to PICA...).

Operative results

See Table 17.8.

Patients with pre-op complaints of pain generally respond well to surgery. Weakness is less responsive to surgery, especially when muscle atrophy is present.17 Sensation may improve when the posterior columns are unaffected and the deficit is due to spinothalamic involvement alone.

Rhoton feels that the main benefit of operation is to arrest progression. The most favorable results occurred in patients with cerebellar syndrome (87% showing improvement, no late deterioration). Factors that correlate with a worse outcome are the presence of atrophy, ataxia, scoliosis, and symptoms lasting longer than 2 years.17

17.1.3 Type 2 (Arnold)-Chiari malformation

General information

Key concepts

- usually associated with myelomeningocele, often accompanied by hydrocephalus pathology includes: caudally displaced cervicomедullary junction, small posterior fossa, tectal beaking. Is probably not due to tethering
- major clinical findings: swallowing difficulties, apnea, stridor, opisthotonos, downbeat nystagmus
- when symptomatic: always check the shunt first! Then, consider surgical decompression (which cannot correct intrinsic brainstem abnormalities)
- cranial and cervical MRI is the diagnostic test of choice.

Usually associated with myelomeningocele (MM), or rarely spina bifida occulta.

Pathophysiology

Probably does not result from tethering of the cord by the associated MM. More likely due to primary dysgenesis of the brainstem with multiple other developmental anomalies.18

Major findings

Caudally dislocated cervicomедullary junction, pons, 4th ventricle and medulla. Cerebellar tonsils located at or below the foramen magnum. Replacement of normal cervicomединullary junction flexure with a “kink-like deformity.”

Other possible associated findings:
1. beaking of tectum
2. absence of the septum pellucidum with enlarged interthalamic adhesion: absence of the septum pellucidum is thought to be due to necrosis with resorption secondary to hydrocephalus, and not a congenital absence19(p 178)
3. poorly myelinated cerebellar folia
4. hydrocephalus: present in most
5. heterotopias
6. hypoplasia of falx
7. microgyria
8. degeneration of lower cranial nerve nuclei
9. bony abnormalities:
   a) of cervicomедullary junction
   b) assimilation of atlas
   c) platybasia
   d) basilar impression
   e) Klippel-Feil deformity (p. 271)
10. hydromyelia
11. craniolacunia of the skull (see below)

Presentation

Findings are due to brain stem and lower cranial nerve dysfunction. Onset is rare in adulthood. The presentation of neonates differs substantially from older children, and neonates were more likely to develop rapid neurological deterioration with profound brain stem dysfunction over a period of several days than were older children in whom symptoms were more insidious and rarely as severe.\textsuperscript{19}

Findings include:\textsuperscript{21,20}
1. swallowing difficulties (neurogenic dysphagia) (69%).\textsuperscript{22} Manifests as poor feeding, cyanosis during feeding, nasal regurgitation, prolonged feeding time, or pooling of oral secretions. Gag reflex often decreased. More severe in neonates
2. apneic spells (58%): due to impaired ventilatory drive. More common in neonates
3. stridor (56%): more common in neonates, usually worse on inspiration (abductor and occasionally adductor vocal cord paralysis seen on laryngoscopy) due to 10th nerve paresis; usually transient, but may progress to respiratory arrest
4. aspiration (40%)
5. arm weakness (27%): may progress to quadriparesis\textsuperscript{23}
6. opisthotonos (18%)
7. nystagmus: especially downbeat nystagmus
8. weak or absent cry
9. facial weakness

Diagnostic evaluation

Skull films
May demonstrate cephalofacial disproportion from congenital HCP. Cranialacunia (AKA lückenschädel) in 85% (round defects in the skull with sharp borders, separated by irregularly branching bands of bone; not due to increased ICP). Low lying internal occipital protuberance (foreshortened posterior fossa). Enlarged foramen magnum in 70% elongation of upper cervical lamina.\textsuperscript{1}

CT and/or MRI findings
Cranial and cervical MRI is the diagnostic test of choice.
- primary findings
  a) “Z” bend deformity of medulla*
  b) cerebellar peg
  c) tectal fusion (“tectal beaking”)
  d) enlarged massa intermedia (interthalamic adhesion)*
  e) elongation/cervicalization of medulla
  f) low attachment of tentorium
- associated findings
  a) hydrocephalus
  b) syringomyelia in the area of the cervicomедullary junction (reported incidence in pre MRI era\textsuperscript{17} ranges from 48–88%)
  c) trapped fourth ventricle
  d) cerebellomedullary compression
  e) agenesis/dysgenesis of corpus callosum*

*items with an asterisk are best appreciated on MRI
La r y n g o s c o p y
Performed in patients with stridor to rule out croup or other upper respiratory tract infection.

Treatment

General information
- insert CSF shunt for hydrocephalus (or check function of existing shunt)
- if neurogenic dysphagia, stridor, or apneic spells occur, expeditious posterior fossa decompression is recommended (see below) (required in 18.7% of MM patients); before recommending decompression, always make sure the patient has a functioning shunt!

Surgical decompression

NB: it has been argued that part of the explanation for the poor operative results in infants is that many of the neurological findings may be due in part to intrinsic (uncorrectable) abnormalities which surgical decompression cannot improve. A dissenting view is that the histologic lesions are due to chronic brain stem compression and concomitant ischemia, and that expeditious brain stem decompression should be carried out when any of the following critical warning signs develop: neurogenic dysphagia, stridor, apneic spells.

A dissenting view is that the histologic lesions are due to chronic brain stem compression and concomitant ischemia, and that expeditious brain stem decompression should be carried out when any of the following critical warning signs develop: neurogenic dysphagia, stridor, apneic spells.

Surgical technique

Decompression of cerebellar tonsils, usually with dural graft to decompress dura. Patients is placed prone, with the neck flexed. A suboccipital craniectomy is combined with a cervical laminectomy which must be carried down to the bottom of the tonsillar tip. A thick constricting dural band is usually found between the Cl arch and foramen magnum. The dura is opened in a “Y” shaped incision. Caution when opening the dura above the level of the foramen magnum in infants as they have a well-developed occipital sinus and may have large dural lakes. DO NOT attempt to dissect tonsils from underlying medulla. In cases with a significant syringomyelic cavity, a syringo-subarachnoid shunt is placed. Tracheostomy (usually temporary) is recommended if stridor and abductor laryngeal palsy were present pre-op. Close post-op respiratory monitoring is needed for obstruction and reduced ventilatory drive (mechanical ventilation is indicated for hypoxia or hypercarbia).

Outcome

68% had complete or near complete resolution of symptoms, 12% had mild to moderate residual deficits, and 20% had no improvement (in general, neonates fared worse than older children).

Respiratory arrest is the most common cause of mortality (8 of 17 patients who died), with the rest due to meningitis/ventriculitis (6 patients), aspiration (2 patients), and biliary atresia (1 patient).

In follow-up ranging 7 mos-6 yrs, 37.8% mortality in operated patients.

Pre-op status and the rapidity of neurologic deterioration were the most important prognosticators. Mortality rate is 71% in infants having cardiopulmonary arrest, vocal cord paralysis or arm weakness within 2 weeks of presentation; compared to 23% mortality in patients with a more gradual deterioration. Bilateral vocal cord paralysis was a particularly poor prognosticator for response to surgery.

17.1.4 Other Chiari malformations

Chiari type 0
Patients with syringohydromyelia without hindbrain herniation that respond to p-fossa decompression have been described (so-called “Chiari zero malformation”).

Chiari type 1.5
Obex situated below foramen magnum, does not respond to suboccipital decompression with or without duroplasty.

Chiari type 3
Rare. Both the definition and even the existence are controversial. Most descriptions are based on 1 or 2 cases. Original description cited dislocation of the cerebellum below the foramen magnum into...
an occipital encephalocele. Some have added herniation of the medulla, fourth ventricle and all of the cerebellum into an occipital and high cervical encephalocele. Some have sided with Raimondi who included occipital encephaloceles associated with caudal displacement of the cerebellum and medulla.

Prognosis is poor for most, as it is usually incompatible with life.

Chiari type 4
Originally described as cerebellar hypoplasia without cerebellar herniation. Existence as a distinct clinical entity is debated.

17.2 Neural tube defects
17.2.1 Classification
General information
There is no universally accepted classification system. Two are presented below.

Lemire classification
A system adapted from Lemire. A neurulation defects: non-closure of the neural tube results in open lesions
a) craniorachischisis: total dysraphism. Many die as spontaneous abortion
b) anencephaly: AKA exencephaly. Due to failure of fusion of the anterior neuropore. Neither cranial vault nor scalp covers the partially destroyed brain. Uniformly fatal. Risk of recurrence in future pregnancies: 3%
c) meningomyelocele: most common in lumbar region
- myelomeningocele (MM) (p.265)
- myelocle
2. postneurulation defects: produces skin-covered (AKA closed) lesions (some may also be considered “migration abnormalities”, see below)
a) cranial
- microcephaly: see below
- hydranencephaly: loss of most of cerebral hemispheres, replaced by CSF (see below). Must R/O maximal hydrocephalus (see below)
- holoprosencephaly: see below
- lissencephaly: see below
- porencephaly: see below to distinguish from schizencephaly
- agenesis of corpus callosum: see below
- cerebellar hypoplasia/Dandy Walker syndrome (p.256)
- macroencephaly AKA megalencephaly: see below
b) spinal
- diastematomyelia, diplomyelia: see Split cord malformation (p.274)
- hydromyelia/syringomyelia (p.1144)

Migration abnormalities
A slightly different classification scheme defines the following as abnormalities of neuronal migration (some are considered postneurulation defects, see above):
1. lissencephaly: The most severe neuronal migration abnormality. Maldevelopment of cerebral convolutions (probably an arrest of cortical development at an early fetal age). Infants are severely retarded and usually don’t survive >2 yrs
a) agyria: completely smooth surface
b) pachygyria: few broad & flat gyri with shallow sulci
c) polymicrogyria: small gyri with shallow sulci. May be difficult to diagnose by CT/MRI, and may be confused with pachygyria
2. heterotopia: abnormal foci of (nonenhancing) gray matter which may be located anywhere from the subcortical white matter to (most commonly) the subependymal lining of the ventricles. May manifest as nodules or as a band of cortex. An early migration defect that results from arrest of radial migration. Almost always presents with seizures
3. cortical dysplasia: a cleft that does not communicate with the ventricle. Heterotopias are common. A migration abnormality not quite as severe as schizencephaly
4. schizencephaly:
   a) sine qua non: cleft that communicates with the ventricle (communication may be confirmed with CT cisternogram if necessary)
   b) cleft lined with cortical grey matter (often abnormal, may have polymicrogyria). This distinguishes it from porencephaly, a cystic lesion lined with connective or glial tissue that may communicate with the ventricular system, often caused by vascular infarcts or following intracerebral hemorrhage or penetrating trauma (including repeated ventricular punctures)
   c) two forms:
      • open lipped: large cleft to ventricle. Very severe forms may mimic hydranencephaly (see below)
      • close lipped (walls fused): look for a dimple in the lateral wall of the lateral ventricle immediately under the cortical cleft (the appearance of which may mimic an enlarged sulcus)
   d) may be unilateral or bilateral
   e) pia and arachnoid fuse
   f) there may be an “abnormal” vein that represents a cortical vein that now looks medullary because it follows the cortex into the cleft)
   g) absence of septum pellucidum in 80–90%
   h) presentation may range from seizures to hemiparesis depending on size and location

17.2.2 Examples of neural tube defects

Hydranencephaly

General information
A post-neurulation defect. Total or near-total absence of the cerebrum (small bands of cerebrum may be consistent with the diagnosis), with intact cranial vault and meninges, the intracranial cavity being filled with CSF. There is usually progressive macrocrania, but head size may be normal (especially at birth), and, occasionally, microcephaly may occur. Facial dysmorphism is rare.

May be due to a variety of causes, the most commonly cited is bilateral ICA infarcts (which results in absence of brain tissue supplied by the anterior and middle cerebral arteries with preservation in the distribution of the PCA). May also be due to infection (congenital or neonatal herpes, toxoplasmosis, equine virus).

Less affected infants may appear normal at birth, but are often hyperirritable and retain primitive reflexes (Moro, grasp, and stepping reflex) beyond 6 mo. They rarely progress beyond spontaneous vowel production and social smiling. Seizures are common.

Differentiation from hydrocephalus

Progressive enlargement of CSF spaces may occur which can mimic severe (“maximal”) hydrocephalus (HCP). It is critical to differentiate the two since true HCP may be treated by shunting which may produce some re-expansion of the cortical mantle. Many means to distinguish hydranencephaly and HCP have been described, including:

1. EEG: shows no cortical activity in hydranencephaly (maximal HCP typically produces an abnormal EEG, but background activity will be present throughout the brain and is one of the best ways to differentiate the two
2. CT, MRI or ultrasound: majority of intracranial space is occupied by CSF. Usually do not see frontal lobes or frontal horns of lateral ventricles (there may be remnants of temporal, occipital or subfrontal cortex). A structure consisting of brainstem nodule (rounded thalamic masses, hypothalamus) and medial occipital lobes sitting on the tentorium occupies a midline position surrounded by CSF. Posterior fossa structures are grossly intact. The falx is usually intact (unlike alobar holoprosencephaly), and is not thickened, but may be displaced laterally. In HCP, some cortical mantle is usually identifiable
3. transillumination of the skull: in a darkened room, a bright light is placed against the surface of the skull. To transilluminate, the patient must be <9 mos old and the cortical mantle under the light source must be <1 cm thick, can also occur if fluid displaces the cortex inward (e.g. subdural effusions). Too insensitive to be very helpful
4. angiography: in “classic” cases resulting from bilateral ICA occlusion, no flow through supracliniroid carotids and a normal posterior circulation is expected
Treatment
Shunting may be performed to control head size, but unlike the case with maximal hydrocephalus, there is no restitution of the cerebral mantle.

Holoprosencephaly
AKA arhinencephaly. Failure of the telencephalic vesicle to cleave into two cerebral hemispheres. The degree of cleavage failure ranges from the severe alobar (single ventricle, no interhemispheric fissure) to semilobar and lobar (less severe malformations). The olfactory bulbs are usually small and the cingulate gyrus remains fused. Median facio cerebro dysplasia is common, and the degree of severity parallels the extent of the cleavage failure Table 17.9). 80% are associated with trisomy (primarily trisomy 13, and to a lesser extent trisomy 18). Survival beyond infancy is uncommon, most survivors are severely retarded, a minority are able to function in society. Some develop shunt dependent hydrocephalus. The risk of holoprosencephaly is increased in subsequent pregnancies of the same couple.

Microcephaly
Definition: head circumference more than 2 standard deviations below the mean for sex and gestational age. Terms that are sometimes used synonymously: microcrania, microcephalus. Not a single entity, many of the conditions in Table 17.9 may be associated with microcephaly. It may also result from maternal cocaine abuse. It is important to differentiate microcephaly from a small skull resulting from craniosynostosis in which surgical treatment may provide opportunity for improved cerebral development.

Macroencephaly
Adapted. AKA macrencephaly, AKA megalencephaly. Not to be confused with macrocephaly (p.1403), which is enlargement of the skull. Not a single pathologic entity. An enlarged brain which may be due to: hypertrophy of gray matter alone, gray and white matter, presence of additional structures (glial overgrowth, diffuse gliomas, heterotopias, metabolic storage diseases...).

Conditions in which macrocephaly may be seen include:
- neurocutaneous syndromes (especially neurofibromatosis)
- megalencephaly-capillary malformation syndrome (MCAP): an overgrowth syndrome with megalencephaly (often with hydrocephalus, Chiari malformation, polymicrogyria and seizures), and capillary malformations in the skin (usually on the face)

Brains may weigh up to 1600–2850 grams. IQ may be normal, but developmental delay, retardation, spasticity and hypotonia may occur. Head circumference is 4–7 cm above mean. The usual signs of hydrocephalus (frontal bossing, bulging fontanelle, “setting sun” sign, scalp vein engorgement) are absent. Imaging studies (CT or MRI) show normal sized ventricles and can be used to rule out extra-axial fluid collections.

17.2.3 Risk factors

1. lack of prenatal folic acid: early administration of folic acid\(^{37,38,39}\) (0.4 mg/d if no history of neural tube defects; 4 mg/d in a carrier or with previous child with NTD) was associated with a 71% reduction in recurrence of NTD\(^{40}\) (confirm that vitamin B12 levels are normal)

2. folate antagonists (e.g. carbamazepine) doubles the incidence of MM

3. mothers with 5, 10-methylenetetrahydrofolate reductase (MTHFR) gene polymorphism. The common variant, C677T, substitutes an alanine residue for valine at position 222 in the folate dependent MTHFR enzyme → reduced enzyme activity → reduced levels of tissue folate, and increased levels of homocysteine in the plasma. This polymorphism may be homozygous (TT genotype) or heterozygous (CT genotype); present in ≈10% and 38% of the population, respectively. The effects with the TT genotype are more pronounced than with the heterozygous CT form, and there is an increased risk of neural tube defects, as well as a lesser increased risk of cardiovascular disease\(^{41}\)

4. use of valproic acid (Depakene\(^\circledR\)) during pregnancy is associated with a 1–2% risk of NTD\(^{42}\)

5. maternal heat exposure in the form of hot-tubs, saunas or fever (but not electric blankets) in the first trimester was associated with an increased risk of NTDs\(^{43}\)

6. obesity (before and during pregnancy) increases the risk of NTD\(^{44,45}\)

7. maternal cocaine abuse may increase the risk of microcephaly, disorders of neuronal migration, neuronal differentiation and myelination\(^{35}\)

17.2.4 Prenatal detection of neural tube defects

**Serum alpha-fetoprotein (AFP)**

See Alpha-fetoprotein (p.600) for background. A high maternal serum AFP (≥2 multiples of the median for the appropriate week of gestation) between 15–20 weeks gestation carries a relative risk of 224 for neural tube defects, and an abnormal value (high or low) was associated with 34% of all major congenital defects.\(^{46}\) The sensitivity of maternal serum AFP for spina bifida was 91% (10 of 11 cases), it was 100% for 9 cases of anencephaly. However, other series show a lower sensitivity. Closed lumbosacral spine defects, accounting for ≈20% of spina bifida patients,\(^{37}\) will probably be missed by serum AFP screening, and may also be missed on ultrasound. Since maternal serum AFP rises during normal pregnancy, an overestimate of gestational age may cause an elevated AFP to be interpreted as normal, and an underestimate may cause a normal level to be interpreted as elevated.\(^{48}\)

**Ultrasound**

Prenatal ultrasound will detect 90–95% of cases of spina bifida, and thus in cases of elevated AFP, it can help differentiate NTDs from non-neurologic causes of elevated AFP (e.g. omphalocele), and can help to more accurately estimate gestational age.

**Amniocentesis**

For pregnancies subsequent to a MM, if prenatal ultrasound does not show spinal dysraphism, then amniocentesis is recommended (even if abortion is not considered, it may allow for optimal post-partum care if MM is diagnosed). Amniotic fluid AFP levels are elevated with open neural tube defects, with a peak between weeks 13–15 of pregnancy. Amniocentesis also carries a ≈6% risk of fetal loss in this population.

17.3 Neurenteric cysts

17.3.1 General information

No uniformly accepted nomenclature. Working definition: CNS cyst lined by endothelium primarily resembling that of the GI tract, or less often, respiratory tract. Congenital. Not true neoplasms. Most common alternate term: enterogenous cyst. Less common terms include: teratomatous cyst, intestinoma, archenteric cyst,\(^{49}\) enterogene cyst, and endodermal cyst. Usually affect the upper thoracic and lower cervical spine.\(^{50}\) Associated developmental vertebral anomalies (e.g. diastematomyelia) are common.\(^{51}\) Rarely intracranial (see below). Spinal neurenteric cysts (NEC) may have a fistulous or fibrous connection to the GI tract (through a spinal dysraphism) and some call these endodermal
sinus cysts. Occurs as a result of persistence of the neurenteric canal (temporary duct between the notochord and the primitive gut (amniotic and yolk sacs) formed during week 3 of embryogenesis by breakdown of the floor of the notochordal canal).

17.3.2 Intracranial neurenteric cysts

General information

Rare, most common in p-fossa. Initially, may be difficult to rule-out metastasis from an extremely well-differentiated primary adenocarcinoma of unknown origin (absence of progressive disease suggests NEC). Locations:

1. posterior fossa
   a) cerebellopontine angle (CPA): usually intradural, extraaxial (case report of extradural lesion with bone destruction)
   b) in midline anterior to brainstem
   c) cisterna magna

2. supratentorial: only 15 case reports as of 2004. Locations: suprasellar (possible confusion with Rathke’s cleft cyst), frontal lobe intraparenchymal, quadrigeminal plate region, dural-based extra-axial. Source of endoderm is controversial since the primitive foregut extends cranially only to the midbrain. Theory: colloid cysts, Rathke cleft cysts, and supratentorial NECs may all arise from remnants of Seessel’s pouch, a transient endodermally derived diverticulum of the cranial end of the embryonic foregut.

Clinical

Most commonly present during the first decade of life. Pain or myelopathy from the intraspinal mass are the most common presentations in older children and adults. Neonates and young children may present with cardiorespiratory compromise from an intrathoracic mass, or with cervical spinal cord compression. Meningitis may occur from the fistulous tract, especially in newborns and infants.

Imaging

Intracranial NEC:
- CT: usually low density, nonenhancing
- T1W1 MRI: isointense or slight hyperintense to CSF (may be hyperintense if there are blood products). T2W1 isointense to CSF. Nonenhancing

Histology

Most are simple cysts lined by cuboidal-columnar epithelium and mucin secreting goblet cells. Less common types of epithelium described include: stratified squamous and pseudostratified columnar, and ciliated epithelial cells. Mesodermal components may be present, including smooth muscle and adipose tissue, and some have called these teratomatous cysts which is not to be confused with teratomas which are true germinal cell neoplasms. May be histologically identical to colloid cysts.

Treatment

Spinal NEC
Surgical removal usually reverses the symptoms. Recurrence is uncommon with complete removal of cyst wall.

Intracranial NEC
Capsule adherent to brainstem may prevent complete resection, which predisposes to delayed recurrence. Apparently successful treatment by evacuation of contents and marsupialization has been reported (5 cases, mean follow-up: 5 yrs). Incomplete removal requires long-term follow-up. Hydrocephalus is shunted if indicated.
References

18 Coma

18.1 General information

Consciousness has two components: arousal and content. Impairment of arousal can vary from mild (drowsiness or somnolence), to obtundation, to stupor to coma. Coma is the severest impairment of arousal, and is defined as the inability to obey commands, speak, or open the eyes to pain.

The Glasgow Coma Scale (GCS) is a widely used scoring system with good repeatability and is shown in Table 18.1 (note: the scale is used to assess level of consciousness and is not designed for following neurologic deficits). General practice is to record a “T” (for “intubated”) next to the verbal score and the total score for patients whose verbal axis cannot be assessed because of intubation. No single GCS score defines a cutoff for coma, however, 90% of patients with GCS $\leq 8$ and none with GCS $\geq 9$ meet the above definition of coma. Thus, GCS $\leq 8$ is a generally accepted operational definition of coma.

A number of scales for use in children have been proposed. One is shown in Table 18.2.

Coma results from one or more of the following:

- dysfunction of high brainstem (central upper pons) or midbrain
- bilateral diencephalic dysfunction
- diffuse lesions in both cerebral hemispheres (cortical or subcortical white matter)

18.2 Posturing

18.2.1 General information

The following terms do not accurately localize the site of the lesion. Decorticate posturing implies a more rostral lesion than extensor posturing, and prognosis may be slightly better.

18.2.2 Decorticate posturing

Classically attributed to disinhibition by removal of corticospinal pathways above the midbrain.

**Overview:** abnormal flexion in UE and extension in LE.

**Detail:**
- UE: slow flexion of arm, wrist and fingers with adduction
- LE: extension, internal rotation, plantarflexion

18.2.3 Decerebrate posturing

Classically attributed to disinhibition of vestibulospinal tract (more caudal) and pontine reticular formation (RF) by removing inhibition of medullary RF (transection at intercollicular level, between vestibular and red nuclei).

**Overview:** abnormal extension in UE and LE.

**Detail:**
- Head & trunk: opisthotonos (head and trunk extended), teeth clenched
- UE: arms extended, adducted and hyperpronated (internally rotated), wrists flexed, fingers flexed
- LE: extended and internally rotated, feet plantarflexed and inverted, toes plantarflexed.

18.3 Etiologies of coma

18.3.1 Toxic/metabolic causes of coma

1. electrolyte imbalance: especially hypo- or hypernatremia, hypercalcemia, renal failure with elevated BUN & creatinine, liver failure with elevated ammonia
2. endocrine: hypoglycemia, nonketotic hyperosmolar state, DKA (diabetic ketoacidosis, AKA diabetic coma), myxedema coma, Addisonian crisis (hypoadrenalism)
3. vascular: vasculitis, DIC, hypertensive encephalopathy (p.194)
4. toxic: ETOH, drug overdose (including narcotics, iatrogenic polypharmacy, barbiturates), lead intoxication, carbon monoxide (CO) poisoning, cyclosporine (causes an encephalopathy that shows white-matter changes on MRI that is often reversible with discontinuation of the drug)
5. infectious/inflammatory: meningitis, encephalitis, sepsis, lupus cerebritis, neurosarcoidosis (p.189), toxic-shock syndrome
6. neoplastic: leptomeningeal carcinomatosis, rupture of neoplastic cyst
7. nutritional: Wernicke's encephalopathy, vitamin B12 deficiency
8. inherited metabolic disorders: porphyria, lactic acidosis
9. organ failure: uremia, hypoxemia, hepatic encephalopathy, Reye's syndrome, anoxic encephalopathy (e.g. post-resuscitation from cardiac arrest), CO2 narcosis
10. epileptic: status epilepticus (including non-convulsive status), post-ictal state (especially with unobserved seizure)

18.3.2 Structural causes of coma

1. vascular:
   a) bilateral cortical or subcortical infarcts (e.g. with cardioembolism due to SBE, mitral stenosis, A-fib, mural thrombus...)
   b) occlusion of vessel supplying both cerebral hemispheres (e.g. severe bilateral carotid stenosis)
   c) bilateral dienccephalic infaracts: well described syndrome. May be due to occlusion of a thalamo-perforator supplying both medial thalamic areas or with "top-of-the-basilar" occlusion. Initially resembles metabolic coma (including diffuse slowing on EEG), patient eventually arouses with apathy, memory loss, vertical gaze paresis
2. infectious: abscess with significant mass effect, subdural empyema, herpes simplex encephalitis
3. trauma: hemorrhagic contusions, edema, hematoma (see below)
4. neoplastic: primary or metastatic
5. herniation from mass effect: presumably brainstem compression causes dysfunction of reticular activating system or mass in one hemisphere causing compression of the other results in bilateral hemisphere dysfunction

6. increased intracranial pressure: reduces CBF

7. acute lateral shift (midline shift) of the brain: e.g. due hematoma (subdural or epidural)

Table 18.3

18.3.3 Pseudocoma

Differential diagnosis:
1. locked-in syndrome: ventral pontine infarction
2. psychiatric: catatonia, conversion reaction
3. neuromuscular weakness: myasthenia gravis, Guillain-Barré

18.3.4 Approach to the comatose patient

General information

This section addresses nontraumatic coma. See Head trauma (p. 824) for that topic.

Initial evaluation: includes measures to protect brain (by providing CBF, O2, and glucose), assesses upper brainstem (Cr. N. VIII), and rapidly identifies surgical emergencies. Keep "pseudocoma" as a possible etiology in back of mind.

Outline of approach to comatose patient

1. cardiovascular stabilization: establish airway, check circulation (heartbeat, BP, carotid pulse), CPR if necessary
2. obtain blood for tests
   a) STAT: electrolytes (especially Na, glucose, BUN), CBC+diff, ABG
   b) others as appropriate: toxicology screen (serum & urine), calcium, ammonia, antiepileptic drug (AED) levels (if patient is taking AEDs)
3. administer emergency supportive medications
   a) glucose: at least 25 ml of D50 IV P. Due to potentially harmful effect of glucose in global ischemia, if possible check fingerstick glucose first, otherwise glucose is given without exception, unless it is known with certainty that serum glucose is normal
   b) naloxone (Narcan®): in case of narcotic overdose. 1 amp (0.4 mg) IVP
   c) flumazenil (Romazicon®): in case of benzodiazepine overdose. Start with 0.2 mg IV over 30 seconds, wait 30 secs, then give 0.3 mg over 30 secs at 1 minute intervals up to 3 mg or until patient arouses
   d) thiamine: 50–100 mg IVP (3%of Wernicke's present with coma)
4. core neuro exam (assesses midbrain/upper pons, allows emergency measures to be instituted rapidly, more thorough evaluation possible once stabilized): see Core neuro exam below
5. if herniation syndrome or signs of expanding p-fossa lesion with brainstem compression (Table 18.4): initiate measures to lower ICP – see Treatment measures for elevated ICP (p.866) -, then get a CT scan if patient begins improving, otherwise emergency surgery. Do NOT do LP
6. if meningitis suspected (altered mental status + fever, meningeal signs…)
   a) if no indication of herniation, p-fossa mass (Table 18.4), focal deficit indicating mass effect or papilledema: perform LP, start antibiotics immediately (do not wait for CSF results); see Meningitis (p.318)
   b) if evidence of possible mass effect, coagulopathy or herniation, CT to R/O mass. If significant delay anticipated, consider empiric antibiotics or careful LP with small gauge needle (≤22

Ga.), measure opening pressure (OP), remove only a small amount of CSF if OP high, replace CSF if patient deteriorates; LP in this setting may be risky, see Lumbar puncture (p.1504).

7. treat generalized seizures if present. If status epilepticus is suspected, treat as indicated (p.470); obtain emergency EEG if available

8. treat metabolic abnormalities
   a) restore acid-base balance
   b) restore electrolyte imbalance
   c) maintain body temperature

9. obtain as complete history as possible once stabilized

10. administer specific therapies

Core neuro exam for coma

Respiratory rate and pattern
The most common disorder in impaired consciousness (this information is often lacking in patients that are intubated early in their course):
• Cheyne-Stokes (Fig. 18.1 a): breathing gradually crescendos in amplitude and then trails off, followed by an inspiratory pause, and then the pattern repeats. Hyperpneic phase is usually longer than apneic. Usually seen with diencephalic lesions or bilateral cerebral hemisphere dysfunction (non-specific), e.g. early increased ICP or metabolic abnormality. Results from an increased ventilatory response to CO₂
• hyperventilation: usually in response to hypoxemia, metabolic acidosis, aspiration, or pulmonary edema. True central neurogenic hyperventilation is rare, and usually results from dysfunction within the pons. If no other brainstem signs are present, may suggest psychiatric disorder
• cluster breathing (Fig. 18.1 b): periods of rapid irregular breathing separated by apneic spells, may appear similar to Cheyne-Stokes, may merge with various patterns of gasping respirations. High medulla or lower pons lesion. Often an ominous sign
• apneustic (rare; Fig. 18.1 c): a pause at full inspiration. Indicates pontine lesion, e.g. with basilar artery occlusion
• ataxic (Biot’s breathing; (Fig. 18.1 d): no pattern in rate or depth of respirations. Seen with medullary lesion. Usually preterminal

Pupil
Record size (in mm) in ambient light, and in reaction to direct/consensual light
1. equal and reactive pupils indicates toxic/metabolic cause with few exceptions (see below) (may have hiripus). The light reflex is the most useful sign in distinguishing metabolic from structural coma
   a) the only metabolic causes of fixed/dilated pupil: glutethimide toxicity, anoxic encephalopathy, anticholinergics (including topically applied atropine), occasionally with botulism toxin poisoning
   b) narcotics cause small pupils (miosis) with a small range of constriction and sluggish reaction to light (in severe overdose, the pupils may be so small that a magnifying glass may be needed to see reaction)

</tbody>
</table>
2. unequal; note: an afferent pupillary defect does not produce anisocoria, see Alterations in pupillary diameter (p.561)
   a) fixed and dilated pupil: usually due to oculomotor palsy. Possible herniation, especially if larger pupil associated with ipsilateral 3rd nerve EOM palsy (eye deviated “down and out”)
   b) possible Horner’s syndrome: consider carotid occlusion/dissection (NB: in Horner’s syndrome, the miotic (smaller) pupil is the abnormal one)
3. bilateral pupil abnormalities
   a) pinpoint with minute reaction that can be detected with magnifying glass: pontine lesion (sympathetic input is lost; parasympathetics emerge at Edinger-Westphal nucleus and are unopposed)
   b) bilateral fixed and dilated (7–10 mm): subtotal damage to medulla or immediate post-anoxia or hypothermia (core temperature <90° F (32.2° C))
   c) midposition (4–6 mm) and fixed: more extensive midbrain lesion, presumably due to interruption of sympathetics and parasympathetics

Extraocular muscle function
1. deviations of ocular axes at rest
   a) bilateral conjugate deviation:
      • frontal lobe lesion (frontal center for contralateral gaze): looks toward side of destructive lesion (away from hemiparesis). Looks away from side of seizure focus (looks at jerking side), may be status epilepticus. Reflex eye movements (see below) are normal
      • pontine lesion: eyes look away from lesion and towards hemiparesis; calorics impaired on side of lesion
      • “wrong way gaze”: medial thalamic hemorrhage. Eyes look away from lesion and towards hemiparesis (an exception to the axiom that the eyes look towards a destructive supratentorial lesion)
      • downward deviation: may be associated with unreactive pupils, Parinaud’s syndrome (p.99). Etiologies: thalamic or midbrain pretectal lesions, metabolic coma (especially barbiturates), may follow a seizure
   b) unilateral outward deviation on side of larger pupil (III palsy): uncal herniation
   c) unilateral inward deviation: VI (abducens) nerve

Fig. 18.1 Respiratory rate and pattern.
   a) Cheyne-Stokes respiratory pattern
   b) Cluster breathing
   c) Apneustic respiratory pattern
   d) Ataxic respirations

---

http://e-surg.com
d) skew deviation
   - III or IV nerve/nucleus lesion
   - infratentorial lesion (frequently dorsal midbrain)

2. spontaneous eye movements
   a) “windshield wiper eyes”: random roving conjugate eye movements. Non-localizing. Indicates an intact III nucleus and medial longitudinal fasciculus
   b) periodic alternating gaze, AKA “ping-pong gaze”: eyes deviate side to side with frequency of ≈ 3–5 per second (pausing 2–3 secs in each direction). Usually indicates bilateral cerebral dysfunction
   c) ocular bobbing (p.570): repetitive rapid vertical deviation downward with slow return to neutral position.

3. internuclear ophthalmoplegia (INO) (p.565): due to lesion in medial longitudinal fasciculus (MLF) (fibers crossing to contralateral III nucleus are interrupted). Eye ipsilateral to MLF lesion does not adduct on spontaneous eye movement or in response to reflex maneuvers (e.g. calories)

4. reflex eye movements (maneuvers to test brainstem)
   a) oculovestibular reflex, AKA ice water caloric: first rule-out TM perforation and occlusion of the EAC by cerumen. Elevate the HOB 30°, irrigate one ear with 60–100 ml of ice water. NB: response is inhibited by neuromuscular blocking agents (NMBA)
      - a comatose patient with an intact brainstem will have tonic conjugate eye deviation to side of cold stimulus which may be delayed up to one minute or more. There will be no fast component (nystagmus) (the cortical component) even if the brainstem is intact. (NB: oculocephalic reflex (doll’s eyes) provides similar information as oculovestibular reflex, but poses a greater risk to the spinal cord if C-spine not cleared)
      - no response: symmetrical, could be specific toxin (e.g. neuromuscular block or barbiturates), metabolic cause, brain death or possibly massive infratentorial lesion
      - asymmetric: infratentorial lesion, especially if response inconsistent with 3rd nerve palsy (herniation). Usually maintained in toxic/metabolic coma
      - nystagmus without tonic deviation (i.e. eyes remain in primary position) virtually diagnostic of psychogenic coma
      - contralateral eye fails to adduct: INO (MLF lesion)
   b) optokinetic nystagmus presence strongly suggests psychogenic coma

Notes:
   a Oculovestibular reflexes (calorics): the anticipated response is commonly misunderstood. In a normal awake patient there is slow deviation towards the side of the cold stimulus with nystagmus (which is named for the rapid, cortical phase) in the opposite direction (hence the mnemonic “COWS” (cold-opposite, warm-same)). Nystagmus will be absent in the comatose patient.
   b HOB at 30° places the horizontal semicircular canal (SCC) vertically for maximal response. Cold water → downward endolymphatic currents, away from the ampulla of the horizontal SCC.
   c Oculocephalic reflex (“doll’s eyes” or “doll’s head”): do not perform if there is any uncertainty about cervical-spine stability. In an awake patient, the eyes will either move with the head, or, if the movement is slow enough and the patient is fixating on an object, there will be contraversive conjugate eye movement (c.f. oculovestibular reflex which does not depend on patient’s level of cooperation). In a comatose patient with an intact brainstem & cranial nerves, there will also be contraversive conjugate eye movement (a positive doll’s eyes response).
   d Oculovestibular reflexes are absent but oculocephalic are maintained only when vestibular inputs are interrupted, e.g. streptomycin toxicity of labyrinths or bilateral vestibular schwannomas.

Motor
Record muscle tone and reflexes, response to pain, plantar reflex (Babinski). Note asymmetries
1. appropriate: implies corticospinal tracts and cortex intact
2. asymmetric: supratentorial lesion (tone usually increased), unlikely in metabolic
3. inconsistent/variable: seizures, psychiatric
4. symmetric: metabolic (usually decreased). Asterixis, tremor, myoclonus may be present in metabolic coma
5. hyporeflexia: consider myxedema coma, especially in patient presenting weeks after transsphenoidal surgery
6. patterns
   a) decorticate posturing: arms flex, legs extend: large cortical or subcortical lesion
   b) decerebrate posturing: arms and legs extend: brainstem injury at or below lower midbrain
c) arms flexed, legs flaccid: pontine tegmentum
d) arms flaccid, legs appropriate ("man-in-the-barrel syndrome"): anoxic injury (poor prognosis)

Ciliospinal reflex
Pupillary dilatation to noxious cutaneous stimuli: tests integrity of sympathetic pathways
1. bilaterally present: metabolic
2. unilaterally present: possible 3rd nerve lesion (herniation) if on side of larger pupil. Possible pre-existing Horner’s syndrome if on side of smaller pupil
3. bilaterally absent: usually not helpful

18.4 Herniation syndromes

18.4.1 General information
Classic teaching has been that shifts in brain tissue (e.g. caused by masses or increased intracranial pressure) through rigid openings in the skull (herniation) compress other structures of the CNS producing the observed symptoms. In actuality it may be that herniation is an epiphenomenon that occurs late in the process and is not actually the cause of the observations. However, herniation models still serve as useful models.

The five most common herniation syndromes are:
- Supratentorial herniation
  - central (transtentorial) herniation (p.303)
  - uncal herniation (p.304)
- Cingulate herniation: cingulate gyrus herniates under falx (AKA subfalcine herniation). Usually asymptomatic unless ACA kinks and occludes causing bifrontal infarction. Usually warns of impending transtentorial herniation
- Infratentorial herniation
  - upward cerebellar (see below)
  - tonsillar herniation (see below)

18.4.2 Coma from supratentorial mass

See reference.

General information
Central and uncal herniation each causes a different form of rostral-caudal deterioration. Central herniation results in sequential failure of: diencephalon, midbrain, pons, medulla (p.303). See also uncal herniation (p.304). “Classic” signs of increased ICP (HTN, bradycardia, altered respiratory pattern) usually seen with p-fossa lesions may be absent in slowly developing supratentorial masses.

Distinction between central and uncal herniation is difficult when dysfunction reaches the midbrain level or below. Predicting the location of the lesion based on the herniation syndrome is unreliable.

Clinical characteristics differentiating uncal from central herniation
- decreased consciousness occurs early in central herniation, late in uncal
- uncal herniation syndrome rarely gives rise to decorticate posturing

Differential diagnosis of supratentorial etiologies
1. vascular: stroke, intracerebral hemorrhage, SAH
2. inflammatory: cerebral abscess, subdural empyema, herpes simplex encephalitis
3. neoplastic: primary or metastatic
4. traumatic: epidural or subdural hematoma, depressed skull fracture

18.4.3 Coma from infratentorial mass

General information
NB: it is essential to identify patients with primary posterior fossa lesions (Table 18.4) as they may require emergent surgical intervention.
Etiologies of infratentorial masses:
1. vascular: brainstem infarction (including basilar artery occlusion), cerebellar infarction or hematoma
2. inflammatory: cerebellar abscess, central pontine myelinolysis, brainstem encephalitis
3. neoplasms: primary or metastatic
4. traumatic: epidural or subdural hematoma

Hydrocephalus
Infratentorial masses can produce obstructive hydrocephalus by compressing the Sylvian aqueduct and/or 4th ventricle.

Upward cerebellar herniation
Occasionally seen with p-fossa masses, may be exacerbated by ventriculostomy. Cerebellar vermis ascends above tentorium, compressing the midbrain, and possibly occluding SCAs → cerebellar infarction. May compress sylvian aqueduct → hydrocephalus.

Tonsillar herniation
Cerebellar tonsils “cone” through foramen magnum, compressing medulla → respiratory arrest. Usually rapidly fatal.

Stage of central herniation
Diencephalic stage
Early. May be due to diffuse bilateral hemisphere dysfunction (e.g. from decreased blood flow from increased ICP) or (more likely) from bilateral diencephalic dysfunction due to downward displacement. This stage warns of impending (irreversible) midbrain damage but is frequently reversible if the cause is treated.

Consciousness: Altered alertness is first sign; usually lethargy, agitation in some. Later: stupor → coma.

Pupils: Small (1 – 3 mm), small range of contraction.

Oculomotor: Conjugate or slightly divergent roving eyes; if conjugate then brainstem intact. Usually positive DOLLS EYES and conjugate ipsilateral response to cold water calorics (CWC). Impaired upgaze due to compression of superior colliculi and diencephalic pretectum: Parinaud’s syndrome (p. 99)

Motor: Early: appropriate response to noxious stimuli, bilateral Babinski, gegenhalten (paratonic resistance). If previously hemiparetic contralateral to lesion: may worsen. Later: motionlessness & grasp reflexes, then DECORTICATE (initially contralateral to lesion in most cases).
Midbrain – upper pons stage
When midbrain signs fully developed (in adults), prognosis is very poor (extreme ischemia of midbrain). Fewer than 5% of cases will have a good recovery if treatment is successfully undertaken at this stage.

Respiration: Moderately dilated midposition (3–5 mm), fixed. Note: in pontine hemorrhage pinpoint pupils appear because the loss of sympathetics leaves the parasympathetics unopposed, whereas in herniation, the parasympathetics are usually lost, too (3rd nerve injury).

Oculomotor: Doll’s eyes & CWC impaired, may be dysconjugate. MLF lesion → internuclear ophthalmoplegia (when doll’s or CWC elicited and dysconjugate, medially moving eye moves less than laterally moving eye).

Motor: Decorticate → bilaterally DECREASE (occasionally spontaneously).

Lower pons – upper medullary stage
Respiration: Regular, shallow and rapid (20–40/min).

Oculomotor: Doll’s eyes and CWC unelicitable.

Medullary stage (terminal stage)
Respiration: Slow, irregular rate and depth, sighs/gasps. Occasionally hyperpnea alternating with apnea

Outcome after central herniation
In a series of 153 patients with signs of central herniation (altered level of consciousness, anisocoria or fixed pupils, abnormal motor findings) 9% had good recovery, 18% had functional outcome, 10% were severely disabled, and 60% died.

Factors associated with a better result were young age (especially age ≤17 yrs), anisocoria with deteriorating Glasgow Coma Score and nonflaccid motor function. Factors associated with poor outcome were bilaterally fixed pupils, with only 3.5% of these patients having a functional recovery.

18.4.5 Uncal herniation
General information
Usually occurs in rapidly expanding traumatic hematomas, frequently in the lateral middle-fossa or temporal lobe pushing medial uncus and hippocampal gyrus over edge of tentorium, entrapping third nerve and directly compressing midbrain. PCA may be occluded (as with central herniation). For CT criteria see below.

Impaired consciousness is NOT a reliable early sign. Earliest consistent sign: unilaterally dilating pupil. However, it is unlikely that a patient undergoing early uncal herniation would be completely neurologically intact except for anisocoria (do not dismiss confusion, agitation, etc.). Once brainstem findings appear, deterioration may be rapid (deep coma may occur within hours).

CT and/or MRI criteria
See reference.

The tentorial incisura surrounds the interpeduncular and pre-pontine cisterns and brainstem. There is great interpersonal variability in the amount of space in the incisura.

Impending uncal or hippocampal herniation may be indicated by encroachment on lateral aspect of suprasellar cistern → flattening of normal pentagonal shape. Once herniation occurs CT may show: brainstem displacement and flattening, compression of contralateral cerebral peduncle, midbrain rotation with slight increase of ipsilateral subarachnoid space. Also, contralateral hydrocephalus may occur.

Obliteration of parasellar and interpeduncular cisterns occurs as uncus and/or hippocampus are forced through hiatus. Brainstem is elongated in AP direction due to lateral compression. Since dural
structures enhance with IV contrast, this may be used to help delineate tentorial margins when necessary.

**Stages of uncal herniation**

**Early third nerve stage**
This is not a brainstem finding, it is due to 3rd nerve compression.
- Pupils: Approach to the comatose patient
  - Oculomotor: Doll’s eyes (oculocephalic reflex) = normal or dysconjugate. CWC (oculovestibular reflex) = slow ipsilateral deviation, impaired nystagmus, may be dysconjugate if external oculomotor ophthalmoplegia (EOO).
  - Respirations: Normal.

**Late third nerve stage**
Midbrain dysfunction occurs almost immediately after symptoms extend beyond those due to focal cerebral lesion (i.e. may skip diencephalic stage, due to lateral pressure on midbrain). Treatment delays may result in irreversible damage.
- Pupils: Pupil fully dilates.
  - Oculomotor: Once pupil blown, then external oculomotor ophthalmoplegia (EOO).
  - Consciousness: Once EOO occurs: stupor → coma
  - Respirations: Sustained hyperventilation, rarely Cheyne-Stokes.
  - Motor: Usually produces contralateral weakness. However, the contralateral cerebral peduncle may be compressed against the tentorial edge causing ipsilateral hemiplegia (Kernohan’s phenomenon, a false localizing sign). Then bilateral decerebration (decortication unusual).

**Midbrain – upper pons stage**
Contralateral pupil fixes in midposition or full dilation. Eventually, both midposition (5–6 mm) and fixed.
- Oculomotor: Impaired or absent.
- Respirations: Sustained hyperpnea.
- Motor: Bilateral decerebrate rigidity.

Following the midbrain – upper pons stage
From this point onward, the uncal syndrome is indistinguishable from central herniation (see above).

**18.5 Hypoxic coma**

Hypoxic encephalopathy may be due to anoxic anoxia (drop in pO₂) or anemic anoxia (following exsanguination or cardiac arrest). Myoclonus is common.

Vulnerable cells:
1. cerebral grey matter: lesions predominate in 3rd cortical layer (white matter is usually better preserved due to lower O₂ requirements)
2. Ammon’s horn is also vulnerable, especially the Sommer section
3. in the basal ganglia (BG):
   a) anoxic anoxia severely affects globus pallidus
   b) anemic anoxia affects the caudate nucleus and putamen
4. in the cerebellum: Purkinje cells, dentate nuclei, and inferior olives are affected

Multivariate analysis yields outcome prognosticators shown in Table 18.5 and Table 18.6. NB: this analysis applies only to hypoxic-ischemic coma; and is based retrospectively on 210 patients, most S/P cardiac arrest with many medical complications. More recent studies confirm the poor prognosis of unreactive pupils and lack of motor response to pain; if either of these findings are seen within a few hours after cardiac arrest there is an 80% risk of death or permanent vegetative state, and if present at 3 days these this rate rose to 100%.

Glucocorticoids (steroids) have been shown to have no beneficial effect on survival rate or neurological recovery rate after cardiac arrest.

19 Brain Death and Organ Donation

19.1 Brain death in adults

The President’s Commission for the Study of Ethical Problems in Medicine first published guidelines for the determination of death in 1981 which contributed to the approval of the Uniform Determination of Death Act (UDDA; policy statement, see box).

**Uniform determination of death act, 1980 (verbatim quote)**

“An individual who has sustained either
1. irreversible cessation of circulatory and respiratory functions, or
2. irreversible cessation of all functions of the entire brain, including the brain stem, is dead.

A determination of death must be made with accepted medical standards.”

Most states have adopted the UDDA, although some have enacted amendments stipulating qualifications of the determining clinician(s). Individual hospitals may also mandate that certain protocols be followed.

As reaffirmed in 2010, when the clinical determination of brain death is made in accordance with the original published guidelines, there has been no report of recovery of neurologic function in adults.

19.2 Brain death criteria

19.2.1 General information

This section deals with brain death in adults. For individuals <5 years age, see Brain death in children (p.312).

When the cause of death is other than natural causes the Medical Examiner or Coroner (depending on the authority in your jurisdiction) will be contacted per hospital policy.

Key point: Criteria shown below may be used to determine the clinical absence of brain and brainstem function. Then to ensure that the total cessation of brain function is irreversible, the clinician must take into consideration the cause of the absence, and exclude conditions that can mimic the clinical appearance of brain death. This may require ancillary confirmatory tests and observation for a period of time.

Waiting periods: There is insufficient evidence to support a specific observation period to ensure that the cessation of neurologic function is irreversible. This requires that the determination of brain death take into consideration all of the available information and circumstances.

19.2.2 Establishing the cause of cessation of brain activity

The cause of the cessation of brain activity (CBA) can usually be determined by a combination of history, physical examination, laboratory tests and imaging studies.

19.2.3 Clinical criteria

See Table 19.1 for a summary of basic requirements and clinical findings that may be used in determining brain death. Details follow below.

Recommendations1,5,3:

1. Absence of brainstem reflexes:
   a) ocular examination:
      • fixed pupils: no response to bright light (caution after resuscitation: see below). The size of the pupils is unimportant (they are usually midposition (4–6 mm) but may vary to dilated range (9 mm): dilated pupils can be compatible with brain death because cervical sympathetic pathways may remain intact)
      • absent corneal reflexes (corneal reflex: eye closing to corneal, not scleral, stimulation)
Table 19.1 Summary of findings in brain death (see text for details)

Absence of brainstem reflexes

| • Fixed pupils                  | No pupillary reaction to light |
| • Absent corneal reflexes       | Touching cornea with a gauze does not cause eye closure |
| • Absent oculovestibular reflex (calorics) | No eye movement of any sort to ice water in ear with HOB elevated to 30° |
| • Absent oculocephalic reflex: “Doll’s eyes” (p. 301) | Turning the head does not cause contralateral eye deviation (clear C-spine first) |
| • Absent gag reflex             | No gagging reaction to movement of ET tube |
| • Absent cough reflex           | No coughing in response to bronchial suctioning |

No response to deep central pain

| Stimulate areas like supraorbital ridge. No limb movement, no eye movement, no facial movement |

Failed apnea challenge

| No respirations with pCO₂ > 60 mm Hg |

- absent oculocephalic “doll’s eyes” reflex (p. 301), contraindicated if C-spine not cleared
- absent oculovestibular reflex (cold water calorics): instill 60–100 ml ice water into one ear (do not do if TM perforated) with HOB at 30°. Brain death is excluded if any eye movement. Wait at least 1 minute for response, and ≥ 5 min before testing the opposite side (to prevent cancellation of opposing response)

b) absent oropharyngeal reflex (gag) to stimulation of posterior pharynx

c) no cough response to bronchial suctioning

2. apnea test AKA apnea challenge: no spontaneous respirations after disconnection from ventilator (assesses function of medulla). Respirations are defined as abdominal or chest excursions that produce adequate tidal volumes; if there is any question, a spirometer may be connected to the patient. Since elevating PaCO₂ increases ICP which could precipitate herniation and vasomotor instability, this test should be reserved for last and only used when the diagnosis of brain death is reasonably certain. Guidelines:

a) Apnea for >2 minutes with PaCO₂ > 60 mm Hg or PaCO₂ > 20 mm Hg over baseline or pH < 7.3 (CO₂ is the most potent stimulus for respirations). If patient does not breathe by this point, they won’t breathe at a higher PaCO₂. Not as valid with severe COPD

b) to prevent hypoxemia during the test (with the danger of cardiac arrhythmia or myocardial infarction):

- preoxygenate for ≥ 10 minutes before the test with 100% FIO₂ to PaO₂ > 200 mm Hg
- prior to the test, reduce the ventilator rate to bring the PaCO₂ to 35-40 mm Hg (to shorten the test time and thus reduce the risk of hypoxemia)
- during the test, have passive O₂ flow administered at 6 L/min through either a pediatric oxygen cannula or a No. 14 French tracheal suction catheter (with the side port covered with adhesive tape) passed to the estimated level of the carina

c) starting from normocapnea, the average time to reach PaCO₂ = 60 mm Hg is 6 minutes (classic teaching is that PaCO₂ rises 3 mm Hg/min, but in actuality this the rate at which PaCO₂ rises varies widely, with an average 3.7 ± 2.3 mm Hg/min if starting at normocarbia). Sometimes as long as 12 minutes may be necessary

d) the test is aborted if:

- the patient breathes (chest or abdominal movement, gasps): incompatible with brain death
- SBP < 90 mm Hg (hypotension)
- if O₂ saturation drops < 80% for > 30 seconds (on pulse oximeter)
- significant cardiac arrhythmias occur
c) if patient does not breathe, send ABG at regular intervals and at the completion of test regardless of reason for termination. If the patient does not breathe for at least 2 minutes after a PaCO2 > 60 mm Hg is documented, then the test is valid and is compatible with brain death (if the patient is stable and ABGs results are available within a few minutes, the apnea challenge may be continued while waiting for results in case the PaCO2 is < 60).

f) if PaCO2 stabilizes below 60 mm Hg and the pO2 remains adequate, try reducing the passive O2 flow rate slightly (O2 flow may be washing out CO2 from lungs).

g) the test is positive (i.e. compatible with brain death) if there are no respirations and PaCO2 is ≥ 60 mm Hg (or there is a 20 mm Hg rise in PaCO2 above baseline).

3. no motor function

a) no response to deep central pain: there should be no movement of limbs, no eye opening or eye movement, no facial movement.

b) true decerebrate or decorticate posturing or seizures are incompatible with the diagnosis of brain death.

c) spinal cord mediated reflex movements (including flexor plantar reflexes, flexor withdrawal, muscle stretch reflexes, and even abdominal and cremasteric reflexes) can be compatible with brain death, and may occasionally consist of complex movements, including bringing one or both arms up to the face, or sitting up (the “Lazarus” sign) especially with hypoxemia (thought to be due to spinal cord ischemia stimulating surviving motor neurons in the upper cervical cord). If complex integrated motor movements occur, it is recommended that confirmatory testing be performed prior to pronouncement of brain death.

4. absence of complicating conditions (that could simulate brain death on exam):

a) hypothermia: core temp should be > 36°C (96.8°F). Below this temp, pupils may be fixed and dilated, respiration may be difficult to detect, and recovery is possible.

b) no evidence of remediable exogenous or endogenous intoxication, including drug or metabolic intoxication (blood alcohol level should be < 0.08%, barbiturates, benzodiazepines, meperidine, methaqualone, trichloroethylene, paralytics, hepatic encephalopathy, hyperosmolar coma…). If there is doubt, depending on circumstances, lab tests including drug levels (serum and urine) may be sent. Pseudocholinesterase deficiency is present in 1/3000 patients which can cause succinycholine to last up to 8 hours (instead of 5 mins). A twitch monitor can rule-out NMB (place the electrodes immediately behind the eye or across the zygomatic arch).

c) shock (neuro exam should be reliable if SBP ≥ 100 mm Hg) and anoxia. Loss of ≥ 45% of circulating blood volume can produce lethargy.

d) immediately post-resuscitation: shock or anoxia may cause fixed and dilated pupils. Atropine (p.311) may cause slight dilatation but not unreactivity. Neuromuscular blockage (e.g. for intubation) does not affect pupils because the iris lacks nicotinic receptors.

e) patients coming out of pentobarbital coma (wait until level ≤ 10 mcg/ml).

5. confirmation of brain death by use of Ancillary confirmatory tests (preferred tests: EEG, CRAG or angiography, see below) is not required. May be used at the discretion of the physician, generally if there is uncertainty about the reliability of other parts of the exam.

6. recommended observation periods: there is insufficient evidence to determine a minimal observation period to ensure that neurologic function has irreversibly ceased:

a) in situation where overwhelming brain damage from an irreversible condition is well established (e.g. massive intracerebral hemorrhage, gunshot wound traversing the brain…), and no uncertainty in the clinical exam, an ancillary confirmatory tests would usually not be necessary.

b) in clear-cut situations as outlined above, if several hours have passed since the onset of the brain insult, a single neurologic examination consistent with brain death should suffice though many states require two examinations by statute (see state and local laws below).

c) in less clear-cut situations (e.g. anoxic brain injury, hypothermia…), longer observation periods are appropriate and ancillary confirmatory tests may be considered (see below).

19.2.4 State and local laws

Most states have adopted the Uniform Determination of Death Act (UDDA) regarding brain death. State amendments and local regulations or hospital policies may dictate that more than 1 practitioner must concur on the diagnosis. It is incumbent that the practitioner know the applicable regulations before making the diagnosis.
19.2.5 Ancillary confirmatory tests

General information

There is insufficient evidence that any ancillary test can accurately determine brain death. Preferred tests: EEG, CRAG or angiography.

Cerebral angiography

Requires absence of cerebral blood flow, which is incompatible with brain survival. Pros: highly sensitive for determining death of cerebral hemispheres. Cons: costly, time-consuming, requires transport of the patient to x-ray department, invasive, potentially damaging to organs that may be used for donation, and is not optimal for detecting small amount of blood flow to brainstem. Requires a radiologist and technician. Criteria: absence of intracranial flow at the level of the carotid bifurcation or circle of Willis. Filling of the superior sagittal sinus may occur in a delayed fashion and is not incompatible with brain death. Interobserver validity has not been studied. Not routinely used in the diagnosis of brain death, but may be employed in difficult situations.

EEG

Can be done at bedside. Requires experienced interpreter. Does not detect brainstem activity, and electrocerebral silence (ECS) (i.e. isoelectric EEG) does not exclude the possibility of reversible coma.

Use ECS as a clinical confirmatory test only in patients without drug intoxication, hypothermia, or shock, and not in patients where brainstem activity might be preserved (i.e. situations where the clinical brainstem exam cannot be performed). Note: a practical problem with EEG for brain-death determination is that it is often difficult to get a tracing that is totally free of electrical signal even in patients who are brain dead by other criteria.

Definition of electrocerebral silence on EEG: no electrical activity >2 mcV with the following requirements:
1. recording from scalp or referential electrode pairs ≥10 cm apart
2. 8 scalp electrodes and ear lobe reference electrodes
3. inter-electrode resistance <10,000 Ω (or impedance <6,000 Ω) but over 100 Ω
4. sensitivity of 2 mcV/mm
5. time constants 0.3–0.4 sec for part of recording
6. no response to stimuli (pain, noise, light)
7. record >30 mins
8. repeat EEG in doubtful cases
9. qualified technologist and electroencephalographer with ICU EEG experience
10. telephone transmission not permissible

Cerebral radionuclide angiogram (CRAG)

General information

Can be done using a gamma camera, or more contemporary HMPAO SPECT (for 99mTc-hexamethylpropyleneamine oxime single-photon emission CT). May not detect minimal blood flow to the brain, especially brainstem. Necessitates transport to the radiology/nuclear medicine department and requires an experienced interpreter.

May be useful to confirm clinical brain death in the following settings:
1. where complicating conditions are present, e.g. hypothermia, hypotension (shock), drug intoxication… (e.g. patients emerging from barbiturate coma), metabolic abnormalities
2. in patients with severe facial trauma where evaluation of ocular findings may be difficult or confusing
3. in patients with severe COPD or CHF where apnea testing may not be valid
4. to shorten the observation period

Technique

Using gallium camera
1. scintillation camera is positioned for an AP head and neck view
2. inject 20–30 mCi of 99mTc-labeled serum albumin or pertechnetate in a volume of 0.5–1.5 ml into a proximal IV port, or a central line, followed by a 30 ml NS flush
3. perform serial dynamic images at 2 second intervals for ≈60 seconds
4. then, obtain static images with 400,000 counts in AP and then lateral views at 5, 15 & 30 minutes after injection
5. If a study needs to be repeated because of a previous non-diagnostic study or a previous exam incompatible with brain death, a period of 12 hours should lapse to allow the isotope to clear from the circulation.

Findings
No uptake in brain parenchyma = “hollow skull phenomenon” (Fig. 19.1). Termination of carotid circulation at the skull base, and lack of uptake in the ACA and MCA distributions (absent “candelabra effect”). There may be delayed or faint visualization of dural venous sinuses even with brain death due to connections between the extracranial circulation and the venous system.

MRI and MR angiography (MRA)
MRA is very sensitive for detecting loss of blood flow in cavernous ICA, however the specificity has not been accurately evaluated (i.e. might give false positives for brain death in comatose patients) and is not considered a valid confirmatory test.

CT angiography (CTA)
Blood flow on CTA (i.e. not consistent with brain death) was seen in patients with isoelectric EEG. False positive rate had not been determined in comatose non-brain dead patients. CTA is not considered to be a valid confirmatory test for brain death.

Transcranial doppler
See reference.

- Not widely used.
- Small peaks in early systole without diastolic flow or reverberating flow (indicative of significantly increased ICP)
- Initial absence of doppler signals cannot be used as criteria for brain death since 10% of patients do not have temporal insonation windows

SSEPs
One protocol requires bilateral absence of N20-P22 response with median nerve stimulation. An alternative criteria is disappearance of the P14 peak (substrate: medial lemniscus and nucleus cuneatus) on nasopharyngeal electrode recordings. Studies were judged as Class III data and that P14 recordings could be a valuable confirmatory test but that this test has not been used routinely and that interobserver variability needed to be studied.

Atropine
In brain death, 1 amp of atropine (1 mg) IV should not affect the heart rate due to the absence of vagal tone (the normal response to atropine of increased heart rate rules out brain death, but...
absence of the response is not helpful since some conditions such as Guillain-Barre may blunt the response).

Systemic atropine in usual doses causes slight pupillary dilatation, but does not eliminate reaction to light (therefore, to eliminate uncertainty, it is prudent to examine the pupils before giving the atropine).

19.2.6 Pitfalls in brain death determination

The following pitfalls may complicate the determination of brain death:

- Movement of body parts after brain death. Movements are sometimes complex in nature, and may occur as long as 32 hours after brain death. Many are mediated by spinal cord discharges as it undergoes cell death. Documented observations include: facial movements, finger tremor, repetitive leg movements, and even sitting up. These movements are often repetitive, usually stereotypical, and do not change with changing stimuli.
- The appearance of breathing. This typically occurs with a ventilator that is set to trigger on detecting respiratory effort. Ventilators may be sensing air movement created by transmission of arterial pulses of the great vessels to the lung or actions of a chest tube.

19.3 Brain death in children

19.3.1 General information

The following is based on 2011 guidelines that are endorsed by the Society of Critical Care Medicine, The Section for Critical Care and Section of Neurology of the American Academy of Pediatrics and the American College of Critical Care Medicine.

Key points:

- The diagnosis of brain death in term newborns, infants and children is a clinical diagnosis requiring absence of neurologic function and a known irreversible cause of loss of function.
- These guidelines are not supported for infants < 37 weeks gestational age because of insufficient data
- Ancillary tests are not required and are not a substitute for a correctly performed neurologic exam
- Two examinations that include apnea testing separated by an observation period is recommended
- Treat and correct conditions that can interfere with the neurologic exam including: hypothermia, hypotension, interfering drugs (high levels of sedatives, analgesics, paralytics, high doses of anti-convulsant drugs) and metabolic disturbances

19.3.2 Clinical examination

Two examinations each including apnea testing, each consistent with brain death, performed by different attending physicians separated by an observation period are required. Apnea testing may be performed by the same physician.

Apnea testing requires documentation of arterial PaCO2 that is 20 mm Hg above the baseline and ≥ 60 mm Hg with no respiratory effort. If apnea testing cannot be safely completed, an ancillary study should be done.

Recommended observation periods between exams:

- For term newborns (37 weeks gestational age) through 30 days of age: 24 hours
- For infants and children (> 30 days to 18 years): 12 hours
- Following cardiopulmonary resuscitation, the diagnosis of brain death should be deferred ≥ 24 hrs if there are concerns or inconsistencies in the examination

19.3.3 Ancillary studies

These tests are not required to make the determination of brain death. Use may be considered:

- When apnea testing cannot be safely completed e.g. due to underlying medical conditions or desaturation to < 85% or inability to achieve PaCO2 ≥ 60 mm Hg
- If there is uncertainty about results of the neurologic examination
- If drugs that interfere with the neurologic exam may be present
- To reduce the inter-examination observation period

When ancillary tests are employed, a second neurologic examination and apnea test should be performed to the extent possible, and there should not be any finding inconsistent with brain death.
19.4 Organ and tissue donation

19.4.1 General considerations

The Center for Medicare Services (CMS) conditions of participation require all hospitals that receive Medicare funds to refer all imminent deaths to the local Organ Procurement Organization (OPO).\(^{20}\) The OPO is responsible for the determination of suitability and for discussion of donation with the legal next of kin. The discussion must be by trained personnel. The OPO is also responsible for organ donor management, allocation and facilitating recovery of organs in the OR.\(^{20}\)

19.4.2 Referral of the potential organ donor

Most OPO’s have developed a process for referral of the potential organ donor by educating the critical care nurses to referral by a set of “triggers.” The triggers usually include patients with a neurologic injury (anoxia, hemorrhage, trauma etc.), on a ventilator and either losing brain stem reflexes, GCS < 5 or for discussion of withdrawal of support. This set of triggers results in the referral of many patients not suitable for donation but allows for the early notification of the OPO and reduces the risk of missed referrals.

19.4.3 Medical management of the potential organ donor

Brain death results in several predictable physiologic aberrations. Many hospitals have developed “Catastrophic Brain Injury” order sets to address these predictable consequences.

Hypotension

With hypovolemia due to diabetes insipidus and destruction of the pontine and medullary vasomotor centers most brain dead patients are hypotensive. Treatment requires restoration of a euvolemic state and support with vasopressors. Usually norepinephrine to supply inotropic support and neosynephrine to increase peripheral vascular resistance is sufficient to support the blood pressure.

Diabetes insipidus

With loss of hypothalamic function brain dead individuals frequently have posterior pituitary dysfunction and diabetes insipidus. This is manifest by large volume dilute urinary output, hypernatremia and hyperosmolar serum. Management options include DDAVP injection (1-2 mcg SC/IV q 12 hours) or a vasopressin drip (0.01 – 0.04 units/min IV). The vasopressin drip may be preferable because the shorter duration of action can help avoid oliguria due to overdosing.

Hypothermia

Loss of temperature regulation frequently causes hypothermia which can worsen coagulopathy and invalidate brain death testing. Application of a warming blanket to support temperature will help restore normal physiology.

19.4.4 Organ Procurement Organization (OPO) process

Authorization

OPO staff will respond to referrals and after discussion with medical staff and nursing staff engage the family in a discussion involving authorization for organ donation. United Network for Organ Sharing (UNOS) data has demonstrated that OPO trained staff have higher authorization rates than medical staff. This is thought to be due to the position of the OPO staff only advocating for donation and if the treating staff advocates for donation there may be a sense of abandonment.

Donor evaluation

The OPO staff will evaluate donor suitability. Donors will be ruled out if there is thought to be a high potential for transmission of malignancy. The OPO will screen for blood-borne pathogens (HIV, HCV, HBV). Each organ will be evaluated for suitability.

- Heart: EF > 50% no LVH, no CAD
- Lungs: P/F Ratio > 300, normal bronchoscopy
- Liver: ALT, AST, GGTP and bilirubin WNL or returning to normal and no known liver disease
- Kidneys: BUN and Creatinine WNL
- Pancreas: normal lipase, amylase and HgbA1c

Allocation and recovery

Once brain death occurs in a patient authorized or organ donation, the OPO will allocate organs according to UNOS allocation policy and UNOS generated allocation lists. When the transplant centers have accepted organs an OR time will be set and the teams will come to the donor hospital for organ recovery. The time frame from authorization until organ recovery frequently takes 24 to 36 hours or longer.

19.4.5 Organ donation after cardiac death

General information

Key concepts

- candidates: ventilator dependent patients (typically with brain or spinal cord injury) where the family has decided to withdraw support and the medical team expects the patient would progress to asystole less than 60 minutes after withdrawal
- consent from legal next of kin for: organ donation, heparin, and femoral lines
- clearance from medical examiner when applicable (usually, cases of unnatural death)
- counsel the family that the procedure cannot be done in $\approx 20\%$ of cases. They are to be notified immediately if this happens and end-of-life care continues
- the transplant team cannot participate in end-of-life care or declaration of death, and should not be in O.R. until after cardiac death is declared

Candidates for organ donation after cardiac death are typically ventilator dependent patients with brain or spinal cord injuries who are so near death that further treatment is futile, but who do not meet brain death criteria. Organs typically recovered in this manner: kidneys, liver, pancreas, lungs, and rarely the heart.

Ethical concerns related to DCD organ recovery have been raised. The Institute of Medicine has reviewed DCD twice (1997 and 2000) and determined DCD to be ethically sound and OPO’s have been encouraged to pursue DCD donation.

Consent

Prior to any discussion of donation, the family should have made their decision to withdraw support and allow the patient to progress to death. After the family has had this discussion with the treating physician, the OPO can discuss DCD with the legal next of kin. Consent must also be obtained for any donation-related procedures prior to death (which typically includes heparin infusion to prolong organ viability and the possibility of femoral catheters). The discussion should also include process to return to ICU if the patient does not progress to asystole.

Clearance from the medical examiner must be obtained in applicable cases (including deaths due to accident, homicide, suicide...).

Procedure

Life sustaining measures are discontinued (typically consisting of extubation) usually in the operating room. Death is pronounced typically $\approx 2$ to 5 minutes after cardiac activity becomes insufficient to generate a pulse, because limited data indicates that circulation will not spontaneously return (NB: EKG activity does not need to cease). After declaration of death, cold perfusion of organs is performed and they are procured.

To avoid potential conflicts of interest, no member of the transplant team can participate in end-of-life care nor the declaration of death. About 20% of the time, the progression to cardiac death does not occur in a timeframe that permits organ retrieval. In these cases, organ donation is cancelled, the family must be immediately notified, and end-of-life care continues.

20 Bacterial Infections of the Parenchyma and Meninges and Complex Infections

20.1 Meningitis

20.1.1 General information

Community acquired meningitis (CAM) is generally more fulminant than meningitis following neurosurgical procedures or trauma (CAM tends to occur with more virulent organisms or in individuals with impaired host defenses). Waterhouse-Friderichs page en syndrome: occurs in 10–20% of children with meningococcal infection (usually disseminated infection in age <10 yrs), produces large petechial hemorrhages in the skin and mucous membranes, fever, septic shock, adrenal failure (due to hemorrhage into adrenal glands) and DIC. Focal neurologic signs are rare in acute purulent meningitis. Community acquired meningitis is a medical emergency, and should be treated immediately. See Lumbar puncture (p.323) for a discussion about when to perform an LP.

The remainder of this chapter discusses meningitis that is not community acquired.

20.1.2 Post-neurosurgical procedure meningitis

1. usual organisms: coagulase-negative staphylococci, S. aureus, Enterobacteriaceae, Pseudomonas sp., pneumococci usually with basilar skull fractures and otorhinologic surgery
2. empiric antibiotics: vancomycin (to cover MRSA), adult 15 mg/kg q 8-12 hours to achieve trough 15-20 mg/dl + cefipime 2 gm IV q 8 hrs
3. if severe PCN allergy, use aztreonam 2gm IV q6-8 H or ciprofloxacin 400 mg IV q8h
4. if severe infection, consider intrathecal therapy delivered daily (use only preservative free drug)
   - vancomycin
   - tobramycin/gentamicin
   - amikacin
   - colistin
5. streamline ABX based on sensitivities, e.g. if organism turns out to be MSSA, change vancomycin oxacillin or nafcillin

For suspected CSF fistula

1. usual organisms: streptococci; see CSF fistula (cranial) (p.384)
2. treatment/work-up; see CSF fistula (cranial) (p.384)
3. immunocompromised host (e.g. AIDS)
   a) usual organisms: as above PLUS Cryptococcus neoformans, M. tuberculosis, HIV aseptic meningitis, L. monocytogenes
   b) empiric antifungal agents for cryptococcal meningitis: Induction therapy: Liposomal amphotericin B 3-4 mg/kg IV daily + flucytosine25 mg/kg PO QID for at least 2 weeks followed by
   c) Consolidation therapy: fluconazole 400 mg PO daily for at least 8 weeks followed by
   d) Chronic maintenance therapy: fluconazole 200 mg PO daily

20.1.3 Post craniospinal trauma meningitis (post-traumatic meningitis)

Epidemiology

Occurs in 1–20% of patients with moderate to severe head injuries.¹ Most cases occur within 2 weeks of trauma, although delayed cases have been described.² 75% of cases have demonstrable basal skull fracture (p.884), and 58% had obvious CSF rhinorrhea.

Pathogens

As expected from above, there is a high rate of infection with organisms indigenous to the nasal cavity. The most common organisms in a series from Greece were Gram-positive cocci (Staph. hemoliticus, S. warneri, S. cohnii, S. epidermidis, and Strept. pneumonia) and Gram-negative bacilli (E. coli, Klebsiella pneumonia, Acinetobacter anitratus).¹
Treatment

1. See also CSF Fistula, Treatment (p.388)
2. Antibiotics: appropriate antibiotics are selected based on CSF penetration and organism sensitivities (adapted to the pathogens common in the patient’s locale; in the above series, all Gram-negative strains appeared resistant to ampicillin and third-generation cephalosporins, but were sensitive to imipenem and ciprofloxacin; Gram-positive strains were all sensitive to vancomycin). For empiric antibiotics: Vancomycin 15 mg/kg IV q8-12 hours to achieve trough 15-20 mg/dl + meropenem 2gm IV q8h
3. Surgical treatment vs. “conservative treatment”: controversial. Some feel that any case of post-traumatic CSF rhinorrhea should be explored, and that cases of spontaneous cessation often represent obscuration by incarcerated brain, so-called “sham healing” with the potential for later CSF leak and/or meningitis. Others support the notion that cessation (possibly with the assistance of lumbar spinal drainage) is acceptable
4. Continue antibiotics for 1 week after CSF is sterilized. If rhinorrhea persists at this time, surgical repair is recommended

20.1.4 Recurrent meningitis
Patients with recurrent meningitis must be evaluated for the presence of abnormal communication with the intraspinal/intracranial compartment. Etiologies include dermal sinus (p.270) (either spinal or cranial), CSF fistula (p.384), or neurenteric cyst (p.290).

20.1.5 Chronic meningitis
Usually due to one of the following etiologies:
1. tuberculosis
2. fungal infections
3. cysticercosis, neurocysticercosis (p.371)

Differential diagnosis includes:
1. sarcoidosis
2. meningeval carcinomatosis

20.1.6 Antibiotics for specific organisms in meningitis
Specific antibiotics
See reference.

Route is IV unless specified otherwise.
   a) if MIC≤0.06: PCN G or ampicillin, alternative: third generation cephalosporin (ceftriaxone)
   b) if MIC≥0.12: third generation cephalosporin (ceftriaxone)
   c) if cephalosporin resistance: vancomycin
   d) alternative: moxifloxacin
2. N. meningitidis: PCN G (2nd choice: chloramphenicol)
   a) if MIC≤0.1 PCN G or ampicillin
   b) if MIC≥0.1: third generation cephalosporin (ceftriaxone)
   c) alternative: moxifloxacin, meropenem
3. H. influenza: a) beta lactamase negative: ampicillin
   b) beta lactamase positive
      • third generation cephalosporin (ceftriaxone)
      • alternative: aztreonam, ciprofloxacin
4. Group B strep
   a) ampicillin
   b) alternative: vancomycin
5. L. monocytogenes
   a) ampicillin ± IV gentamicin
   b) alternative: IV sulfamethoxazole/trimethoprim
6. S. aureus
   a) if methicillin susceptible
      • oxacillin or nafcillin
      • PCN allergy: vancomycin
b) if methicillin resistant
   • vancomycin ± rifampin
   • alternative: linezolid ± rifampin
7. aerobic Gram negative bacilli (GNB)
   a) ceftriaxone, or cefotaxime, or moxifloxacin (in order of preference, make alterations based on sensitivities)
   b) if aminoglycoside required, intraventricular therapy may be indicated after the newborn period
8. P. aeruginosa
   a) ceftazidime or cefepime
   b) alternative meropenem or aztreonam
   c) if ventriculitis: consider IT gentamicin or tobramycin
9. Candida spp: Liposomal amphotericin B 3-4 mg/kg IV daily + flucytosine25 mg/kg PO QID

Length of treatment for meningitis
Generally continue antibiotics for 10–14 days total. Duration is dependent on organism and clinical response. Treatment should be 21 days for listeria, group B strep and some GN bacilli.

20.2 Cerebral abscess
20.2.1 General information

Key concepts

- may arise from hematogenous spread, contiguous spread, or direct trauma
- risk factors: pulmonary abscess or AV fistulas, congenital cyanotic heart disease, immune compromise, chronic sinusitis/otitis, dental procedures
- symptoms are similar to any other mass lesions but tend to progress rapidly
- peripheral WBC may be normal or slightly ↑, CRP usually ↑
- organisms: Streptococcus is most common, up to 60% are polymicrobial
- imaging: usually round with thin enhancing ring on CT or MRI. T2WI → high signal lesion with thin rim of low intensity surrounded by high signal (edema). Unlike with tumor, DWI often shows core of restricted diffusion (not reliable)
- treatment: IV antibiotics, needle drainage for some, excision infrequently (for fungal or resistant abscess)

20.2.2 Epidemiology
Approximately 1500–2500 cases per year in the U.S. Incidence is higher in developing countries. Male:female ratio is 1.5–3:1.

20.2.3 Risk factors
Risk factors include: pulmonary abnormalities (infection, AV-fistulas…, see below), congenital cyanotic heart disease (see below), bacterial endocarditis, penetrating head trauma (see below), chronic sinusitis or otitis media, and immunocompromised host (transplant recipients on immunosuppressants, HIV/AIDS).

20.2.4 Vectors
General information
Prior to 1980, the most common source of cerebral abscess was from contiguous spread. Now, hematogenous dissemination is the most common vector. In 10–60% no source can be identified.⁶
Hematogenous spread

Abscesses arising by this means are multiple in 10–50% of cases.7 No source can be found in up to 25% of cases. The chest is the most common origin:

1. in adults: lung abscess (the most common), bronchiectasis and empyema
2. in children: congenital cyanotic heart disease (CHHD) (estimated risk of abscess is 4–7% which is ≈10-fold increase over general population), especially tetralogy of Fallot (which accounts for ≈50% of cases). The increased Hct and low PO2 in these patients provides an hypoxic environment suitable for abscess proliferation. Those with right-to-left (veno-atrial) shunts additionally lose the filtering effects of the lungs (the brain seems to be a preferential target for these infections over other organs). Streptococcal oral flora is frequent, and may follow dental procedures. Coexisting coagulation defects often further complicate management8
3. pulmonary arteriovenous fistulas: ≈50% of these patients have Osler-Weber-Rendu syndrome (AKA hereditary hemorrhagic telangetasia), and in up to 5% of these patients a cerebral abscess will eventually develop
4. bacterial endocarditis: only rarely gives rise to brain abscess.9 More likely to be associated with acute endocarditis than with subacute form
5. dental abscess
6. GI infections: pelvic infections may gain access to the brain via Batson’s plexus

In patients with septic embolization, the risk of cerebral abscess formation is elevated in areas of previous infarction or ischemia.10

Contiguous spread

1. from purulent sinusitis: spreads by local osteomyelitis or by phlebitis of emissary veins. Virtually always singular. Rare in infants because they lack aerated paranasal and mastoid air cells. This route has become a less common source of cerebral abscess due to improved treatment of sinus disease (with antibiotics and, especially with surgery for chronic otitis media and mastoiditis)
   a) middle-ear and mastoid air sinus infections → temporal lobe and cerebellar abscess. The risk of developing a cerebral abscess in an adult with active chronic otitis media is ≈1/10,000 per year11 (this risk appears low, but in a 30 year-old with active chronic otitis media the lifetime risk becomes ≈1 in 200)
   b) ethmoidal and frontal sinusitis → frontal lobe abscess
   c) sphenoid sinusitis: the least common location for sinusitis, but with a high incidence of intracranial complications due to venous extension to the adjacent cavernous sinus → temporal lobe
2. odontogenic → frontal lobe. Rare. Associated with a dental procedure in the past 4 weeks in most cases.12 May also spread hematogenously

Following penetrating cranial trauma or neurosurgical procedure

Following penetrating trauma: The risk of abscess formation following civilian gunshot wounds to the brain is probably very low with the use of prophylactic antibiotics, except in cases with CSF leak not repaired surgically following traversal of an air sinus. An abscess following penetrating trauma cannot be treated by simple aspiration as with other abscesses, open surgical debridement to remove foreign matter and devitalized tissue is required.

Post-neurosurgical: especially with traversal of an air sinus. Abscess has been reported following use of intracranial pressure monitors and halo traction.13

20.2.5 Pathogens

1. cultures from cerebral abscesses are sterile in up to 25% of cases
2. organisms recovered varies with the primary source of infection
3. in general: Streptococcus is the most frequent organism, 33–50% are anaerobic or microaerophilic. Multiple organisms may be cultured to varying degrees (depends on care of technique), usually in only 10–30% of cases, but can approach 60%8 and usually includes anaerobes (Bacteroides sp. common)
4. when secondary to fronto-ethmoidal sinusitis: Strep. milleri and Strep. anginosus may be seen
5. from otitis media, mastoiditis, or lung abscess: usually multiple organisms, including anaerobic strep., Bacteroides, Enterobacteriaceae (Proteus)
6. post traumatic: usually due to S. aureus or Enterobacteriaceae
7. odontogenic (dental) source: may be associated with Actinomyces
8. following neurosurgical procedures: Staph. epidermidis and aureus may be seen
9. immunocompromised hosts including transplant patients (both bone marrow and solid organ) and AIDS: fungal infections are more common than otherwise would be seen. Organisms include:
   a) Toxoplasma gondii (p.334); see also treatment (p.333)
   b) Nocardia asteroides (p.336)
   c) Candida albicans
   d) Listeria monocytogenes
   e) mycobacterium
   f) Aspergillus fumigatus often from a primary pulmonary infection
10. infants: Gram negatives are common because IgM fraction of antibodies don’t cross the placenta

20.2.6 Presentation
Adults: no findings are specific for abscess, and many are due to edema surrounding the lesion. Most symptoms are due to increased ICP (H/A, N/V, lethargy). Hemiparesis and seizures develop in 30–50% of cases. Symptoms tend to progress more rapidly than with neoplasms.
Newborns: patent sutures and poor ability of infant brain to ward off infection → cranial enlargement. Papilledema is rare before 2 yrs of age. Common findings: seizures, meningitis, irritability, increasing OFC, and failure to thrive. Most newborns with abscess are afebrile. Prognosis is poor.

20.2.7 Stages of cerebral abscess
Table 20.1 shows the four well recognized histologic stages of cerebral abscess, and correlates this with the resistance to insertion of an aspirating needle at the time of surgery. It takes at least 2 weeks to progress through this maturation process, and steroids tend to prolong it.

20.2.8 Evaluation
Bloodwork
Peripheral WBC: may be normal or only mildly elevated in 60–70% of cases (usually >10,000).
   Blood cultures: should be obtained when abscess is suspected, usually negative.
   ESR: may be normal (especially in congenital cyanotic heart disease CCID where polycythemia lowers the ESR).
   C-reactive protein (CRP): hepatic synthesis increases with inflammatory conditions, however, infection anywhere in body (including brain abscess and dental abscess) can raise the CRP level. May also be elevated in noninfectious inflammatory conditions and brain tumor. Sensitivity for abscess is ≈ 90%, specificity is ≈ 77%. See also normal values (p.347).

</table>

*aabscess is = the only process in the brain that leaves a collagen scar, all other scars are glial scars
Lumbar puncture (LP)
The role of LP is very dubious in abscess. Although LP is abnormal in >90% there is no characteristic finding diagnostic of abscess. The OP is usually increased, and the WBC count and protein may be elevated. The offending organism can rarely be identified from CSF obtained by LP (unless abscess ruptures into ventricles) with positive cultures in ≈ 6–22%15. There is a risk of transtentorial herniation, especially with large lesions.

Due to the risk involved and the low yield of useful information, avoid the use of LP in evaluating patients with suspected cerebral abscess if not already done.

Brain imaging
CT
Ring enhancing. Sensitivity ≈ 100% For CT staging of abscess see below.

MRI
See Table 20.2 for findings. Enhanced T1WI → thin-walled ring enhancement surrounding low intensity central region (Fig. 89.1). Fluid-fluid levels may be seen. Occassionally gas producing organisms may cause pneumocephalus.

Diffusion MRI: DWI → bright, ADC → dark (restricted diffusion suggesting viscous fluid)16 (Fig. 89.1). Unlike most tumors which are dark on DWI (Fig. 89.2). More reliable with pyogenic abscess, less reliable e.g. with fungal17 or TB abscess.

MR-spectroscopy: presence of amino acids and either acetate or lactate are diagnostic for abscess.

Infrequently used imaging
Leukocyte scan with 99mTc-HMPAO: patient's own WBCs are tagged and reinjected. Close to 100% sensitivity and specificity (sensitivity will be reduced if patient is treated with steroids within 48 hrs prior to the scan).14

Staging cerebral abscess on imaging
CT staging
Late cerebritis (stage 2) has similar features to early capsule (stage 3) on routine contrast and non-contrast CT. There is some therapeutic importance in differentiating these two stages; the following aids in distinguishing18:

1. cerebritis: tends to be more ill-defined
   a) ring-enhancement: usually appears by late cerebritis stage, usually thick
   b) further diffusion of contrast into central lumen, and/or lack of decay of enhancement on delayed scan 30–60 min after contrast infusion
2. capsule:
   a) faint rim present on pre-contrast CT (necrotic center with edematous surrounding brain cause collagen capsule to be seen)
   b) thin ring enhancement AND (more importantly) delayed scans → decay of enhancement

NB: Thin ring enhancement but lack of delayed decay correlates better with cerebritis
NB: Steroids reduce degree of contrast enhancement (especially in cerebritis)

</tr>
</tbody>
</table>
MRI staging

Table 20.2 shows MRI findings in cerebral abscess. In the cerebritis stage, the margins are ill defined.

Additional evaluation

CXR and chest CT (if indicated) to look for pulmonary source.
Cardiac echo (including TEE, Doppler and/or echo with agitated saline injection (bubble study)): for suspected hematogenous spread, to look for patent foramen ovale or cardiac vegetations.

20.2.9 Treatment

General information

There is no single best method for treating a brain abscess. Treatment usually involves:
- Surgical treatment: needle drainage or excision
- correction of the primary source
- long-term use of antibiotics: often IV x 6–8 weeks and possibly followed by oral route x 4–8 weeks.
  Duration should be guided by clinical and radiographic response

Surgical vs. pure medical management

General information

In a patient with suspected cerebral abscess, tissue should be obtained in almost every case to confirm diagnosis and to isolate pathogens (preferably before initiation of antibiotics).

Medical treatment

In general, surgical drainage or excision is employed in the treatment. Purely medical treatment of early abscess (cerebritis stage) is controversial. NB: pathogens were cultured from well encapsulated abscesses despite adequate levels of appropriate antibiotics in 6 patients who failed medical therapy. Failure may be due to poor blood supply and acidic conditions within the abscess (which may inactivate antibiotics in spite of concentrations exceeding the MIC).

Medical therapy alone is more successful if:
1. treatment is begun in cerebritis stage (before complete encapsulation), even though many of these lesions subsequently go on to become encapsulated
2. small lesions: diameter of abscesses successfully treated with antibiotics alone were 0.8–2.5 cm (1.7 mean). Those that failed were 2–6 cm (4.2 mean).
   3 cm is suggested as a cutoff above this diameter surgery should be included
3. duration of symptoms ≤ 2 wks (correlates with higher incidence of cerebritis stage)
4. patients show definite clinical improvement within the first week

Medical management alone considered if:
1. poor surgical candidate (NB: with local anesthesia, stereotactic biopsy can be done in almost any patient with normal blood clotting)
2. multiple abscesses, especially if small
3. abscess in poorly accessible location: e.g. brain stem
4. concomitant meningitis/ependymitis

Indications for surgical treatment

Indications for initial surgical treatment include:
1. significant mass effect exerted by lesion (on CT or MRI)
2. difficulty in diagnosis (especially in adults)
3. proximity to ventricle: indicates likelihood of intraventricular rupture which is associated with poor outcome
4. evidence of significantly increased intracranial pressure
5. poor neurologic condition (patients responds only to pain, or does not even response to pain)
6. traumatic abscess associated with foreign material
7. fungal abscess
8. multiloculated abscess
9. follow-up CT/MRI scans cannot be obtained every 1–2 weeks
10. failure of medical management: neurological deterioration, progression of abscess towards ventricles, or after 2 wks if the abscess is enlarged. Also considered if no decrease in size by 4 wks.

http://e-surg.com
Management

**General outline**
- obtain blood cultures
- initiate antibiotic therapy (preferably after biopsy specimen obtained), regardless of which mode of treatment (medical vs. surgical) is chosen (see below)
- LP (p. 323): avoid in most cases of cerebral abscess
- anticonvulsants: indicated for seizures, prophylactic use is optional
- steroids: controversial. Reduces edema, but may impede therapy (see below)

**Antibiotic selection**

1. initial antibiotics of choice when pathogen unknown, and especially if S. aureus suspected (if there is no history of trauma or neurosurgical procedure, then the risk of MRSA is low):
   - vancomycin: covers MRSA. 15 mg/kg IV q8-12 hours to achieve trough 15-20 mg/dl PLUS
   - a 3rd generation cephalosporin (ceftriaxone); utilize cefepime if post surgical PLUS
   - metronidazole (Flagyl®). Adult: 500 mg q6-8 hours
   - alternative to cefepime + metronidazole: meropenem 2gm IV q8h
   - make appropriate changes as sensitivities become available
2. if culture shows only strep, may use PCN (high dose) alone or with ceftriaxone
3. if cultures show methicillin sensitive staph aureus and the patient does not have a beta lactam allergy, can change vancomycin to nafcillin (adult: 2 gm IV q 4 hrs. peds: 25 mg/kg IV q 6 hrs)
4. Cryptococcus neoformans, Aspergillus sp., Candida sp.: Liposomal amphotericin B 3-4 mg/kg IV daily + flucytosine25 mg/kg PO QID.
5. in AIDS patients: Toxoplasma gondii is a common pathogen, and initial empiric treatment with sulfadiazine + pyrimethamine + leucovorin is often used (p. 332)
6. for suspected or confirmed nocardia asteroides, see details (p. 336)

**Antibiotic duration**

IV antibiotics for 6–8 wks (most commonly 6), may then D/C even if the CT abnormalities persist (neovascularity remains). NB: CT improvement may lag behind clinical improvement. Duration of treatment may be reduced if abscess and capsule entirely excised surgically. Oral antibiotics may be used following IV course.

**Glucocorticoids (steroids)**

Reduces edema and decreases likelihood of fibrous encapsulation of abscess. May reduce penetration of antibiotics into abscess. Immune suppression may also be deleterious.

Reserved for patients with clinical and imaging evidence of deterioration from marked mass effect, and duration of therapy should be minimized.

**Follow-up imaging**

If therapy is successful, imaging should show decrease in:
1. degree of ring enhancement
2. edema
3. mass effect
4. size of lesion: takes 1 to 4 wks (2.5 mean). 95% of lesions that will resolve with antibiotics alone decrease in size by 1 month

**Surgical treatment**

**Options**
See reference.
1. needle aspiration: the mainstay of surgical treatment. Especially well-suited for multiple or deep lesions (see below) may also be used with thin walled or immature lesions
2. surgical excision: Shortens length of time on antibiotics and reduces risk of recrudescence. Recommended in traumatic abscess to debride foreign material (especially bone), and in fungal abscess because of relative antibiotic resistance (see below)
3. external drainage: controversial. Not frequently used
4. instillation of antibiotics directly into the abscess: has not been extremely efficacious, although it may be used as for refractory Aspergillus abscesses
Needle aspiration
Most often implemented with stereotactic localization especially for deep lesions. May be performed under local anesthesia if necessary (e.g. in patients who are poor surgical candidates for general anesthesia). May be combined with irrigation with antibiotics or normal saline. Repeated aspirations are required in up to 70% of cases. May be the only surgical intervention required (in addition to antibiotics), but sometimes must be followed with excision (especially with multiloculated abscess).

Performed through a trajectory chosen to:
1. minimize the path length through the brain
2. avoid traversing the ventricles or vital neural or vascular structures
3. avoid traversing infected structures outside the intracranial compartment (infected bone, paranasal sinuses, and scalp wounds)
4. in cases of multiples abscesses, target:
   a) when the diagnosis is unknown: the largest lesion or the one causing the most symptoms
   b) once the diagnosis of abscess is confirmed:
      • any lesion ≥ 2.5 cm diameter
      • lesions causing significant mass effect
      • enlarging lesions

Cultures
Send aspirated material for the following:
1. stains
   a) Gram stain
   b) acid-fast stain for Mycobacterium (AFB stain, acid-fast resist decolorization with an acid-alcohol mixture and retain the initial dye carbolfuchsin and appear red. The genus Mycobacterium and the genus Nocardia are acid-fast, all other bacteria will be decolorized and stain blue, the color of the counterstain methylene blue)
   c) modified acid-fast stain (for Nocardia, see below) looking for branching acid fast bacillus
   d) special fungal stains (e.g., methenamine silver, mucicarmine)
2. culture
   a) routine cultures: aerobic and anaerobic
   b) fungal culture: this is not only helpful for identifying fungal infections, but since these cultures are kept for longer period and any growth that occurs will be further characterized, fastidious or indolent bacterial organisms may sometimes be identified
   c) TB culture
   d) molecular testing: PCR (mycobacteria, EBV, JC virus)

Excision
Can only be performed during the “chronic” phase (late capsule stage). Abscess is removed as any well encapsulated tumor. The length of time on antibiotics can be shortened to ≈ 3 days in some cases following total excision of an accessible, mature abscess (e.g. located in pole of brain). Recommended for abscesses associated with foreign body and most Nocardia abscesses (see below). May also be needed necessary for: fungal abscess, multiloculated or resistant lesions.

20.2.10 Outcome
In the pre-CT era, mortality ranged from 40–60%. With advances in antibiotics, surgery, and the improved ability to diagnose and follow response with CT and/or MRI, mortality rate has been reduced to ≈ 10% but morbidity remains high with permanent neurologic deficit or seizures in up to 50% of cases. Current outcomes are shown in Table 20.3. A worse prognosis is associated with poor neurologic function, intraventricular rupture of abscess, and almost 100% mortality with fungal abscesses in transplant recipients.

20.3 Subdural empyema

20.3.1 General information

Referred to as subdural abscess prior to 1943. Subdural empyema (SDE) is a suppurative infection that forms in the subdural space, which has no anatomic barrier to spread over the convexity and into the interhemispheric fissure (and occasionally to the opposite hemisphere and posterior fossa). Antibiotic penetration into this space is poor. Distinguished from abscess which forms within brain substance, surrounded by tissue reaction with fibrin and collagen capsule formation. Hence, SDE tends to be more emergent.

SDE may be complicated by cerebral abscess (seen in 20–25% of imaging studies in patients with SDE), cortical venous thrombosis with risk of venous infarction, or localized cerebritis.

20.3.2 Epidemiology

Less common than cerebral abscess (ratio of abscess:empyema is $\approx 5:1$). Found in 32 cases in 10,000 autopsies. Male:female ratio is 3:1.

Location: 70–80% are over the convexity, 10–20% are parafalcine.

20.3.3 Etiologies

See Table 20.4 for etiologies. Most often occurs as a result of direct extension of local infection (rarely following septicemia). Spread of the infection to the intracranial compartment may occur through the valveless diploic veins, often with associated thrombophlebitis.

Chronic otitis media was the leading cause of SDE in the preantibiotic era, but in the U.S. this has now been surpassed by paranasal sinus disease especially with frontal sinus involvement (may also follow mastoid sinusitis). SDE is a rare but sometimes fatal complication of cranial traction devices. Infection of preexisting subdural hematomas (both treated and untreated, in infants and adults) have been reported (bacteremic seeding of an unoperated SDH is very rare).

Trauma includes compound skull fractures and penetrating injuries. Other etiologies include: osteomyelitis, pneumonia, unrelated infection (e.g. foot cellulitis) in diabetics.

20.3.4 Organisms

The causative organism varies with the specific source of the infection. SDE associated with sinusitis is often caused by aerobic and anaerobic streptococci (Table 20.5). Following trauma or neurosurgical procedures, staphylococci and Gram-negative species predominate (whereas S. aureus was not a common pathogen in sinusitis related SDE). Sterile cultures occur in up to 40% (some of which may be due to fastidious anaerobes and/or previous exposure to antibiotics).

http://e-surg.com
20.3.5 Presentation

Neurologic findings are shown in Table 20.6. Symptoms are due to mass effect, inflammatory involvement of the brain and meninges, and thrombophlebitis of cerebral veins and/or venous sinuses. SDE should be suspected in the presence of meningismus + unilateral hemisphere dysfunction. Marked tenderness to percussion or pressure over affected air sinuses is common. Forehead or eye swelling (from emissary vein thrombosis) may occur. Focal neurologic deficit and/or seizures usually occur late.

20.3.6 Evaluation

- CT: IV contrast is usually helpful. CT may miss some cases (related to early generation scanners, failure to give IV contrast, poor scan quality…). If normal, repeat the CT at a later time or do an MRI if clinical suspicion persists. Findings: hypodense (but denser than CSF) crescentic or lenticular extracerebral lesion with dense enhancement of medial membrane; inward displacement of gray-white interface; ventricular distortion and effacement of basal cisterns are common findings.
- MRI: low signal on T1W1, high signal on T2W1. Pial ependymal line: a non-specific MRI finding in CNS infection.

*from a review of multiple articles*
• LP: potentially hazardous (risk of herniation). Organisms are usually present only in cases originating from meningitis. If no meningitis, usually see findings consistent with a parameningeal inflammatory process: moderate sterile pleocytosis (150–600 WBC/mm³) with PMNs predominating; glucose normal; opening pressure is usually high; protein is usually elevated (range: 75–150 mg/dl).

20.3.7 Treatment

1. surgical drainage: indicated in most cases (nonsurgical management has been reported, but should only be considered with minimal neurologic involvement, limited extension and mass effect of SDE, and early favorable response to antibiotics) usually done relatively emergently
2. early in the course, the pus tends to be more fluid and may be more amenable to burr hole drainage; later, loculations develop which may necessitate craniotomy
3. there has been controversy over the optimal surgical treatment. Early studies indicated a better outcome with craniotomy than with burr holes. Recent studies show less difference
   a) critically ill patients with localized SDE may be candidates for burr-hole drainage (usually inadequate if loculations are present). Repeat procedures may be needed, and up to 20% will later require a craniotomy
   b) craniotomy: to debride and, if possible, drain. A wide craniotomy is often required because of septations. The dura appears white because of pus underneath. Open and wash out subdural space. Do not try to remove material adherent to cortex (may cause infarction)
4. antibiotics: similar to treatment for cerebral abscess
5. anticonvulsants: usually used prophylactically, mandatory if seizures occur

20.3.8 Outcome

See Table 20.7. Mortality has dropped from near 100% in the pre-antibiotic era to ≈ 10%. Neurologic deficits tend to improve following treatment, but were present in 55% of patients at the time of discharge from the hospital. Age ≥60 years, obtundation or coma at presentation, and SDE related to surgery or trauma (rather than sinusitis) carry a worse prognosis. Burr-hole drainage may be associated with a worse outcome than with craniotomy, but this may have been influenced by the poorer condition of these patients. Fatal cases may have associated venous infarction of the brain.

20.4 Neurologic involvement in HIV/AIDS

20.4.1 Types of neurologic involvement

General information

40–60% of all patients with acquired immunodeficiency syndrome (AIDS) will develop neurologic symptoms, with one-third of these presenting initially with their neurologic complaint. Only ≈ 5% of patients that die with AIDS have a normal brain on autopsy. One study found the CNS complications of AIDS shown in Table 20.8.

The most common conditions producing focal CNS lesions in AIDS:

1. toxoplasmosis
2. primary CNS lymphoma
3. progressive multifocal leukoencephalopathy (PML)
4. cryptococcal abscess
5. TB (tuberculoma)

Primary effects of HIV infection

Aside from opportunistic infection and tumors caused by the immunodeficient state, infection with the Human Immunodeficiency Virus (HIV) itself can cause direct neurologic involvement including:
1. AIDS encephalopathy: the most common neurologic involvement, occurs in ≈ 66% of patients with AIDS involving the CNS
2. AIDS dementia AKA HIV dementia complex
3. aseptic meningitis
4. cranial neuropathies: including “Bell’s palsy” (occasionally bilateral)
5. AIDS related myelopathy: vacuolization of spinal cord; see Myelopathy (p.1407)
6. peripheral neuropathies

*aCMV encephalitis occasionally occurs
*bmore recent estimate37 of the incidence of PML in AIDS: 4%
CNS toxoplasmosis in AIDS

May present as:
1. mass lesion (toxoplasmosis abscess): the most common lesion causing mass effect in AIDS patients (70–80% of cerebral mass lesions in AIDS) (see below for CT/MRI findings)
2. meningoencephalitis
3. encephalopathy

CNS toxoplasmosis occurs late in the course of HIV infection, usually when CD4 counts are <200 cells/mm³.

PML in HIV/AIDS

Progressive multifocal leukoencephalopathy (PML):
1. Is caused by a ubiquitous polyomavirus (a subgroup of papova virus, small nonenveloped viruses with a closed circular double DNA-stranded genome) called “JC virus” (JCV, named after the initials of the patient in whom it was first discovered, not to be confused with Jakob-Creutzfeldt – a prion disease – nor with Jamestown Canyon virus, also confusingly called JC virus, a single-stranded RNA virus that occasionally causes encephalitis in humans). 60–80% of adults have antibodies to JCV.
2. frequently manifests in patients with suppressed immune systems, including:
   a) AIDS: currently the most common underlying disease associated with PML
   b) prior to AIDS, the most common associated diseases were chronic lymphocytic leukemia & lymphoma
   c) allograft recipients: due to immunosuppression
   d) chronic steroid therapy
   e) PML also occurs with other malignancies, and with autoimmune disorders (e.g. SLE)
3. pathologic findings: focal myelin loss (demyelination, effects white matter) with sparing of axon cylinders, surrounded by enlarged astrocytes and bizarre oligodendrogial cells with eosinophilic intranuclear inclusion bodies. EM can detect the virus. Sometimes occurs in brainstem and cerebellum
4. clinical findings: mental status changes, blindness, aphasia, progressive cranial nerve, motor, or sensory deficits and ultimately coma. Seizures are rare
5. imaging findings: see below
6. clinical course: usually rapidly progressive to death within a few months, occasionally longer survival occurs inexplicably. There is no effective treatment. Some promise initially with antiretroviral therapy
7. definitive diagnosis requires brain biopsy (sensitivity: 40–96%) although it is infrequently employed. JCV has been isolated from brain and urine. Polymerase chain reaction (PCR) of JCV DNA from CSF has been reported, and is specific but not sensitive for PML.

Primary CNS lymphoma (PCNSL) in AIDS

Occurs in ≈10% of patients with AIDS. PCNSL is associated with the Epstein-Barr virus (p. 711).

Neurosyphilis

1. AIDS patients can develop neurosyphilis in as little as 4 mos from infection (unlike the 15–20 yrs usually required in non-immunocompromised patients)
2. neurosyphilis can develop in spite of what would otherwise be adequate treatment for early syphilis with benzathine PCN
3. CDC recommendations: treat patients having symptomatic or asymptomatic neurosyphilis with:
   • penicillin G 3-4-million units IV q 4 hrs (total of 24-million units/d) for 10-14 days or
   • penicillin G procaine 2.4 million units IM daily + probenecid 500 mg QID orally, both for 10-14 days
   • alternative: Rocephin 2gm IV once daily for 10-14 days for patients with a mild beta-lactam allergy
   • for severe beta-lactam allergy: PCN desensitization

20.4.2 Neuroradiologic findings in AIDS

Overview

MR with gadolinium is recommended as the initial screening procedure of choice for AIDS patients with CNS symptoms (lower false negative rate than CT). See Table 20.9 for a comparison of neuroradiologic findings in toxoplasmosis, PCNSL and PML.
CT/ MRI findings in toxoplasmosis abscess

See Table 20.9.

1. most common findings: large area (low density on CT) with mild to moderate edema, ring enhancement with IV contrast in 68% compatible with abscess (of those that did not ring enhance, many showed hypodense areas with less mass effect with slight enhancement adjacent to lesion), well circumscribed margins

2. most commonly located in basal ganglia, are also often subcortical

3. often multiple (typically >5 lesions) and bilateral

4. usually with little to moderate mass effect (in BG, may compress third ventricle and sylvian aqueduct causing obstructive hydrocephalus)

5. most patients with toxoplasmosis had evidence of cerebral atrophy

CT/MRI findings in PML

See Table 20.9. Note: the appearance of PML may differ in AIDS patients from its appearance in non-AIDS patients.

1. CT: diffuse areas of low density. MRI: high intensity on T2WI

2. normally involves only white matter (spares cortex), however in AIDS patients gray matter involvement has been reported

3. no enhancement (on either CT or MRI), unlike most toxoplasmosis lesions

4. no mass effect

5. no edema

6. lesions may be solitary on 36% of CTs and on 13% of MRIs

7. borders are usually more ill-defined than in toxoplasmosis

CT/MRI findings in primary CNS lymphoma (PCNSL)

See Table 20.9. NB: the appearance of PCNSL may differ in AIDS patients from non-AIDS patients.

1. multiple lesions with mild mass effect and edema that tend to ring-enhance on CT, or appear as areas of hypointensity surrounding central area of high intensity (target lesions) on T2WI MRI (unlike non-AIDS cases which tend to enhance homogeneously)

2. there is a greater tendency to multicentricity in AIDS patients than in the nonimmunosuppressed population

20.4.3 Management of intracerebral lesions

Neurosurgical consultation is often requested for biopsy in an AIDS patient with questionable lesion(s). The diagnostic dilemma is usually for low density lesions on CT, and in the United States is primarily between the following:

- toxoplasmosis: treated with pyrimethamine and sulfadiazine + leucovorin (see below)
- PML: no proven effective treatment (initiate or optimize antiretroviral therapy may help)
- CNS lymphoma: usually treated with RTX; see CNS lymphoma (p. 710)
• note: cryptococcus is more common than PML or lymphoma, but usually manifests as cryptococcal meningitis (p.376), and not as a ring enhancing lesion

Recommendations

PML can usually be identified radiographically. However, radiographic imaging alone cannot reliably differentiate toxoplasmosis from lymphoma or from some other concurrent conditions (patients with toxoplasmosis may have other simultaneous diseases). Therefore, the following recommendations are made:

1. obtain baseline toxoplasmosis serology (IgG) on all known AIDS patients (NB: 50% of the general population have been infected by toxo and have positive titer by age 6 years, 80–90% will be positive by middle adulthood).

2. multiple enhancing lesions with basal ganglion involvement in a patient whose toxo titer is positive have a high probability of being toxo

3. primary CNS lymphoma (PCNSL): with a single lesions, lymphoma is more likely than toxo. If the possibility of PCNSL is strong
   a) consider LP (contraindicated in presence of mass effect)
      • high volume LP for cytology: PCNSL can be diagnosed in ~10–25% of cases using ~10 ml of CSF
      • or send CSF for polymerase chain reaction (PCR) amplification of viral DNA of Epstein-Barr virus or JC-virus52 (the agents responsible for AIDS-related PCNSL and PML, respectively)
   b) some centers recommend early biopsy to identify PCNSL cases to avoid delaying RTX for 3 weeks while assessing response to antibiotics18; instead of biopsy, a few centers advocate empiric radiation treatment (for possible lymphoma)

4. in patient with possible toxoplasmosis (i.e. positive toxo serology and imaging findings typical for toxo) even if other conditions have not been excluded:
   a) initial therapy: sulfadiazine 1000 mg four times daily for patients <60 kg or 1500 mg four time daily for patients ≥60 kg + pyrimethamine 200 mg loading dose, then 50 mg daily for patients <60 kg or 75 mg daily for patients ≥60 kg + folinic acid 10-25 mg daily to prevent pyrimethamine induced hematologic toxicity
   b) for patients who cannot take sulfadiazine (including those who develop sulf allergy), change sulfadiazine to clindamicin 600 mg IV or PO q 6 hrs
   c) alternative regimens:
      • atovaquone 1500 mg PO BID + pyrimethamine 200 mg loading dose, then 50 mg daily for patients <60 kg or 75 mg daily for patients ≥60 kg + folinic acid 10-25 mg daily
      • atovaquone 1500 mg PO BID + sulfadiazine 1000 mg four times daily for patients <60 kg or 1500 mg four time daily for patients ≥60 kg
   d) there should be a clinical and radiographic response within 2-3 weeks53
   e) if no response to therapy after 3 weeks (some recommend 7-10 days54), then consider alternative diagnosis (brain biopsy should be considered)
   f) if response is good, reduce dosage of sulfadiazine after 6 to 50% of the above dose for chronic maintenance therapy: sulfadiazine 1000 mg twice daily for patients <60 kg or 1500 mg four twice daily for patients ≥60 kg + pyrimethamine 25-50 mg daily + folinic acid 10-25 mg daily
   g) chronic maintenance therapy can be discontinued in asymptomatic patients who have completed initial therapy if they are receiving antiretroviral therapy (ART), have a suppressed HIV viral load, and have maintained a CD4 count >200 cells/mcl for at least six months

5. perform biopsy in the following settings:
   a) in patient with a negative toxo titer (note: patients occasionally have negative titer because of anergy)
   b) accessible lesion(s) atypical for toxo (i.e. non-enhancing, sparing basal ganglia, periventricular location)
   c) in the presence of extraneural infections or malignancies that may involve the CNS
   d) lesion that could be either lymphoma or toxo (e.g. single lesion, see 3. A)
   e) in patients who have lesions not inconsistent with toxo but fail to respond to appropriate anti-toxo medications in the recommended time (see above)
   f) the role of biopsy for non-enhancing lesions is less well defined as the diagnosis does not influence therapy (most are PML or biopsies are non-diagnostic), it may be useful only for prognostic purposes54
   g) note: the risk of open biopsy in AIDS patients may be higher than nonimmunocompromised patients. Stereotactic biopsy may be especially well suited, with up to 96% efficacy, fairly low morbidity (major risk: significant hemorrhage, ≈ 8% incidence) and low mortality55,56

6. stereotactic biopsy guidelines:
   a) if multiple lesions are present, choose the most accessible lesion in the least eloquent brain area, or the lesion not responding to treatment
b) biopsy the center of non-enhancing lesions, or the enhancing portion of ring-enhancing lesions
c) recommended studies on biopsy: histology; immunoperoxidase stain for Toxoplasma gondii; stains for TB and fungus; culture for TB, fungi, pyogens

20.4.4 Prognosis
Patients with CNS toxo have a median survival of 446 days, which is similar to that with PML but longer than AIDS-related PCNSL.49

Patients with CNS lymphoma in AIDS survive on average a shorter time than similarly treated CNS lymphoma in nonimmunosuppressed patients (3 months vs. 13.5 mos). Median survival is <1 month with no treatment. CNS lymphoma in AIDS tends to occur late in the disease, and patients often die of unrelated causes (e.g. Pneumocystis carinii pneumonia).54

20.5 Lyme disease – neurologic manifestations

20.5.1 General information
Lyme disease (LD) is a complex multisystem disease caused by various species of Borrelia spirochetes (in North America: Borrelia burgdorferi) transmitted to humans by the Ixodes scapularis or pacificus ticks (the American dog tick is not involved). It was first recognized in Lyme, Connecticut in 1975, and is now the most common arthropod-borne infection in the U.S.57

20.5.2 Clinical findings
There are 3 clinical stages which can overlap or occur separately.

Stage 1 (early localized disease, erythema migrans and flu-like illness). Systemic signs of infection usually begin with a flu-like illness within days to weeks of infection, symptoms include: fever, chills, malaise, fatigue or lethargy, backache, headache, arthralgia, and myalgia. Regional or generalized lymphadenopathy may occur.

The hallmark of LD is erythema chronicum migrans (ECM) (classically a “bulls-eye rash”) which begins 3–30 days after the tick bite, and occurs in 60–75% of patients. ECM usually begins in the thigh, inguinal region, or axilla, and consists of an expanding macular rash with bright red borders and central clearing and induration that usually fades without scarring in 3–4 weeks. In addition to ECM, other dermatologic findings include: malar rash (13%), diffuse erythema, and urticaria. Within 30 days of the tick bite, spirochetes may be demonstrated in acellular spinal fluid.

Stage 2 (early disseminated disease). Several weeks to months after infection, untreated patients develop signs of more serious organ involvement. Cardiac and neurologic involvement may occur. Manifestations include:

1. cardiac: occurs in 8% Conduction defects (usually A-V block, generally brief and mild) and myopericarditis
2. ocular: panophthalmitis, ischemic optic atrophy, and interstitial keratitis occur rarely
3. neurologic: occurs in 10–15% of patients with stage 2 disease
   a) the clinical triad of neurologic manifestations of Lyme disease is58:
      • cranial neuritis (especially that mimicking Bell’s palsy: Lyme disease is the most common cause of bilateral “Bell’s palsy” (facial diplegia) in endemic areas)
      • meningitis
      • radiculopathy
   b) other possible neurologic involvement includes: encephalitis, myelitis, peripheral neuritis

Neurologic findings are frequently migratory, and ≈ 60% of patients have multiple neurologic findings simultaneously. In Europe, Bannwarth’s syndrome (chronic lymphocytic meningitis, peripheral neuropathy, and radiculopathy) is the most common manifestation, and primarily affects the peripheral nervous system.59 Neurologic symptoms usually resolve gradually.

Stage 3 (late disease). Arthritis and chronic neurologic syndromes may occur in this stage. Arthralgias are common in stage 1, but true arthritis usually does not begin for months to years after infection, and is seen in ≈ 60% of cases.60 When arthritis occurs, it may affect the knee (89%), hip (9%), shoulder (9%), ankle (7%) and/or elbow (2%).61 Neurologic involvement includes62:
1. encephalopathy (chronic, manifestation may be subtle)
2. encephalomyelitis (chronic, manifestation may be subtle)
3. peripheral neuropathy (chronic, manifestation may be subtle)
4. ataxia
5. dementia
6. sleep disorder
7. neuropsychiatric disease and fatigue syndromes

20.5.3 Diagnosis

Diagnostic criteria

There is no test indicative of active infection. The spirochete is difficult to culture from infected humans. Diagnosis is easy if a history of travel to endemic areas, tick bite, and ECM are identified. Table 20.10 shows the CDC criteria for diagnosis.

Serology

It takes 7–10 days from initial infection to develop antibodies to B. burgdorferi, but it takes ≈ 2–3 wks before antibodies can reliably be detected in untreated patients (antibiotics can reduce the immune response). If the first serum test is negative, it should be repeated in 4–6 weeks if the clinical suspicion of LD is strong (seroconversion from negative to positive is supportive of B. burgdorferi infection). False positives can occur with other borrelial and treponemal infections (e.g. syphilis, however, VDRL test will differentiate the two).

Enzyme-linked immunosorbent assay (ELISA) detects IgM or IgG. Antibodies to B. burgdorferi is the usual test method. IgM is elevated acutely, and IgG gradually rises and is elevated in almost all patients at 4–6 weeks and is usually highest in patients with arthritis. Western blot may help identify false-positive ELISA results (more sensitive and specific than ELISA, however, results may vary between labs). Amplification of B. burgdorferi DNA by polymerase chain reaction (PCR) yields a more very sensitive test that may have significant false positives, and can be positive even if the DNA is from dead organisms.

CSF

Elevated CSF IgG antibody titer to B. burgdorferi may occur with neurologic involvement. CSF findings in late disease are usually compatible with aseptic meningitis. Oligoclonal bands and increased ratio of IgG to albumin may occur.

20.5.4 Treatment

See references. Antibiotic therapy is more effective early in the illness.

20.6 Nocardia brain abscess

20.6.1 General information

Nocardia infections may involve the CNS in multiple ways.

²either musculoskeletal, neurologic or cardiac
Nocardiosis is caused primarily by Nocardia asteroides (other Nocardia species such as N. brasi-
liensis are less common), a soil-born aerobic actinomycete (a bacteria, not a fungus) that is usually
inoculated through the respiratory tract and produces a localized or disseminated infection. Hema-
togenous spread frequently results in cutaneous lesions and CNS involvement. Nocardia is responsi-
bile for 2% of all brain abscesses, the majority of these are N. asteroides.

Nocardiosis occurs primarily in patients with chronic debilitating illnesses including:
1. neoplasms: leukemia, lymphoma...
2. conditions requiring long-term corticosteroid treatment
3. Cushing’s disease
4. Paget’s disease of bone
5. AIDS
6. renal or cardiac organ transplant recipients

The diagnosis is suspected in high-risk patients presenting with soft-tissue abscesses and CNS
lesions. CNS involvement occurs in about one-third and includes:
1. cerebral abscess: often multiloculated
2. meningitis
3. ventriculitis in patients with CSF shunt
4. epidural spinal cord compression from vertebral osteomyelitis

20.6.2 Diagnosis

Brain biopsy may not be needed in high-risk patients with confirmed nocardia infection in other
sites, except possibly in AIDS patients where the risk of multiple organism infections or infection
plus tumor (particularly lymphoma) is considerable.

20.6.3 Treatment

General information

Surgical indications (p. 324) are the same as for other abscesses.

Antibiotics

See references.71,72

- Primary choice: trimethoprim-sulfamethoxazole (TMP-SMZ 15 mg/kg IV of trimethoprim compo-

nent per day in two to four divided doses PLUS imipenem 500 mg IV q6h ± amikacin 7.5 mg/kg IV
q12h (if CNS disease with multiorgan involvement)

- Alternative if sulfap allergy: imipenem 500 mg IV q6h PLUS amikacin 7.5 mg/kg IV q12h

Antimicrobial susceptibility testing should be conducted on all isolates.

Duration: because of risks of relapse or hematogenous spread, treatment is recommended for at
least one year with CNS involvement, possibly indefinitely in for immunocompromised hosts.

21 Skull, Spine, and Post-Surgical Infections

21.1 Shunt infection

21.1.1 Epidemiology

Acceptable shunt infection rate\(^1\): <5–7% (although many published series have a rate near 20%\(^2\) possibly due to different patient population).

Risk of early infection after shunt surgery: reported range is 3–20% per procedure (typically \(\approx 7\)%).

Over 50% of staph infections occur within 2 weeks post-shunt, 70% within 2 mos. Source is often the patient’s own skin.\(^3\) It is estimated that in \(\approx 3\)% of operations for shunt insertion the CSF is already infected (therefore CSF during shunt insertion is recommended).

21.1.2 Morbidity of shunt infections in children

Children with shunt infections have an increased mortality rate and risk of seizure than those without shunt infection. Those with myelomeningocele who develop ventriculitis after shunting have a lower IQ compared to those without infection.\(^3\) Mortality ranges from 10–15%.

21.1.3 Risk factors for shunt infection

Many factors have been blamed. Some that seem to be better documented include:

- young age of patient\(^2\): in myelomeningocele (MM) patients, waiting until the child is 2 weeks old may significantly lower the infection rate
- length of procedure
- open neural tube defect

21.1.4 Pathogens

Early infection

Most commonly:

- Staph. epidermidis (coagulase-negative staph): 60–75% of infections (most common)
- S. aureus
- Gram-negative bacilli (GNB): 6–20% (may come from intestinal perforation)

In neonates E. coli and Strep. hemolyticus dominate.

Late infection (>6 months after procedure)

Risk: 2.7–31% per patient (typically 6%). Almost all are S. epidermidis. 3.5% of patients account for 27% of infections.\(^4\)

“Late” shunt infections may be due to:

- an indolent infection due to Staph. epidermidis
- seeding of a vascular shunt during episode of septicemia (probably very rare)
- colonization from an episode of meningitis

Fungal infections

Candida spp. infections

Candida spp. are responsible for the majority of fungal ventricular shunt infections. Usually occurs in children <1 year age. Incidence: 1–7%\(^5\). The 4th leading pathogen causing meningitis in neurosurgical patients in 1 study, possibly related to the use of prophylactic antibiotics used for ICP monitoring and CSF drainage. Higher incidence in VP shunt patients with abdominal infections and shunts placed in patients with previous bacterial meningitis.\(^6\) CSF typically shows: elevated WBCs and protein, normal glucose. Management recommendations:

1. completely remove the contaminated shunt (may be more important than with bacterial infections)
2. place a fresh external ventricular drain (if patient is shunt dependent)
3. treat with antifungal therapy
4. place a fresh shunt after \( \geq 5–7 \) days of therapy and clinical response is apparent
5. continue antifungal agents for 6–8 weeks

### 21.1.5 Presentation

#### Signs and symptoms

Non-specific syndrome: fever, N/V, H/A, lethargy, anorexia, irritability. May also present as shunt malfunction; 29% of patients presenting with shunt malfunction had positive cultures. Erythema and tenderness along shunt tubing may occur. Distal infection of ventriculoperitoneal shunts may mimic acute abdomen. In neonates may manifest as apnic episodes, anemia, hepatosplenomegaly, and stiff neck. S. epidermidis infections tend to be indolent (smoldering). GNB infections usually cause more severe illness; abdominal findings are more common; main clinical manifestation is fever, usually intermittent and low grade. Shunt nephritis may occur with chronic low level infection of a ventriculovascular shunt causing immune complex deposition in renal glomeruli, characterized by proteinuria and hematuria.

#### Blood tests

- WBC: \(< 10K\) in one fourth of shunt infections. It is \(> 20K\) in one–third.
- ESR: rarely normal in shunt infections.
- Blood cultures: positive in less than one–third of cases.
- CSF: WBC is usually not \(> 100 \text{ cells/mm}^3\). Gram stains may be positive \( \approx 50\% \) (yield with S. epidermidis is much lower). Protein is often elevated, glucose may be low or normal. Rapid antigen tests used for community acquired meningitis are usually not helpful for the organisms that tend to cause shunt infections. CSF cultures are negative in 40\% of cases (higher culture yield if CSF WBC count is \(> 20K\)).

#### Evaluation of shunt for infection

1. history and physical directed at determining presence of above signs and symptoms with emphasis on
   a) history suggestive of infection at another site
      - exposure to others with viral syndromes, including sick siblings
      - GI source (e.g. acute gastroenteritis). Often associated with diarrhea.
      - otitis media (check tympanic membranes)
      - tonsillitis/pharyngitis
      - appendicitis (peritoneal inflammation may impede VP shunt outflow)
      - URI
      - UTI
      - pneumonia
   b) physical exam to R/O meningismus (stiff neck, photophobia…)
2. bloodwork
   a) serum WBC count with differential
   b) acute phase reactants: ESR & CRP
   c) blood cultures
3. shunt tap: should be done in cases of suspected shunt infection. Clip hair (do not shave) and prep carefully to avoid introducing infection. GNB requires different therapy and has higher morbidity than staph, thus it is desirable to identify these rare patients: \( > 90\% \) of these had positive Gram-stained CSF smear (only a few Gram-positive infections have positive results). GNB have higher protein and lower glucose, and neutrophils predominate in differential (unpublished data)
4. imaging
   a) CT: usually not helpful for diagnosing infection. Ependymal enhancement when it occurs is diagnostic of ventriculitis. CT may demonstrate shunt malfunction
   b) abdominal U/S or CT: the presence of an abdominal pseudocyst is suggestive of infection
5. LP: usually NOT recommended. May be hazardous in obstructive hydrocephalus (HCP) with a nonfunctioning shunt. Often does not yield the pathogen even in communicating HCP, especially if the infection is limited to a ventriculitis. If positive, may obviate a shunt tap
21.1.6 Treatment

Antibiotics alone (without removal of shunt hardware)

Although eradication of shunt infections without removal of hardware has been reported, this has a lower success rate than with shunt removal, may require protracted treatment (up to 45 days in some), risks problems associated with draining infected CSF into the peritoneum (reduced CSF absorption, abdominal signs/symptoms including tenderness to full-blown peritonitis (p.235) or vascular system – shunt nephritis (p.340), sepsis – and often requires at least partial shunt revision at some point in most cases. Treatment with antibiotics without shunt removal is therefore recommended only in cases where the patient: is terminally ill, is a poor anesthetic risk, or has slit ventricles that might be difficult to catheterize.

Removal of shunt hardware

In most instances, during the initial treatment with antibiotics the shunt is either externalized (i.e. tubing is diverted at some point distal to the ventricular catheter and connected to a closed drainage system), or sometimes the entire shunt may be removed. In the latter case, some means of CSF drainage must be provided in shunt dependent cases; either by insertion of an external ventricular drain (EVD), or by intermittent ventricular taps (rarely employed) or LPs (with communicating HCP). EVD allows easy monitoring of CSF flow, control of ICP, and repeated sampling for signs of resolution of infection (normalization of WBC count and surveillance cultures). In addition, EVD allows for possible administration of intrathecal antibiotics. In symptomatic patients or those with a positive CSF culture, any hardware removed should be cultured as only ~ 8% are sterile in shunt infections. Skin organisms are fastidious and may take several days to grow.

If there is an abdominal pseudocyst, the fluid should be drained through the peritoneal catheter before removing it.

Antibiotics

Empiric antibiotics

See reference.14

1. Vancomycin (adult) 15 mg/kg IV q8-12 hours to achieve trough 15-20 mg/dl for MRSA coverage + cefepime 2gm IV q8h or meropenem 2gm q8h to cover gram negative pathogens. Streamline therapy based on culture and sensitivity results

2. Intraventricular injection of preservative-free antibiotics may be used in addition to IV therapy. Clamp EVD for one hour after injection

Treatment for specific organisms

Positive cultures from shunt hardware removed at the time of shunt revision in the absence of clinical symptoms or a positive CSF culture may be due to contamination and do not always require treatment.13

1. S. aureus and S. epidermidis
   a) if methicillin sensitive: nafcillin or oxacillin ± ITvancomycin
   b) if methicillin resistant: continue IV vancomycin + PO rifampin ± ITvancomycin

2. Enterococcus: IV ampicillin ± IT gent

3. Other streptococci: either antistreptococcal or above enterococcal regimen

4. Aerobic GNR: base on susceptibilities. Both IV beta-lactam & IT aminoglycoside indicated

5. Serratia marcescens: a rare cause of VP shunt infection but the high morbidity may warrant aggressive antibiotic therapy (IV ceftriaxone + IT aminoglycoside) and surgical therapy

6. Corynebacterium spp. & Propionibacterium spp. (diphtheroids)
   a) if PCN sensitive: use enterococcal regimen above
   b) if PCN resistant: IV + IT vancomycin

7. Candida spp.: see protocol and drugs (p.320). Systemic antifungal therapy and removal of shunt is warranted. Avoid echinocandins (antifungal drugs that inhibit synthesis of glucan in the fungal cell wall) as they have poor CNS penetration
Subsequent management

Once the CSF is sterile × 3 days, convert the EVD to a shunt (if an EVD was not used, it is still recommended that the shunt be replaced with new hardware). Continue antibiotics an additional 10–14 days.

Managing ventriculoperitoneal shunts in patients with peritonitis

Peritonitis may occur as a result of:
1. perforation of a viscus (sometimes as a result of penetration by the peritoneal catheter tip, more common with obsolete Raimondi wire-reinforced tubing)
2. spontaneous bacterial peritonitis (SBP): absence of an identifiable intra-abdominal source. Most commonly diagnosed in patients with cirrhotic ascites
3. or as a result of seeding through a VP shunt in a patient with a shunt infection: predominantly gram-positive, cutaneous organisms

Concerns following an episode of peritonitis in a patient with VP shunt:
1. ascending infection into the CNS: uncommon, especially in the acute setting while on appropriate antibiotics with shunts containing a 1-way valve (as most do). CSF grows predominantly mixed, gram-negative intestinal flora
2. contamination of the distal shunt: prevents permanent eradication of infection (appendicitis in the absence of peritonitis does not produce shunt infection)
3. shunt malfunction due to distal shunt obstruction: often as a result of walling off of the catheter tip, usually by omentum in reaction to the infection

Management recommendations following an episode of peritonitis (many viable options):
1. immediate appropriate treatment of peritonitis, usually managed by general surgeon (e.g. for ruptured appendix: appendectomy and appropriate antibiotics), with initial attempt to address shunt not being mandatory
2. anecdotally, cases have been managed successfully by cleaning off the peritoneal catheter with bacitracin solution, and then wrapping the catheter in a bacitracin soaked lap sponge until the time to close the abdomen
3. if the peritonitis was diffuse or if the shunt catheter is believed to have been contaminated, an option is to externalize the distal catheter, preferably once the patient has stabilized from the peritonitis (afebrile, stable vital signs, normal WBC)
   a) externalization is done in a manner to avoid pulling contaminated catheter up towards hopefully sterile portions of the shunt. This can be accomplished by reopening the skin incision used for inserting the peritoneal catheter, and making a second incision over the shunt tubing, well above this entry point. The catheter is then divided at the upper incision. The catheter is grasped at the lower incision and is pulled, extracting both ends (the peritoneal end and the end just cut). The remaining catheter coming from above is connected to an external drainage system
   b) CSF cultures are monitored daily
   c) if 3 consecutive cultures are negative, a new distal catheter may be implanted
   d) if cultures continuously grow organisms, then the shunt may be contaminated and should then be replaced with an entirely new shunt system
   e) when it is time to replace the shunt, some authors recommend using an alternative site other than the peritoneum, but this is not mandatory

21.2 External ventricular drain (EVD)-related infection

21.2.1 General information

Key concepts

- Common organisms: S. epidermidis and S. aureus followed by gram negative bacilli and propionibacterium acne.
- Diagnosis: Hypoglycorrhea (CSF glucose/Blood glucose < 0.2), rising cell index, and CSF pleocytosis >1000 in the presence of positive CSF culture suggests EVD-related infection
In CSF drain-related ventriculitis the diagnostic utility of CSF leucocyte count, glucose and protein is limited as noninfectious entities like intracranial hemorrhage and neurosurgical procedures can also cause abnormalities in these parameters.

Management: remove EVD when clinically acceptable. Empiric coverage with IV vancomycin (for gram positives) + IV ceftazidime or cefepime (for gram negatives). Consider intraventricular/intrathecal antimicrobial for resistant organisms or non-responsiveness to IV antimicrobials.

Prevention: antibiotic-coated catheters and catheter tunneling decrease infection rate.

21.2.2 Definitions
Suggested classification system and approach to a patient with suspected external ventricular drain (EVD) AKA ventriculostomy infection (modification of Lozier’s definitions).

- Cell index, see Eq (21.1) 22,23
- Contamination: isolated positive CSF culture and/or Gram stain, with expected CSF cell count and glucose with NO attributable symptoms or signs.
- Ventriculostomy colonization: Multiple positive CSF cultures and/or Gram stain, with expected CSF cell count and glucose levels with NO attributable symptoms or signs.
- Possible ventriculostomy-related infection: Progressive rise in cell index or progressive decrease in CSF: blood glucose ratio or an extreme value for CSF WBC count (>1000/micro L) or CSF:blood glucose ratio (<0.2), with attributable symptoms and signs, but NEGATIVE Gram stain & cultures
- Probable ventriculostomy-related infection: CSF WBC count or CSF: blood glucose ratio MORE abnormal than expected, but NOT an extreme value (CSF WBC count 1000/micro L or CSF:blood glucose ratio <0.2) and stable (not progressively worsening) attributable symptoms and signs and POSITIVE Gram stain & cultures
- Definitive meningitis: Progressive rise in cell index or progressive decrease in CSF: blood glucose ratio or an extreme value for CSF WBC count (>1000/micro L) or CSF:blood glucose ratio (<0.2), with attributable symptoms or signs and a POSITIVE Gram stain & cultures

\[
\text{Cell index} = \frac{\text{Leucocytes}_{\text{CSF}}}{\text{Erythrocytes}_{\text{CSF}}} = \frac{\text{Leucocytes}_{\text{Blood}}}{\text{Erythrocytes}_{\text{Blood}}} \times 21:1 \Phi
\]

21.2.3 Epidemiology
Incidence. The incidence of EVD infection is approximately 9.5\%24

Risk factors. Factors associated with EVD infections:
- Duration of EVD21,25,26
- Site leakage
- Blood in CSF (IVH and SAH)27
- Irrigation and flushing25,26

21.2.4 Microbiology
- Unlike organisms that cause acute community-acquired meningitis those causing neurosurgical procedure-related meningitis are slow to grow on cultures and may require anaerobic media.
- The usual organisms that cause EVD-related infections are either:
  - Organisms that usually colonize the skin, especially the scalp (coagulase negative Staphylococcus, Staphylococcus aureus, and Propionibacterium acnes).
  - Organisms that can be present in the healthcare environment: S. aureus, both methicillin sensitive and resistant, gram-negative bacteria like E. coli, Klebsiella, pseudomonas, and Acinetobacter species, some of which can be multi-drug resistance.
- Infectious organisms can form a polysaccharide layer (biofilm) on the surface of catheters which increases the resistant to antimicrobials.
21.2.5 Clinical presentation

Clinical signs and symptoms may include the following; however, these symptoms are nonspecific as they are commonplace in the neuro-ICU as a result of the underlying pathology (e.g. intracranial hemorrhage or hydrocephalus)\(^{28}\)

- change in mental status
- fever: alternative sources of fever may include intracranial hemorrhage, central fever, thrombotic episodes, drug fevers, in addition to non-CNS infection like blood-borne infections, hospital-acquired pneumonias and urinary tract infections
- meningismus: stiff neck, Brudzinski or Kernig’s sign.

21.2.6 Diagnosis

Blood parameters. These parameters can suggest the diagnosis but should not be relied upon exclusively.

- A prospective study showed likely EVD infections in the presence of these parameters\(^{29}\): peripheral WBC count > 15 in EVD infections (vs. < 11 in non-infected)
- Serum inflammatory markers: there is very limited literature on the diagnostic utility of ESR and CRP. Procalcitonin alone was found not to be helpful.\(^{30}\)

CSF parameters. There are limited studies on the diagnostic accuracy of CSF parameters in post craniotomy meningitis and ventriculitis. Often the surgery itself can cause “chemical meningitis” or postoperative meningitis, particularly posterior fossa surgeries or in the presence of intraventricular hemorrhage. The CSF leucocyte and CSF glucose values can look very similar to infectious meningitis making it hard to distinguish these entities based on these parameters. The following could help in confirming underlying EVD infection.

- Hypoglycorrhachia (low CSF glucose): ratio of [CSF glucose]/[blood glucose] < 0.2
- CSF pleocytosis > 1000 or rising Cell index (p. 343)
- CSF protein was not a reliable predictor for incipient ventricular catheter infection\(^{31}\)

Routine CSF sampling: CSF sampling should be performed only when symptoms appear. There is no evidence of benefit to obtaining CSF cultures or cell count at the time of EVD insertion (false positive cultures may occur from contamination).\(^{32}\)

21.2.7 Principles of management

- It is difficult to achieve high CSF antimicrobial levels due to blood-CSF barrier.
- Some hospital-acquired organisms have higher MICs (minimal inhibitory concentration) for antimicrobials than community-acquired organisms.
- Organisms often form biofilms on the catheters which resist antimicrobial penetration. For this reason, catheter should be removed if it is safe to do so.
- Empiric antibiotics: initiate if ventriculitis is suspected once the appropriate sampling has been obtained
  - If no penicillin allergy:
    - vancomycin as a continuous infusion or divided doses (2–3) of 60 mg per kg of body weight per day after a loading dose of 15 mg per kg of body weight, aiming for trough (15 – 25 mcg/ml) PLUS
    - ceftazidime 2 g IV Q 8 hrs or cefepime 2 g IV Q 8hrs
  - For penicillin allergy:
    - vancomycin as a continuous infusion or divided doses (2–3) of 60 mg per kg of body weight per day after a loading dose of 15 mg per kg of body weight PLUS
    - meropenem 2 g IV q8 or aztreonam 2 g IV Q 6 hrs
- Switch to more selective agents as appropriate based on culture and susceptibility when they become available (see Table 21.1)
- Duration of treatment should be individualized to the patient but as a rule of thumb: treat for 2 weeks if the infection was with S. aureus and S. epidermidis, and 3 weeks if it was gram negatives.\(^{33}\)
- Failing to respond to systemic treatment or infection with a resistant organism might require Intrathecal/Intraventricular antibiotic administration. Choose the antimicrobial based on susceptibility. Dosages for intraventricular antibiotics:
  - Vancomycin: for slit ventricles 5 mg, 10 mg with normal-sized ventricles, 15–20 mg for patients with enlarged ventricles.
Aminglycoside: Dosing can also be tailored to ventricular size. Frequency can be adjusted based on drain output as well: once daily for drain output >100 ml/day, every other day if drain output =50 –100 ml/day, every third day if drainage <50 ml/day

- **Genamycin**: 4–8 mg
- **Tobramycin**: 5–20 mg
- **Amikacin**: 5–30 mg

- **Colistimethate sodium**: 10 mg CMS, which is 125,000 IU or 3.75 mg CBA (Colistin Base units)
- **Daptomycin**: 2–5 mg

- After IT administration of an antimicrobial, clamp the drain for 15–60 minutes to allow the antimicrobial concentration to equilibrate in the CSF before opening the drain\(^{34}\)
- Expert opinion: wait at least 7–10 days after the CSF cultures become sterile to implant a shunt if needed.

### 21.2.8 Prevention
- Tunneling >5 cm away from the burr hole\(^{35}\)
- Antibiotic coated catheters (e.g., Rifampin + minocycline) significantly reduce the risk of EVD infection\(^{36,37,38,39,40}\)
- Routine catheter exchange at day 5 did not show reduction in the rate of infection\(^{41,42,43}\) Therefore a single catheter may be employed as long as clinically required\(^{44}\)
- Prolonged antibiotic prophylaxis while the EVD is in place does not decrease the risk of infection and may select for resistant organisms. However one dose pre-procedure antimicrobial may be administered.

### 21.3 Wound infections

#### 21.3.1 Laminectomy wound infection

**General information**

Occurs in 0.9–5% of cases\(^{45}\) May range from superficial to severe dehiscent wound infection to deeper infection (discitis/osteomyelitis ± epidural abscess). The risk is increased with age, long term steroid use, obesity, and possibly DM. Intraoperative mild hypothermia (as commonly occurs in the operating room) may also increase the risk of wound infection (as demonstrated with colorectal resection\(^{46}\)). Most are caused by *S. aureus*.

**Superficial wound infection**

**Management**

1. culture the wound and/or any purulent drainage
2. start the patient empirically on vancomycin plus cefepime or meropenem
3. modify antibiotics appropriately when culture and sensitivity results available
4. debride wound of all necrotic and devascularized tissue and any visible suture material (foreign bodies). Superficial wound infections may be debrided in the office or treatment room, deep infections must be done in OR
5. shallow defects may be allowed to heal by secondary intention, and the following is one possible regimen
   a) pack the wound defect with 1/4" Iodophor® gauze
   b) dressing changes at least BID (for hospitalized patients, change q 8 hrs), remove and trim ≈ 0.5–1" of packing with each dressing change
      • while wound is purulent, utilize 1/2 strength Betadine® wet to dry dressings
      • when purulence subsides, switch to normal saline wet to dry
   c) antibiotics, may be useful as an adjunct to wound treatment initially, switch to oral antibiotics as early as possible, a duration of 10–14 days total is probably adequate if local wound care is being done
6. some prefer to close wound by primary intention, it is critical that there be no tension on the wound for healing to occur. Some close over an irrigation system or antibiotic beads. Retention sutures may be helpful
7. with large defects or when bone and/or dura becomes exposed, the use of a muscle flap (often performed by a plastic surgeon) is probably required
8. CSF leakage requires exploration in the OR with watertight dural closure to prevent meningitis

Postoperative discitis

Epidemiology
Incidence after lumbar discectomy: 0.2–4% (realistic estimate is probably at the lower end of this range). May also occur after LP, myelogram, cervical laminectomy, lumbar sympathectomy, discography, fusions (with or without instrumentation) and other procedures. Very rare after ACDF. Risk factors include: advanced age, obesity, immunosuppression, systemic infection at the time of surgery.

Pathophysiology
There is some controversy as to whether some cases of post-op discitis are not infectious, an autoimmune process has been implicated in some of these so-called “vascular” or “chemical” or “aseptic” discitis cases. These cases are less common than infectious ones. ESR and CRP abnormalities may be less pronounced in these patients, and biopsy of the disc space fails to grow organisms or show signs of infection (infiltrates of lymphocytes or PMNS) on microscopy.

In septic cases, various mechanisms for infection have been proposed: direct inoculation at the time of surgery, infection following aseptic necrosis of disc material...

Pathogens
See Table 21.2. Most studies report S. aureus as the most commonly identified organism, accounting for ≈ 60% of positive cultures, followed by other staph species. Also reported: Gram-negative organisms (including E. coli), Strep viridans, Streptococcus species anaerobes, TB and fungi. Enteric flora in post-op discitis may due to unrecognized breach of the anterior longitudinal ligament with bowel perforation.

Blood cultures were positive in 2 of 6 patients (both S. aureus) in one series.

For culture techniques, see surgical management section below.

Clinical
1. interval from operation to onset of symptoms: 3 days to 8 mos (most commonly 1–4 wks post-op, usually after an initial period of pain relief and recovery from surgery). 80% present by 3 wks

Table 21.2 Culture results (14 patients, Craig needle biopsy)

2. symptoms:
   a) moderate to (usually) severe back pain at the site of operation was the most common symptom, exacerbated by virtually any motion of the spine, often accompanied by paraspinal muscle spasms. Back pain is usually out of proportion to the findings.
   b) fever (>38°C in 9 patients; literature reports only 30–50% are febrile) and chills
   c) pain radiating to hip, leg, scrotum, groin, abdomen or perineum (true sciatica is uncommon)

3. signs: in 27 patients, all had paravertebral muscle spasm and limited range of motion of the spine. 13 (48%) were virtually immobilized by pain. Point tenderness over the infected level occurred in 9, expressible pus in 2 (literature reports 0–8%). No new neurologic deficits were noted. Only 10–12% have associated wound infection.

4. lab findings:
   a) ESR: in a series of 27 patients, 96% had ESR>20 mm/hr (60 = ave.; >40 in 17 patients; >100 in 5 patients; the single patient <20 was on steroids). ESR increases after uncomplicated discectomy, peaking at 2–5 days, and can fluctuate for 3–6 weeks before normalizing. An elevated ESR that never decreases after surgery is a strong indicator of discitis. NB: ESR in anemic patients is unreliable and no reference range can be established (use CRP in these cases).
   b) C-reactive protein (CRP): an acute phase protein synthesized by hepatocytes that because of rapid decomposition may be a more specific indicator of post-op infection than ESR. Values vary from lab to lab, but CRP is normally not detectable in the blood (i.e. <0.6 mg/dl = 6 mg/L). After uncomplicated discectomy (i.e. in the absence of discitis), CRP peaks ≈2–3 days post-op (to 4.6 ± 2.1 mg/dl after lumbar microdiscectomy, 9.2 ± 4.7 after conventional lumbar discectomy, 7.0 ± 2.3 after anterior lumbar fusion, and 17.3 ± 3.9 after PLIF), and returns to normal between 5–14 days post-op.
   c) WBC: >10,000 in only 8/27 patients (prevalence in literature: 18–30%).

Radiographic evaluation
In postoperative discitis (POD), the average time from surgery to changes on plain x-ray is 3 mos (range: 1–8 mos). Average time from first change to spontaneous spinal fusion: 2 yrs.
MRI: The triad of gadolinium enhancement shown in Table 21.3 is strongly suggestive of discitis (some asymptomatic patients may have some of these findings, but they rarely have all).
MRI also rules-out other causes of post-op pain (epidural abscess, recurrent/residual disc herniation...).

Management
1. initial labs (in addition to routine): ESR, C-reactive protein, CBC, blood cultures
2. analgesics + muscle relaxants (e.g. diazepam (Valium®) 10 mg PO TID)
3. antibiotics:
   a) IV antibiotics for 1-6 wks then PO for 1-6 mos
   b) most start with anti-staphylococcal antibiotics (initial empiric therapy: vancomycin ± PO rifampin) and cefepime or meropenem. Modify based on sensitivities if positive cultures are obtained
   c) duration of therapy depends on depth of infection and presence of hardware
      • superficial infection: 1-2 weeks
      • deep infection 4-8 weeks, possibly up to 12 weeks in complex cases
      • consider chronic PO therapy if hardware not removed
4. activity restriction (one of the following used, usually until significant pain relief):
   a) spinal immobilization with brace
   b) strict bed rest
   c) advance activity with brace as tolerated
5. some authors recommend steroid therapy initially to assist pain relief

Table 21.3 Gadolinium enhancement in discitis

6. cultures: performed if radiographs suspicious, usually performed utilizing percutaneous CT-guided technique
   a) sites
      • disc aspiration if evidence of disc space involvement
      • needling of paraspinal mass if present
   b) send culture for the following
      • Stains: (a) Gram stain (b) fungal stain (c) AFB stain
      • Cultures: (a) routine cultures: aerobic and anaerobic (b) fungal culture: this is not only helpful for fungus, but since these cultures are kept for longer period and any growth that occurs will be further characterized, fastidious or indolent bacterial organisms may sometimes be identified (c) AFB (TB) culture

7. 3 out of 27 patients underwent anterior discectomy and fusion after unsuccessful medical therapy

Outcome
9 patients developed bony bridging in 12–18 mos; 10 developed bony fusion in 18–24 mos
All patients eventually become pain free (or significantly improve). This is not the case in all series, where some report 60% were pain free at F/U, others found slight back pain in most patients, and yet others report severe chronic LBP in 75% 69–88% return to their previous work, and 12–25% received disability pension; these numbers are similar to the outcome from disc surgery in general.

No difference in outcome was found for the various activity restrictions specified, except for earlier pain relief with first two types listed above.

21.3.2 Craniotomy wound infection
Also; see under meningitis, post-neurosurgical procedure (p.318).

C-reactive protein
Following uncomplicated craniotomy for microsurgery for brain tumors, C-reactive protein (CRP) peaked on post-op day (POD) 2 with a mean value of 32 ± 38 mg/l.55 Values declined from POD 3 through 5, reaching a mean of 6.7 ± 11 on POD 5. These values may be lower than with most post-op infections.

21.4 Osteomyelitis of the skull
21.4.1 General information
The skull is normally very resistant to osteomyelitis, and hematogenous infection is rare. Most infections are due to contiguous spread (usually from an infected air sinus, occasionally from scalp abscess) or to penetrating trauma (including surgery and fetal scalp monitors56). With longstanding infection, edema and swelling in the area may become visible (usually over the forehead, but also may occur over the mastoids), and is called “Pott puffy tumor” (after Percival Pott).

21.4.2 Pathogens
Staphylococcus is the most common organism, with S. aureus predominating, followed by S. epidermidis. In neonates, E. coli may be the infecting organism.

21.4.3 Imaging
Imaging findings may include: bony resorption, periosteal reaction, contrast enhancement.

21.4.4 Treatment
Antibiotics alone are rarely curative. Treatment usually involves surgical debridement of infected skull, biting off infected bone with rongeurs until a normal snapping sound replaces the more muted sound made by rongeuring infected bone. In the case of an infected craniotomy bone flap, the flap usually must be removed and discarded, and the edges of the skull rongeured back to healthy bone. Bone suspected of infection should be sent for cultures.
Closure of the scalp is then performed either leaving an bone defect (for later cranioplasty) or cranioplasty can be performed using titanium mesh.

Debridement surgery is followed by at least 6–12 weeks of antibiotics.57 Until MRSA is ruled out: vancomycin + cefepime or meropenem. Culture results guide choice of antibiotic. Once MRSA is ruled out, vancomycin may be changed to a penicillinase resistant synthetic penicillin (e.g. nafcillin). Most treatment failures occurred in patients treated with <4 weeks of antibiotics following surgery.

Cranioplasty may be performed ≈ 6 months post-op if there are no signs of residual infection.

21.5 Spine infections

Spine infections may be divided into the following major categories:

1. vertebral osteomyelitis (p.353) (spondylitis):
   a) pyogenic
   b) nonpyogenic, granulomatous
      • tuberculous spondylitis
      • brucellosis
      • aspergillosis
      • blastomycosis
      • coccidiomycosis
      • infection with Candida tropicalis
2. discitis (p.356): usually associated with vertebral osteomyelitis (spondylodiscitis) (p.353)
   a) spontaneous
   b) post-operative/post-procedure
3. spinal epidural abscess (see below)
4. spinal subdural empyema
5. meningitis
6. spinal cord abscess

MRI experience suggests that patients with infectious spondylitis will develop an associated epidural abscess if untreated, and that epidural empyema is unusual in the absence of vertebral osteomyelitis.58 Thus, the discovery of one of these conditions should prompt a search for the other.

21.5.1 Spinal epidural abscess

General information

Key concepts

- should be considered in a patient with back pain, fever, and spine tenderness
- major risk factors: diabetes, IV drug abuse, chronic renal failure, alcoholism
- may produce progressive myelopathy, sometimes with precipitous deterioration, therefore early surgery has been advocated by some even if no neuro deficit
- fever, sweats or rigors are common, but normal WBC and temperature can occur
- classical presentation of a skin boil (furuncle) occurs in only ≈ 15% somewhere on the body
- treatment: controversial. Many patients improve with antibiotics alone, but some may deteriorate precipitously

Epidemiology

Incidence: 0.2–1.2 per 10,000 hospital admissions annually,59 possibly on the rise.60 Average age: 57.5 ± 16.6 years.61 Thoracic level is the most common site (≈ 50%), followed by lumbar (35%) then cervical (15%).61 82% were posterior to the cord, and 18% anterior in one series.59 SEA may span from 1 to 13 levels.62 Spinal epidural abscess (SEA) is often associated with vertebral osteomyelitis (in one series of 40 cases, osteomyelitis occurred in all cases of anterior SEA, in 85% of circumferential SEA, and no cases of posterior SEA) and intervertebral discitis.
Co-morbid conditions

Chronic diseases associated with compromised immunity were identified in 65% of 40 cases. Associated conditions included diabetes mellitus (32%), IV drug abuse (18%), chronic renal failure (12%), alcoholism (10%), and the following in only 1 or 2 patients: cancer, recurrent UTI, Pott’s disease, and positivity for HIV. Chronic steroid use and recent spinal procedure or trauma (e.g., GSW) are also risk factors. Skin infection (e.g., furuncle).

Clinical features

Usually presents with excruciating pain localized over spine with tenderness to percussion. Radicular symptoms follow with subsequent distal cord findings, often beginning with bowel/bladder disturbance, abdominal distension, weakness progressing to para- and quadriplegia. Average time is 3 days from back pain to root symptoms; 4.5 days from root pain to weakness; 24 hrs from weakness to paraplegia.

Fever, sweats or rigors are common, but are not always present. A furuncle (skin boil) somewhere on the body may be identified in 15%.

Patients may be encephalopathic. This may range from mild to severe and may further delay diagnosis. Meningismus with a positive Kernig’s sign may occur.

 Patients with post-operative SEA may demonstrate surprisingly few signs or symptoms (including lack of leukocytosis, lack of fever) aside from local pain.

Pathophysiology of spinal cord dysfunction

Although some cord symptoms may be due to mechanical compression (including that due to vertebral body collapse), this is not always found. A vascular mechanism has also been postulated, and various combinations of arterial and venous pathology have been described (one autopsy series showed little arterial compromise, but did show venous compression and thrombosis, thrombophlebitis of epidural veins, and venous infarction and edema of the spinal cord). Occasionally, there may be infection of the spinal cord itself, possibly by extension through the meninges.

Differential diagnosis

SEA should be considered in any patient with backache, fever, and spine tenderness, especially diabetics, IV drug abusers or immunocompromised patients. Also see Differential diagnosis, Myelopathy (p. 1407).

Differential diagnosis:
1. meningitis
2. acute transverse myelitis (paralysis is usually more rapid, radiographic studies are normal)
3. intervertebral disc herniation
4. spinal cord tumors
5. post-op SEA may appear similar to pseudomeningocele

Source site of infection

1. hematogenous spread is the most common source (26–50% of cases) either to the epidural space or to the vertebra with extension to epidural space. Reported foci include:
   a) skin infections (most common): furuncle may be found in 15% of cases
   b) parenteral injections, especially with IV drug abuse
   c) bacterial endocarditis
   d) UTI
   e) respiratory infection (including otitis media, sinusitis, or pneumonia)
   f) pharyngeal or dental abscess
2. direct extension from:
   a) decubitus ulcer
   b) psoas abscess: see below
   c) penetrating trauma, including: abdominal wounds, neck wounds, GSW
   d) pharyngeal infections
   e) mediastinitis
   f) pyelonephritis with perinephric abscess
   g) dermal sinus
3. following spinal procedures (3 of 8 of these patients had readily identified perioperative infections of periodonta, UTL or AV-fistula63)
   a) open procedures: especially lumbar discectomy (incidence≈0.67%)
   b) closed procedures: e.g. epidural catheter insertion for spinal epidural anesthesia,69,70,71 lumbar puncture72...
4. a history of recent back trauma is common (in up to 30%)
5. no source can be identified in up to 50% of patients in some series73

Organisms

Operative cultures are most useful in identifying the responsible organism, these cultures may be negative (possibly more common in patients previously on antibiotics) and in these cases blood cultures may be positive. No organism may be identified in 29–50% of cases.

1. Staph. aureus: the most common organism (cultured in >50%) possibly due to its propensity to form abscesses, its ubiquity, and its ability to infect normal and immunocompromised hosts (these facts help explain why many SEA arise from skin foci)
2. aerobic & anaerobic streptococcus: second most common
3. Ecoli
4. Pseudomonas aeruginosa
5. Diplococcus pneumoniae
6. Serratia marcescens
7. Enterobacter
8. chronic infections:
   a) TB is the most common of these, and although it has become less widespread in the U.S. it is still responsible for 25% of cases of SEA,74 it is usually associated with vertebral osteomyelitis, see Pott’s disease (p.354)
   b) fungal: cryptococcosis, aspergillosis, brucellosis
   c) parasitic: Echinococcus
9. multiple organisms in ≈10%
10. anaerobes cultured in ≈8%

Laboratory tests

CBC: leukocytosis common in acute group (average WBC=16,700/mm³), but usually normal in chronic (ave. WBC=9,800/mm³).59
   ESR elevated in most,73 usually > 30.63 CRP.
   LP: performed cautiously in suspected cases at a level distant to the clinically suspected site (C1–2 puncture may be needed to do myelogram) with constant aspiration while approaching thecal sac to detect pus (danger of transmitting infection to subarachnoid space); if pus is encountered, stop advancing, send the fluid for culture, and abort the procedure. CSF protein & WBC usually elevated; glucose normal (indicative of parameningeal infection). 5 of 19 cases grew organisms identical to abscess.
   Blood cultures: may be helpful in identifying organism in some cases.
   Anergy battery: (e.g. mumps and Candida) to assess immune system.

Radiographic studies

Plain films

Usually normal unless there is osteomyelitis of adjacent vertebral bodies (more common in infections anterior to dura). Look for lytic lesions, demineralization, and scalloping of endplates (may take 4–6 weeks after onset of infection).

MRI

Imaging study of choice. Differentiates other conditions (especially transverse myelitis or spinal cord infarction) better than myelo/CT, and doesn’t require LP.

   Typical findings: T1WI→hypointense epidural mass, vertebral osteomyelitis shows up as reduced signal in bone. T2WI→high intensity epidural mass that often enhances with gadolinium (3 patterns of enhancement: 1) dense homogeneous, 2) inhomogeneous with scattered areas of sparse or no uptake, and 3) thin peripheral enhancement76) but may show minimal enhancement in the acute stage when comprised primarily of pus with little granulation tissue. Vertebral osteomyelitis shows up as increased signal in bone, associated discitis produces increased signal in disc and loss of intranuclear cleft. Unenhanced MRI may miss some SEA,77 gadopentetate dimeglumine enhancement may slightly increase sensitivity.78
Myelogram-CT

Usually shows findings of extradural compression (e.g. “paintbrush appearance” when complete block is present). In the event of complete block, C1–2 puncture may be needed to delineate upper extent (unless post-myelographic CT shows dye above the lesion). See cautions above regarding LP.

CT scan

Intraspinal gas has been described on plain CT. Post-myelographic CT is more sensitive.

Treatment

General information

Controversial. In most cases, treatment consists of early surgical evacuation combined with antibiotics as the treatment of choice. Argument: although there are reports of management with antibiotics alone and immobilization, rapid and irreversible deterioration has occurred even in patients treated with appropriate antibiotics who were initially neurologically intact. 86% of those who deteriorated were initially treated with antibiotics alone. Therefore it has been recommended that nonsurgical management be reserved for the following patients (reference modified):

1. those with prohibitive operative risk factors
2. involvement of an extensive length of the spinal canal
3. complete paralysis for >3 days

To add fuel to the argument, in many cases, at the time of surgery, instead of a true abscess, inflammatory tissue that is not easily or effectively debrided is encountered.

Surgery

Goals are establishing diagnosis and causative organism, drainage of pus and debridement of granulation tissue, and bony stabilization if necessary. Most SEA are posterior to the dura and are approached with extensive laminectomy. For posteriorly located SEA and no evidence of vertebral osteomyelitis, instability will usually not follow simple laminectomy and appropriate postoperative antibiotics. Thorough antibiotic irrigation is employed intra-operatively. Primary closure is often employed. Post-op drainage is not necessary in cases with only granulation tissue and no pus. For recurrent infections, reoperation and post-op suction-irrigation may be needed.

Patients with associated osteomyelitis of the vertebral body may develop instability after laminectomy especially if significant bony destruction is present. Thus for anterior SEA, usually with osteomyelitis (especially Pott’s disease), a posterolateral extracavitary approach is utilized whenever possible (to avoid transabdominal or transthoracic approach in these debilitated patients) with removal of devitalized bone usually followed by posterior instrumentation and fusion. Strut grafting with autologous bone (rib or fibula) can be done acutely in Pott’s disease with little risk of graft infection. With purulent osteomyelitis, metal hardware is not contraindicated (titanium is more resistant to harboring bacteria than stainless steel for several reasons, including the fact that titanium does not permit bacteria to form a glycocalyx on its surface), but bone grafting may run the risk of perpetuating the infection. In this situation, some surgeons use beads of calcium sulfate bone void filler impregnated with antibiotic (e.g. Stimulan® Rapid Cure™ antibiotic beads).

Specific antibiotics

If organism and source unknown, S. aureus most likely. Empiric antibiotics:

- Ceftriaxone or cefepime (use when pseudomonas is a concern)
  PLUS
- metronidazole
  PLUS
- vancomycin:
  - until methicillin resistant S. aureus (MRSA) can be ruled out
  - once MRSA is ruled out switch to synthetic penicillin (e.g. nafcillin or oxacillin)
- ± rifampin PO

Modify antibiotics based on culture results or knowledge of source (e.g. IV drug abusers have a higher incidence of Gram-negative organisms).

Modify antibiotics based on culture results or knowledge of source (e.g. IV drug abusers have a higher incidence of Gram-negative organisms).
Duration of treatment
For spinal epidural abscess (SEA), treatment should continue for a minimum of 6 weeks. Longer therapy may be warranted in complicated infections and for patients who have spinal implants or hardware. Immobilization for at least 6 weeks during antibiotic therapy is recommended.

Outcome
Fatal in 4–31% (the higher end of the range tends to be in older patients and those paralyzed before surgery). Patients with severe neurologic deficit rarely improve, even with surgical intervention within 6–12 hrs of onset of paralysis, although a few series have shown a chance for some recovery with treatment within 36 hrs of paralysis. Reversal of paralysis of caudal spinal cord segments if present for more than a few hours is rare (exception: Pott’s disease has 50% return). Mortality is usually due to original focus of infection or as a complication of residual paraplegia (e.g. pulmonary embolism).

21.5.2 Vertebral osteomyelitis

General information

Key concepts
- presentation and risk factors similar to spinal epidural abscess (p.349)
- percutaneous needle biopsy for C&S and to rule-out tumor can usually be done by neurosurgeon or interventional radiologist
- treatment: most cases can be managed nonsurgically with long-term antibiotics
- surgery is considered for instability, and infrequently for severe resistance to Abx

For differential diagnosis, see Destructive lesions of the spine (p.1392). Often associated with discitis, which may be grouped together under the term spondylodiscitis. VO has features similar to spinal epidural abscess (SEA) (p.349).

Vertebral body collapse and kyphotic deformity may occur with possible retropulsion of necrotic bone and disc fragments, compressing the spinal cord or cauda equina.

Complications that may accrue
1. spinal epidural abscess
2. subdural abscess
3. meningitis
4. bony instability
5. progressive neurologic impairment
6. unique to cervical spine involvement: pharyngeal abscess
7. unique to thoracic spine involvement: mediastinitis

Epidemiology
Vertebral osteomyelitis (VO) comprises 2–4% of all cases of osteomyelitis. Incidence is 1:250,000 in general population. Incidence appears to be rising. Male:female ratio is 2:1. Incidence increases with age, most patients are >50 years old. The lumbar spine is the most common site, followed by thoracic, cervical and sacrum. Thoracic VO may → empyema.

Risk factors
1. IV drug abuse
2. diabetes mellitus: susceptible to unusual bacterial infections and even fungal osteomyelitis
3. hemodialysis: a diagnostic challenge since radiographic changes of osteomyelitis can occur even in the absence of infection, see Destructive lesions of the spine (p.1392)
4. immunosuppression
   a) AIDS
   b) chronic corticosteroid use
   c) ethanol abuse
5. infectious endocarditis
6. following spinal surgery or invasive diagnostic or therapeutic procedures
7. may occur in elderly patients with no other identifiable risk factors
Clinical

Signs/symptoms: localized pain (90%), fever (52% with fever spikes and chills being rare), weight loss, paraspinal muscle spasm, radicular symptoms (50–93%) or myelopathy. VO sometimes produces few systemic effects (e.g. WBC and/or ESR may be normal). 17% of patients with VO have neurologic symptoms. The risk of paralysis may be higher in the older patient, in cervical VO (vs. thoracic or lumbar), in those with DM or rheumatoid arthritis, and in those with VO due to S. aureus. Neurologic findings are uncommon initially, which may delay the diagnosis. Sensory involvement is less common than motor and long-tract signs because compression is primarily anterior.

Pathogenesis

Source of infection

Sources of spontaneous VO: UTI (the most common), respiratory tract, soft-tissues (e.g. skin boils, IV drug abuse...), dental flora. In 37% of cases a source is never identified.

Potential routes of spread

Three main routes: arterial, venous, and direct extension:

1. hematogenous: hematogenously disseminated spondylodiscitis in adults usually involves bone initially, and once infection is established in the subchondral space, spread is to the adjacent disc and thence to the next VB.
   a) arterial
   b) via spinal epidural venous plexus (Batson’s plexus)
2. direct extension (e.g. following surgery/LP, trauma, or local infection)

Organisms

1. Staphylococcus aureus is the most common pathogen (>50%) as in SEA
2. E. coli is a distant second
3. organisms associated with some primary infection sites:
   a) IV drug abusers: Pseudomonas aeruginosa and S. aureus are common
   b) urinary tract infections: E. coli & Proteus spp. are common
   c) respiratory tract infections: Streptococcus pneumoniae
   d) alcohol abuse: Klebsiella pneumoniae
   e) endocarditis:
      • acute endocarditis: Staph. aureus
      • subacute endocarditis: Streptococcus spp.
4. tuberculous VO: Mycobacterium tuberculosis (see below)
5. unusual organisms include: nocardia (p.335)
6. Mycobacterium avium complex (M. Avium and M. intracellulare) (MAC) can cause pulmonary disease in nonimmunocompromised patients (usually elderly or on chronic steroids), but can also cause VO similar to TB as part of disseminated disease which usually occurs in HIV patients
7. polymicrobial infections: rare (<2.5% of pyogenic VO infections)

Tuberculous vertebral osteomyelitis: AKA tuberculous spondylitis, AKA Pott’s disease. More common in third world countries. Typically symptomatic for many months. Usually affects more than one level. The most common levels involved are the lower thoracic and upper lumbar levels. Has a predilection for the vertebral body, sparing the posterior elements. Psoas abscess is common (the psoas major muscle attaches to the bodies and intervertebral discs from T12-L5). Sclerosis of the involved vertebral body may occur. Definitive diagnosis requires the identification of acid fast bacilli on culture or Gram stain of biopsy material (may be done percutaneously).

Neurologic deficit develops in 10–47% of patients, and may be due to medullary and radicular artery inflammation in most cases. The infection itself rarely extends into the spinal canal, however, epidural granulation tissue or fibrosis or a kyphotic bony deformity may cause cord compression.

The role of surgical debridement and fusion with TB is controversial, and good results may be obtained with either medical treatment or surgery. Surgery may be more appropriate when definite cord compression is documented or for complications such as abscess or sinus formation or spinal instability.
Diagnostic tests

Laboratories
WBC: elevated in only ≈35% (rarely >12,000), associated with poor prognosis.
ESR: elevated in almost all. Usually >40 mm/hr. Mean: 85.
CRP: may be more sensitive than ESR, and may tend to normalize more quickly with appropriate treatment. See also normal values (p.347).

Cultures/biopsy
Culture: blood (positive in ≈50%), urine and any focal suppurative process.
Needle biopsy with cultures: can usually be done percutaneously via transpedicular approach with CT or fluoroscopic guidance. May be helpful even if blood cultures are positive (different organisms retrieved in 15%). An attempt at direct culture from the involved site should be made. Ideally, cultures should be done before antibiotics are started. The yield of needle biopsy cultures ranges from 60–90%. Open biopsy is more sensitive, but morbidity is higher.

Imaging
A comparison of sensitivities and specificities of various imaging modalities is shown in Table 21.4.
NB: CT may be negative if done too early in the course.
MRI: T1 WI → confluent low signal in vertebral bodies and intervertebral disc space. T2 WI → increased intensity of involved VBs and disc space. Contrast: enhancement of VB and disc, also look for paraspinal and epidural mass.
CT scan: helpful for demonstrating bony involvement as well as detailed bony anatomy in case instrumentation is required during treatment.
Plain x-ray: changes take from 2–8 weeks from the onset of infection to develop. Earliest changes are loss of cortical endplate margins and loss of disc space height.
Bone scan: three phase bone scan (p.236) has reasonably good sensitivity and specificity. Gallium scan (p.236) has better accuracy, findings include increased uptake in the 2 adjacent VBs with loss of intervening disc. Indium-111 labeled WBC scan: low sensitivity for vertebral osteomyelitis.

Work-up
In patients with suspected vertebral osteomyelitis (VO) (see text above for details):
1. clinical: history of IV drug abuse, DM, immunocompromise, skin boil
2. physical exam: R/O radiculopathy & myelopathy, point tenderness over spine
3. diagnostic tests:
   a) bloodwork: WBC, ESR & CRP (a normal ESR is almost incompatible with VO), blood cultures
   b) imaging:
      • MRI without and with contrast
      • If MRI is contraindicated: CT-myelogram assesses bony anatomy and can demonstrate spinal canal compromise. Bone scan may occasionally be helpful if the diagnosis is still uncertain when suspicion is high
   c) percutaneous needle biopsy with cultures: usually by radiologist. Cultures should include: fungal, aerobic and anaerobic bacterial, and TB

Treatment
Also see more details (p.352). 90% of cases can be managed non-surgically with antibiotics and immobilization. Characteristics of potential candidates for non-surgical treatment are listed in Table 21.5. Must also take into account level(s) involved and patient's condition.

In cases with high suspicion for VO, antibiotics may be started as soon as biopsy has been performed (some treat even earlier). For details of antimicrobials, see Treatment (p. 352) under spinal epidural abscess.

Improvement on imaging can lag behind clinical response and ESR/CRP.

Indications for neurosurgical intervention (note: intervention by a general surgeon may be indicated for empyema, psoas abscess...):
1. progression of disease despite adequate best-case antibiotic therapy
2. spinal instability
3. spinal epidural abscess (p.349)
4. chronic infection refractory to medical management

For patients not being treated surgically:
1. percutaneous biopsy to obtain ID & sensitivity of organism
2. antibiotics:
   a) IV antibiotics for at least 6 weeks (the rate of treatment failure is increased when IV antibiotics are given for <4 weeks; longer, e.g. 12 weeks, if ESR not normalizing or if extensive bone involvement and paravertebral infection)
   b) followed by 6–8 weeks of oral agents
3. pain medication as appropriate for pain
4. TLSO brace: to reduce pain (due to movement at involved site) and to reduce stress on weakened bone until healing
5. check upright films in the TLSO to verify stability in the brace
6. follow-up at approximately 8 and 12 weeks with x-rays in brace, then consider discontinuing brace if infection and pain are under control

Surgical treatment
Decompression of neural elements, removal of inflammatory tissue and infected bone to decrease bioburden. Use of instrumented fusion is not contraindicated even for pyogenic infections. Although not routinely used, bone morphogenic protein (rhBMP-2) in 14 patients undergoing circumferential fusion for refractory infections did not produce complications.

21.5.3 Discitis

General information
Infection of the nucleus pulposus. May start in the cartilaginous endplate and spread to the disc and vertebral body (VB). Similar to vertebral osteomyelitis, except osteomyelitis primarily involves the VB and spreads secondarily to the disc space.

Setting: may be “post-op” or “spontaneous”
- Spontaneous discitis: Occurs in the absence of any procedure. Discussed below
- Post-op discitis: Can occur following a number of procedures; see Postoperative discitis (p.346).
  This is covered under post-op infections

Many radiographic features of spondylodiscitis and tumor (metastatic and primary) are similar, but tumors rarely involve the disc space, whereas most infections begin in, or before too long, involve the disc space; for more details, see Differentiating factors (p.1392).

Two distinct types:
1. juvenile: age usually <20 yrs (see below)
2. adult: usually occurs in susceptible patients (diabetics, IV drug abusers)
Juvenile discitis
Age usually <20 yrs, with a peak between 2–3 years. Probably due to the presence of primordial feeding arteries that nourish the nucleus pulposus and which involute at ≈ 20–30 yrs age. Lumbar spine is more commonly involved than thoracic or cervical.

Common presentation in young children: refusal to walk or stand progressing to refusal to sit. Back pain is most common in children >9 yrs age. Low grade fever may be present. ESR is usually 2–3 × normal. WBC is sometimes elevated. H. flu is a more commonly seen pathogen in this group.

In most cases, there is complete resolution in 9–22 weeks without recurrence in long-term follow-up studies. Surgery is reserved for the rare case that progresses in spite of antibiotics, for spinal instability, or for recurrent cases.

Most authors reserve antibiotics for patients with:
1. positive cultures (blood cultures or biopsy cultures)
2. elevated WBC count, constitutional symptoms, or high fever
3. poor response to rest or immobilization
4. neurologic sequelae (very rare)

Antibiotics should be given for a total of 4–6 weeks. Start with IV antibiotics, and when clinical symptoms improve convert to PO for the remainder of therapy.

Clinical
1. symptoms:
   a) pain (the primary symptom)
      • local pain, moderate to severe, exacerbated by virtually any motion of the spine, usually well localized to the level of involvement
      • radiating to abdomen, hip, leg, scrotum, groin, or perineum
      • radicular symptoms: occurs in 50% to 93% depending on the series
   b) fever and chills: up to 70% are afebrile
2. signs:
   a) localized tenderness
   b) paravertebral muscle spasm
   c) limitation of movement

Work-up
Overview
See following sections for details.
• blood tests
  ○ WBC
  ○ ESR & CRP
  ○ blood cultures
• imaging
  ○ MRI of the region of concern without and with contrast: the diagnostic test of choice.
  ○ If MRI is contraindicated: CT-myelogram, bone scan
• percutaneous needle biopsy: usually performed by interventional radiologist
• a source of the infection should be sought
  ○ thorough history for possible risk factors: skin lesions, IV drug abuse, immunocompromise
  ○ echocardiogram TEE: rule-out endocarditis or valvular vegetations

Radiographic evaluation
General information
A characteristic radiographic finding that helps distinguish infection from metastatic disease is that destruction of the disc space is highly suggestive of infection, whereas in general, tumor does not cross the disc space; see Differentiating factors (p. 1392).

Plain x-rays
Usually not helpful for early diagnosis. Sequence of changes on plain films:
• earliest changes: interspace narrowing with some demineralization of the VB. Not seen <2–4 wks following onset of clinical symptoms, nor later than 8 wks

http://e-surg.com
• sclerosis (eburnation) of adjacent cortical margins with increased density of adjacent areas of VB representing new bone formation, starting 4–12 weeks following onset of clinical symptoms
• irregularity of the adjacent vertebral endplates, with sparing of the pedicles (except for tuberculosis, which may involve the pedicles)
• in 50% of cases, the infection remains confined to the disc space, in the other 50% it spreads to adjacent VB
• a late finding is widening (ballooning) of the disc space with erosion of the VB
• circumferential bone formation may lead to exuberant spur formation between VBs 6–8 months into course of illness
• spontaneous fusion of the VB may occur

MRI
Without and with gadolinium contrast. Demonstrates involvement of disc space and of VBs. MRI can R/O paravertebral or epidural spinal abscess but is poor in assessing bony fusion and bone integrity. As sensitive as radionuclide bone scan. Characteristic finding: decreased signal from the disc and adjacent portion of VBs on T1WI, and increased signal from these structures on T2WI. Enhancement is common. Characteristic findings may occur 3–5 days after onset of symptoms.

CT and myelo-CT
Like MRI, may also R/O paravertebral or epidural spinal abscess, and while it is better for assessing bony fusion and integrity, by itself it is poor for demonstrating canal compromise. With the addition of water soluble intrathecal contrast (myelo-CT), also assesses the spinal canal for compromise.

Diagnostic criteria
Three basic changes on CT\(^1\) (if all 3 are present, pathognomonic for discitis; if only the 1st 2 are present, then only 87% specific for discitis):
1. endplate fragmentation
2. paravertebral soft-tissue swelling with obliteration of fat planes
3. paravertebral abscess

Nuclear medicine
Very sensitive for discitis and vertebral osteomyelitis (85% sensitivity), but may be negative in up to 85% of patients with Pott's disease. Uses either technetium-99 (abnormal as early as 7 days following onset of clinical symptoms) or gallium-67 (abnormal within 14 days). A positive scan shows focal increased uptake in adjacent endplates, and may be differentiated from osteomyelitis which will involve only one endplate. A positive scan is not specific for infection, and may also occur with neoplasms, fractures, and degenerative changes.

Laboratory studies
ESR: In non-immunocompromised patients, ESR will be elevated in almost all cases with an average value of 60 mm/hr (although discitis with a normal ESR occurs rarely, it should call the diagnosis into question. ESR may be useful to follow as an indicator of response to treatment.
C-reactive protein (CRP): Often used in conjunction with ESR
WBC: Peripheral WBC is often normal, and rarely is elevated above 12,000.
PPD (Purified Protein Derivative, AKA Mantoux screening test): May be helpful to R/O Pott's disease in cases of spontaneous discitis (p.354), may be negative in 14% of cases.\(^1\)
Cultures: An attempt should be made to obtain direct cultures from the involved disc space. These may be obtained percutaneously (e.g. Craig needle biopsy) with CT or other radiographic guidance (reported up to 60% positive culture rate), or from intra-operative specimen (NB: surgery for open biopsy alone is usually not indicated). Staining for acid fast bacilli (AFB) to identify Mycobacterium tuberculosis (TB) should be done in all cases.
Blood cultures may be positive in \(\approx 50\)% of cases, and can be helpful in guiding choice of antimicrobial agent when positive.

Pathogens
Staphylococcus aureus is the most common organism when direct cultures are obtained, followed by S. albus and S. epidermidis. Gram negative organisms may also be found, including E. coli and Proteus species.
Pseudomonas aeruginosa may be more common in IV drug abusers.
H. flu is common in juvenile discitis (see below).
Mycobacterium tuberculosis: Tuberculous spondylitis (Pott's disease) may also occur.
Treatment

General information
Outcome is generally good, and antibiotics together with spinal bracing (immobilization) are adequate treatment in approximately 75% of cases. Occasionally surgery is required. See also under postoperative discitis for other aspects of management (p.347).

Most patients are started on strict bed rest, and are then mobilized with or without a brace as tolerated.

Spinal bracing
Probably does not affect final outcome. Affords earlier pain relief for some, and may allow return to activity at an earlier time. For thoracic or upper lumbar discitis, the patient is fitted with a clamshell-type body jacket which is used for 6–8 weeks on the average. As a practical matter, most patients find that the discomfort from the brace is worse than that without the brace. Alternative forms of immobilization include spica cast (provides better immobilization for lower lumbar discitis) or a corset-type brace (less immobilization but better tolerated).

Antibiotics
Choice of antibiotics is guided by the results of direct cultures when positive. In the 40–50% of cases where no organism is isolated, broad spectrum antibiotics should be used. Positive blood culture results may also help guide choice of antibiotics.

Two alternative treatment plans suggested:
1. treat with IV antibiotics for an arbitrary period of time, usually 4–6 weeks, followed with oral antibiotics for an additional 4–6 weeks
2. treat with IV antibiotics until the ESR normalizes, then change to PO

Surgery
Required in only approximately 25% of cases.
Indications for surgery:
1. situations where the diagnosis is uncertain, especially when neoplasm is a strong consideration (CT guided needle biopsy usually helps here)
2. decompression of neural structures, especially with associated spinal epidural abscess or compression by reactive granulation tissue. Ascending numbness, weakness, or onset of neurogenic bladder herald cauda equina syndrome
3. drainage of associated abscess, especially septated abscesses that might be recalcitrant to CT guided percutaneous needling
4. rarely, to fuse an unstable spine. Most cases go on to spontaneous fusion

Approaches
- anterior approaches: generally used in the cervical or thoracic regions. Removes some or most of the offending infected tissue
  - cervical spine: anterior discectomy and fusion for limited involvement; corpectomy with strut graft and plating with posterior instrumentation (360° fusion) for more extensive involvement
  - thoracic spine: a posterolateral approach (e.g. transpedicular or costotransversectomy approach) or lateral approach (e.g. trans-thoracic or retro-coelomic) may be used
- posterior laminectomy
  - may be used in the lumbar region (below the conus medullaris)
  - laminectomy alone is not appropriate in the thoracic or cervical spine when there is anterior compression of the spinal cord.

21.5.4 Psoas abscess

General information

1. Applied anatomy of psoas muscle:
   a) one of 2 heads of the iliopsoas muscle (the other head is iliacus)
   b) origin: inner surface of ilium, base of sacrum, and transverse processes, vertebral bodies (VB) and intervertebral discs of spinal column starting from the inferior margin of T12 VB, extending to the upper part of L5 VB. Insertion: lesser trochanter of the femur. Psoas is the primary hip flexor
   c) 30% of people also have a psoas minor which lies anterior to the psoas major
d) innervation: branches of L2–4 nerve roots proximal to the formation of the femoral nerve
e) susceptibility to infection
  - rich vascular supply makes it vulnerable to hematogenous spread
  - proximity to structures that may be a source of infection: sigmoid colon, jejunum, vermi-
    for m appendix, ureters, aorta, renal pelvis, pancreas, iliac lymph nodes and spine

2. may be primary (no identifiable underlying disease) or secondary in which it may be associated
   with one of the conditions shown in Table 21.6

3. risk factors: IV drug abuse, HIV/AIDS, age >65 years, DM, immunosuppression, renal failure

Clinical findings

Physical findings: signs of iliopsoas inflammation include:
1. active: pain on flexing the hip against resistance
2. passive: with the patient lying on the unaffected side, hyperextension of the affected hip
   stretches the psoas muscle and produces pain.

Diagnostic tests

1. routine infection work-up: WBC (often elevated), blood cultures, U/A+C&S (pyuria may be seen)
2. AP abdominal x-ray: psoas shadow may be obliterated
3. CT: sensitivity is 80–100% (MRI is not better). Enlargement of psoas muscle on affected side
   best seen inside iliac wing.

Treatment often includes drainage of the psoas abscess either surgically or percutaneously with CT-
guidance.

Mortality rates associated with psoas abscess: 2.4% with primary, 19% with secondary, with sepsis
being the usual cause of death.

22 Other Nonbacterial Infections

22.1 Viral encephalitis

Encephalitides that come to the attention of the neurosurgeon usually cause imaging findings that may mimic mass lesions, for cases where biopsy may be helpful, and shunting for hydrocephalus is needed. Those covered in this book:
1. herpes simplex encephalitis: see below
2. multifocal herpes varicella-zoster virus leukoencephalitis (p.366)
3. progressive multifocal leukoencephalopathy (PML) (p.331)

22.1.1 Herpes simplex encephalitis

General information

Key concepts

- a hemorrhagic viral encephalitis with a predilection for temporal lobes
- definitive diagnosis requires brain biopsy
- optimal treatment: early administration of IV acyclovir

Herpes simplex encephalitis (HSE) AKA multifocal necrotizing encephalomyelitis, is caused by the herpes simplex virus (HSV) type I. It produces an acute, often (but not always) hemorrhagic, necrotizing encephalitis with edema. There is a predilection for the temporal and orbitofrontal lobes and limbic system.

Epidemiology

Estimated incidence of HSE: 1 in 750,000 to 1 million persons/yr. Equally distributed between male and females, in all races, in all ages (over 33% of cases occur in children 6 mos to 18 yrs), throughout the year.1

Presentation

Patients are often confused and disoriented at onset, and progress to coma within days. Adult presentations are shown in Table 22.1, and for pediatrics in Table 22.2. Other symptoms include headache.

Diagnostic studies

Diagnosis can often be made on the basis of history, CSF, and MRI. Treatment should be instituted rapidly without waiting for biopsy, before the onset of coma.

1. CSF: leukocytosis (mostly monos), RBCs 500–1000/mm³, (NB: 3% have no pleocytosis), protein rises markedly as disease progresses. HSV antibodies may appear in the CSF but takes at least ≈ 14 days and is thus not useful for early diagnosis

<table>

</tr>
<tr>
<td>personality changes</td>
</tr>
<tr>
<td>hemiparesis</td>
</tr>
</tbody>
</table>
2. EEG: periodic lateralizing epileptiform discharges (PLEDs) (triphasic high-voltage discharges every few seconds) usually from the temporal lobe. EEG may vary rapidly over few days (unusual in conditions mimicking HSE).

3. CT: edema predominantly localized in temporal lobes (poorer prognosis once hemorrhagic lesions visible). In one review, 38% of initial CTs were normal² (many were on early generation CT scanners or were done within 3 days of onset). Hemorrhages were apparent in only 12% of the initially abnormal CTs.

4. MRI: more sensitive than CT,³ demonstrates edema as high signal on T2WI, primarily within the temporal lobe, with some extension across sylvian fissure ("transsylvian sign"),² especially suggestive of HSE if bilateral. Differentiate from MCA infarct (which may also span sylvian fissure) by typical arterial distribution of the latter. Enhancement doesn't occur until the 2nd week.

5. technetium brain scan: process localized to temporal lobes

6. brain biopsy: false negatives may occur⁴; see details below

**Brain biopsy**

**Indications:** reserved for questionable cases. May not be necessary in patients with fever, encephalopathy, compatible CSF findings, focal neuro findings (focal seizure, hemiparesis, or cranial nerve palsy), and supporting evidence of at least one of the following: focal EEG, CT, MRI or technetium brain scan abnormality.

Should be performed within ≤48 hrs of starting acyclovir (otherwise false negatives may occur).

**Biopsy results:** of 432 brain biopsies performed using the technique below, 45% had HSE, 22% had identifiable but non HSE pathology (e.g. vascular disease, other viral infection, adrenal leukodystrophy, bacterial infection…), and 33% remained without a diagnosis.⁵

**Technique**

1. anterior inferior temporal lobe is preferred site
   a) the side chosen for biopsy is the one showing maximal involvement based on clinical information (e.g. localizing seizures), EEG and/or imaging studies⁶
   b) 10×10×5 mm deep specimen obtained from anterior portion of the inferior temporal gyrus with NO COAGULATION on specimen side (cut surface with #11 blade, then cauterize pial surface on non-specimen side)
   c) 2nd specimen obtained from beneath surface specimen with fenestrated pituitary biopsy forceps

2. virus isolation is the most specific (100%) and sensitive (96–97%) test for HSE. Other findings (less accurate): perivascular cuffing, lymphocytic infiltration, hemorrhagic necrosis, neuronophagia, intranuclear inclusions (present in 50%)

3. if electron microscopy (EM) or immunohistofluorescence is available, 70% may be diagnosed within ≈3 hrs of biopsy

4. biopsy tissue handling
   a) avoid macerating specimens for histology
   b) tissue for EM: placed in glutaraldehyde
   c) tissue for permanent histology: placed in formalin
   d) tissue for culture:

• handling: specimen is placed in sterile specimen container and sent directly to virology lab. If lab is closed, tissue may be placed in regular refrigerator for up to 24 hrs or placed in –70° C freezer for indefinite time (virus remains viable for up to 5 yrs). DO NOT place specimen in regular freezer (destroys virus)
• cultures generally take at least 1 week to become positive
• cultures checked for 3 weeks before being declared negative

Treatment

General treatment measures
General supportive measures: to control elevated ICP from edema, includes: elevate HOB, mannitol, hyperventilation (dexamethasone unproven efficacy); also see Treatment measures for elevated ICP (p.866). Anticonvulsants are used for seizure prophylaxis.

Antiviral medications
Acyclovir is the drug of choice for HSE.

Drug info: Acyclovir (Zovirax®)

Adult: 30 mg/kg/day, in divided q 8 hr doses in minimum volume of 100 ml IV fluid over 1 hr (caution: this fluid load may be hazardous, especially since cerebral edema is already usually problematic) for 14–21 days (some relapses have been reported after only 10 days of treatment).
Children >6 mos age: 500 mg/m² IV q 8 hrs × 10 days.
Neonatal: 10 mg/kg IV q 8 hrs for 10 days.

Drug info: Vidarabine (Vira-A®)

Six month mortality following treatment with acyclovir was influenced by:
• age (6% under age 30, 36% over age 30)
• Glasgow coma score (GCS) at time of treatment initiation (25% for GCS ≤ 10, 0% for GCS > 10)
• duration of disease before therapy (0% for initiating therapy within 4 days of onset of symptoms, 35% if after 4 days)

22.1.2 Multifocal varicella-zoster leukoencephalitis

Caused by the herpes varicella-zoster virus (VZV) which is responsible for varicella (chickenpox), herpes zoster (HZ) (shingles), and post-herpetic neuralgia (p.493). VZV is a herpesvirus that is distinct from the herpes simplex virus.

Symptomatic zoster-related encephalitis occurs in <5% of immunocompromised patients (including AIDS patients) with cutaneous zoster. It typically follows cutaneous HZ by a short time (average time: 9 days) although cases have been reported where many months have lapsed. Manifestations include: altered level of consciousness, headache, photophobia, meningismus. Although focal neurologic deficits may occur, these are uncommon. Recently, vasculopathy following VZV reactivation has been increasingly recognized. MRI may show multiple, discrete, round and oval lesions with minimal edema (best seen on T2WI) and minimal enhancement. Unlike herpes simplex virus, VZV is difficult to isolate in culture. On brain biopsy, look for multiple discrete lesions within grey and white matter, with Cowdry type A intranuclear inclusion bodies in oligodendrocytes, astrocytes, and neurons, and a positive direct fluorescent antibody test directed against VZV.

There is a case report of VZVencephalitis treated with IV acyclovir.
22.2 Creutzfeldt-Jakob disease

22.2.1 General information

**Key concepts**

- an invariably fatal encephalopathy characterized by rapidly progressive dementia, ataxia and myoclonus
- death usually occurs within 1 yr of onset of symptoms
- 3 forms: 1) transmissible (possibly via prions), 2) autosomal dominant inherited, 3) sporadic
- characteristic EEG finding: bilateral sharp wave (0.5–2 per second)
- pathology: status spongiosus without inflammatory response

Creutzfeldt-Jakob disease (CJD) is one of 4 known rare human diseases associated with transmissible spongiform encephalopathy agents, also called prions (proteinaceous infectious particles). Although sometimes also referred to as a “slow virus”, these agents contain no nucleic acids and are also resistant to processes that inactivate conventional viruses (Table 22.4). Prions do not provoke an immune response. The other human prion diseases are kuru, Gerstmann-Sträussler-Scheinker disease, and fatal familial insomnia (described in 2 families). The protease-resistant protein associated with disease is designated PrPres or PrPSc, and is an isoform of a naturally occurring protease-sensitive protein designated PrPsen or PrPC. In the abnormal state, PrPsen which is a predominantly alpha-helical structure, undergoes a post-translational conformation change to PrPres which has large beta-sheets, and which accumulates in neural cells, disrupting function and leading to cell death and vacuolization. The famous choreographer George Balanchine died of CJD in 1983.

CJD occurs in 3 forms: transmissible, inherited and sporadic.

22.2.2 Epidemiology

Annual incidence of CJD: 0.5–1.5 per million population with little change over time and no geographic clustering (except in locations with large numbers of familial cases). Over 200 people die of CJD in the U.S. each year.

22.2.3 Acquired prion diseases

Natural route of infection is unknown and virulence appears low, with lack of significant dissemination by respiratory, enteric, or sexual contact. There is no increased incidence in spouses (only a single conjugal pair of cases has been verified), physicians or laboratory workers. There is no evidence of transplacental transmission. The only known cases of horizontal transmission of CJD have occurred iatrogenically (see below). Kuru has been transmitted via handling and ingestion of infected brains in ritualistic funereal cannibalism practiced among the Fore (pronounced: “fore-ay”) linguistic group in the eastern highlands of Papua, New Guinea, a practice which was generally abandoned in the 1950s. Kuru is a subacute, uniformly fatal disease involving cerebellar degeneration (the word “kuru” means “to tremble” in the local language). Most noniatrogenically transmitted cases of CJD occur in patients >50 yrs old, and is rare in age <30. The incubation period can range from months to decades. The onset of symptoms following direct inoculation is usually faster (common range: 16–28 mos), but still may be much longer (up to 30 years with corneal transplant and 4–21 yrs with hGH transmission). In experimental models of CJD, higher inoculation doses produce shorter incubation periods.

22.2.4 Inherited CJD

5–15% of cases of CJD occur in an autosomal dominant inheritance pattern with abnormalities in the amyloid gene on chromosome 20 with a penetrance of 0.56. Since familial CJD is dominantly inherited, analysis for the PrP gene is not indicated unless there is a history of dementia in a first degree relative.
22.2.5 Sporadic CJD

In ≈90% of cases of CJD, no infectious or familial source can be identified, and these cases are considered sporadic. 80% occur in persons 50–70 yrs old. Sporadic cases show no abnormality in the PrP gene.

There appears to be a genetic susceptibility in the sporadic and iatrogenically transmitted CJD cases, with the majority of these showing specific changes in the human prion protein.

22.2.6 New variant CJD

Cases of atypical CJD are well-recognized. A new variant of CJD (vCJD) was identified in 10 cases of unusually young individuals (median age at death: 29 yrs) during 1994–95 in the United Kingdom, and has been strongly linked to the 1980s epidemic of bovine spongiform encephalopathy (BSE), dubbed “mad cow” disease by the lay press. The BSE epidemic may have been exacerbated by the practice of feeding discarded sheep organs (called offals) to the cows (a practice banned since 1989). This raises the question of possible transmission and mutation of the sheep slow-virus disease, scrapie (which resembles kuru in man) to cows. None of the vCJD patients had periodic spikes on EEG characteristic of classic CJD, the clinical course was atypical (having prominent psychiatric symptoms and early cerebellar ataxia, somewhat similar to kuru), and brain plaques showed unusual features also reminiscent of amyloid plaques seen in kuru. A comparison of vCJD to sporadic CJD is shown in Table 22.3.

22.2.7 Iatrogenic transmission of CJD

Described only in cases of direct contact with infected organs, tissues or surgical instruments. Has been reported with: corneal transplants, intracerebral EEG electrodes sterilized with 70% alcohol and formaldehyde vapor after use on a CJD patient, operations in neurosurgical O.R.s after procedures on CJD patients, in recipients of pituitary-derived human growth hormone (hGH) (most cases have occurred in France; there is no longer a risk of CJD with growth hormone in the U.S. since distribution of pituitary derived hGH was halted in 1985 and current hGH is obtained from recombinant DNA technology), and dural graft with cadaveric dura mater (Lyodura®) (most cases have occurred in Japan). Ethylene oxide, autoclaving, formalin and ionizing radiation do not inactivate the CJD agent (see Table 22.4 for other ineffective procedures). Recommended sterilization procedures for suspected CJD tissues and contaminated materials also appear in Table 22.4.

22.2.8 Pathology

The typical form of CJD produces the classic histologic triad of neuronal loss, astrocytic proliferation, and cytoplasmic vacuoles in neurons and astrocytes (status spongiosus), all in the absence of an inflammatory response. There is a predilection for cerebral cortex and basal ganglia, but all parts of the CNS may be involved. In 5–10% of cases, these changes are accompanied by the deposition of amyloid plaques (plaques are common in kuru, vCJD and some familial spongiform encephalopathies). Immunostaining for PrPres is definitive.

22.2.9 Presentation

One-third initially express vague feelings of fatigue, sleep disorders, or reduced appetite. Another third have neurologic symptoms including memory loss, confusion, or uncharacteristic behavior. The last third have focal signs including cerebellar ataxia, aphasia, visual deficits (including cortical blindness), or hemiparesis.

The typical course is inexorable, progression of dementia, often noticeably worse week by week, with subsequent rapid development of pyramidal tract findings (limb weakness and stiffness, pathologic reflexes), and late extrapyramidal findings (tremor, rigidity, dysarthria, bradykinesia) and myoclonus (often stimulus triggered). Clinical signs of sporadic CJD are shown in Table 22.5.

Supranuclear gaze palsy is an occasional finding, also usually late. In early stages, CJD may resemble Alzheimer’s disease (SDAT). 10% of cases present as ataxia without dementia or myoclonus. Cases with predominant spinal cord findings may be initially mistaken for ALS.

Myoclonus subsides in the terminal phases, and akinetic mutism ensues.

22.2.10 Diagnosis

Diagnostic criteria

The complete “diagnostic triad” (dementia, myoclonus and periodic EEG activity) may be absent in up to 25% of cases. Diagnostic criteria have been published as shown in Table 22.6. No patients in...
their series with a diagnosis other than CJD fulfilled the criteria for clinically definite CJD. The most common condition other than CJD fulfilling the criteria for clinically probable CJD was SDAT (especially difficult to distinguish in the early stages). There is a CSF immunoassay for the 14–3-3 brain protein (see below).

### Differential diagnosis

CSF examination to exclude infections such as tertiary syphilis or SSPE is recommended. Toxicity from bismuth, bromides and lithium must be ruled-out. Myoclonus is usually more prominent early in toxic/metabolic disorders than in CJD, and seizures in CJD are usually late.13

### Diagnostic tests

1. **Imaging:** no characteristic CT or MR finding. These studies are frequently normal, but are essential to rule-out other conditions (e.g. herpes-simplex encephalitis, recent stroke…). Diffuse atrophy may be present, especially late. MRI may show increased intensity on T2WI in areas typically involved (basal ganglion, striatum) in up to 79% of cases (retrospectively).30 This is nonspecific but may help differentiate CJD from SDAT.31

2. **Blood tests:** serum assays for S-100 protein are so insensitive and nonspecific that it can only be used as a diagnostic adjunct

3. **CSF:**
   - **a)** routine labs: usually normal, although protein may occasionally be elevated
   - **b)** abnormal proteins:
     - abnormal proteins (designated 130 & 131) have been identified in the CSF of patients with CJD,13 but the assay is technically difficult and is therefore not practical for routine clinical use
     - proteins 130/131 were identified as the normal neuronal protein 14–3-3, and a relatively simple immunoassay for this was developed for use on as little as 50 mcL of CSF.14 Detection of the 14–3-3 protein in the CSF has 96% sensitivity and specificity for CJD among patients with dementia. False positives may occur in other conditions involving extensive neuronal destruction including: acute stroke, herpes encephalitis, multi-infarct dementia, primary CNS lymphoma and rarely SDAT (most cases of SDAT test negative). Requires CSF (cannot be done on blood)

4. **EEG:** characteristic finding of bilateral, symmetrical, periodic bi- or triphasic synchronous sharp-wave complexes, AKA periodic spikes, AKA pseudoperiodic sharp-wave complexes (0.5–2 per second) have ≥ 70% sensitivity and 86% specificity.15 They resemble PLEDs (p. 238), but are responsive to noxious stimulus (may be absent in familial CJD10 and in the recent UK variant (see above))

5. **SPECT scan:** may be abnormal in vCJD even when EEG is normal,16 however the findings are not specific for vCJD

6. **Brain biopsy:** see below

7. **Tonsillar biopsy:** patients with variant CJD (vCJD) may have detectable levels of variant type 4 of the abnormal prion protein (PrPSc) in their lymphoreticular system, which may be accessed by a 1 cm wedge-biopsy of one palatine tonsil (using careful aseptic precautions)17
Brain biopsy

Due to lack of an effective treatment and the potential for iatrogenic infection in surgery, biopsy is reserved for cases where establishing the diagnosis is deemed important, or as part of a research study, or when diagnostic tests are equivocal and other potentially treatable etiologies are suspected.

Technique: to prevent aerosolization of the infectious agent, a manual saw is recommended over a power craniotome, and every effort should be made to avoid cutting the dura with the saw. Recommended decontamination procedures should be followed (Table 22.4 and references). Specimens should be clearly labeled as being from suspected CJD patients to alert laboratory personnel to the hazard. Tissue should be fixed in a saturated 15% phenolized formalin (15 g of phenol per dl of 10% neutral buffered formalin with the undissolved phenol layering at the bottom of the solution).

Analysis for classic histologic findings (see above) and/or immunostaining for PrPres are the gold standards of diagnosis.

22.2.11 Treatment and prognosis

Given the lack of demonstrated infectivity (with tissues other than brain or CSF), isolation precautions such as gowns or masks are felt to be unnecessary. There is no known treatment. The disease is rapidly progressive. Median survival is 5 months, and 80% of patients with sporadic CJD die within 1 year of diagnosis.

22.3 Parasitic infections of the CNS

22.3.1 General information

A number of parasitic infections may involve the central nervous system. Immunosuppression (including HIV) increases the susceptibility. CNS parasitic infections include (those that potentially involve neurosurgical intervention have a dagger †):

1. cysticercosis †: see Neurocysticercosis below
2. toxoplasmosis †: may occur as a congenital TORCH infection, or in the adult usually with AIDS; see Neurologic manifestations of AIDS (p.329). Toxoplasma gondii is an obligate intracellular protozoan that is ubiquitous but does not cause clinical infection except in immunocompromised hosts. Histologic features: necrosis containing 2–3 nm tachyzoites (cysts)
3. echinococcus † (p.375)
4. amebiasis † = exclusively Naegleria fowleri (p.377)
5. schistosomiasis
6. malaria

† parasitic infections with a dagger are those that are more likely to come to neurosurgical attention.

22.3.2 Neurocysticercosis

General information

Key concepts

- intracranial encystment of larva of Taenia solium (pork tapeworm)
- the most common parasitic infection of the CNS
- neurological symptoms: seizures or progressive intracranial hypertension
- occurs from ingesting the parasite’s eggs, not from eating infested meat
- characteristic imaging finding: low density cysts with eccentric punctate high density (the scolex = tapeworm head). Hydrocephalus is common
- medical treatment: all patients get steroids. Start antihelmintic drugs (praziquantel or albendazole) when no signs of intracranial hypertension
- biopsy sometimes needed for diagnosis. Surgery: may be required for spinal, intraventricular or subarachnoid cysts (more refractory to medical therapy) or for giant cysts (>50 mm) when intracranial hypertension persists despite steroids
Cysticercosis is the most common parasitic infection involving the CNS and in some low-income countries it is the most common cause of acquired epilepsy. It is caused by Cysticercus cellulosae, the larval stage of the pork tapeworm Taenia solium, which has a marked predilection for neural tissue. Cysticercosis is endemic in areas of Mexico, Eastern Europe, Asia, Central and South America, and Africa. The incidence of neurocysticercosis (encystment of larva in the brain) may reach 4% in some areas. The incubation period varies from months to decades, but 83% of cases show symptoms within 7 years of exposure.

Life cycle of T. Solium

Stages
There are 3 stages to the life cycle: larva, embryo (or oncosphere) and adult. T. solium can infect man in two different ways: as the adult worm or as the larva.

Infection with the adult worm (taeniasis – a parasitic infection)
Human intestinal tapeworm infection (taeniasis) results from eating undercooked infested (measly) pork. The encysted tapeworm infection (taeniasis) results from eating undercooked infested (measly) pork. The encysted larvae are released in the small bowel and can then mature within the intestine into an adult over about 2 months. The scolex (head) of the segmented adult worm attaches by means of four suckers and two rows of hooklets to the wall of the small intestine where the worm absorbs food directly through its cuticle. Man is the only known definitive host for the adult tapeworm, for which the GI tract is the sole habitat. Proglottids (mature segments, each containing reproductive organs) produce eggs which are liberally excreted along with gravid proglottids segments in the feces.

Infection with the larva
The disease cysticercosis occurs when animals or humans become an intermediate host for the larval stage by ingesting viable eggs produced by the proglottid. The most common routes of ingestion of viable eggs are:

1. food (usually vegetables) or water contaminated with human feces containing eggs or gravid proglottids (this is the means whereby pigs acquire the disease)
2. fecal-oral autoinoculation in an individual harboring the adult form of the tapeworm due to lack of good sanitary habits or facilities
3. autoinfestation by reverse peristalsis of gravid proglottids from the intestine into the stomach (unproven theoretical possibility)

In the duodenum of man and pig, the shell of the ova dissolves and the thusly hatched embryos (oncospheres) burrow through the small bowel wall to enter the lymphatics or systemic circulation and gain access to the following commonly involved sites:

- brain: involved in 60–92% of cases of cysticercosis. Latency from ingestion of eggs to symptomatic neurocysticercosis: 2–5 years
- skeletal muscle
- eye: immunologically privileged, like brain
- subcutaneous tissue
- heart

Once in the tissue of the intermediary host, embryos develop a cyst wall in ≈ 2 months (immature cyst) which matures in ≈ 4 months to a larva. Larval cysts are usually rapidly eliminated by the immune system. Many larvae die naturally within 5–7 yrs or with cysticidal therapy producing an inflammatory reaction with collapse of the cyst (granular nodular stage), these sometimes calcify (nodular calcified stage). In pigs, the larva lie dormant in the muscle, “waiting” to be eaten after which the cycle repeats.

Types of neurologic involvement

Spinal cord and peripheral nerves involvement is rare.

Giant cysts: definition: cyst with diameter > 50 mm. Two types of cysts tend to develop in the brain:

1. cysticercus cellulosae: regular, round or oval thin-walled cyst, ranging in size from ≈ 3 to 20 mm tending to form in the parenchyma or narrow subarachnoid spaces. This cyst contains a scolex (head), is usually static, and produces only mild inflammation during the active phase
2. cysticercus racemosus: larger (4–12 cm), grows actively producing grape-like clusters in the basal subarachnoid spaces and produces intense inflammation. There are no larvae in these cysts. These cysts usually degenerate in 2–5 years, in which the capsule thickens and the clear cyst contents are replace by a whitish gel which undergoes calcium deposition with concomitant shrinkage of the cyst.

Location of the cysts tends to fall into 1 of 4 groups:
1. meningeal: found in 27–56% of cases with neural involvement. Cysts are adherent or free-floating and are located either in:
   a) dorsolateral subarachnoid space: usually C. cellulosa type, causing minimal symptoms
   b) basal subarachnoid space: usually the expanding C. racemosus form producing arachnoiditis and fibrosis comprising a chronic meningitis with hypoglycorrachia. Can obstruct foramina of Luschka and Magendie producing hydrocephalus, or can cause entrapment of basal cisterns → cranial neuropathies (including visual disturbance). Extremely high mortality with this form
2. parenchymal: found in 30–63% focal or generalized seizures occurs in ≈ 50% of cases (up to 92% in some series)
3. ventricular: found in 12–18% possibly gaining access via the choroid plexus. Pedunculated or free floating cysts occur, can block CSF flow and cause hydrocephalus with intermittent intracranial hypertension (Brun syndrome). There may be adjacent ependymal enhancement (ependymitis)
4. mixed lesions: found in ≈ 23%

Clinical Presentation: seizures, signs of elevated ICP (36% of patients with CNS cysticercosis present with increased ICP46), focal deficits related to the location of the cyst, and altered mental status are the most common findings. Increased ICP may be due to hydrocephalus or to giant cysts. Symptoms may also be produced by the immunologic reaction to the infestation (cysticercotic encephalitis). Cranial nerve palsies can occur with basal arachnoiditis. Subcutaneous nodules may sometimes be felt.

Diagnosis

General information
Diagnosis is usually made by imaging studies and confirmatory serologic tests.

Laboratory evaluation
Mild peripheral eosinophilia can occur, but is inconsistent and thus unreliable.
CSF may be normal. Eosinophils are seen in 12–60% of cases and suggests parasitic infection. Protein may be elevated.
Stool: less than 33% of cases have T. solium ova in the stool.

Serology
Most centers use enzyme-linked immunoelectrotransfer blot (EIBT) against glycoprotein antigens (western blot) which is ≈ 100% specific and 98% sensitive, although sensitivity is less (70%) in cases with a solitary cyst.48 May be used on serum or CSF. EIBT has effectively superseded ELISA where titer is considered significant at 1:64 in serum, and 1:8 in the CSF; checking for titer exceeding these thresholds in the serum produces a test that is more sensitive and in the CSF is more specific for cysticercosis. False negative rates are higher in cases without meningitis.

Radiographic evaluation
Soft-tissue x-rays may show calcifications in subcutaneous nodules, and in thigh and shoulder muscles.
Skull x-rays show calcifications in 13–15% of cases with neurocysticercosis. May be single or multiple. Usually circular or oval in shape.

CT
The following findings on brain CT have been described (modified45,49):
1. ring enhancing cysts of various sizes representing living cysticerci. Little inflammatory response (edema) occurs as long as larva is alive. Characteristic finding: small (<2.5 cm) low density cysts with eccentric punctate high density that may represent the scolex.
2. low density with ring enhancement seen as an intermediate stage between living cyst and calcified remnant representing intermediate stage in granuloma formation. Resultant inflammatory reaction can cause edema, and basal arachnoiditis in cysts located in basal subarachnoid space. Often ring enhancing
3. intraparenchymal punctate calcifications (granuloma) sometimes with, but usually without surrounding enhancement, seen with dead parasites
4. hydrocephalus. Sometimes with intraventricular cysts which may be isointense with CSF on plain CT and may require contrast CT ventriculography or MRI to be demonstrated

MRI
Early findings: nonenhancing cystic structure(s) with eccentric T1WI hyperintensity (scolex) with no inflammatory response. Lesions may be seen in parenchyma, ventricle, and subarachnoid space. The cyst collapses in later stages of parasitic evolution, with initial edema that gradually resolves with time.

Treatment
Overview
Combination of:
1. antihelmintic medication: antiparasitic and/or cysticidal regimens
2. antiepileptics: to treat seizures, which may sometimes be medically refractory
3. steroids (see below)
4. surgery:
   a) surgical resection of lesions when appropriate
   b) ventricular CSF diversionary procedures

Steroids
Corticosteroids should be used in all patients. May temporarily relieve symptoms, and may help decrease edema that tends to occur initially during treatment with antihelmintic drugs. If possible, start 2–3 d before antihelmintics (e.g. dexamethasone 8 mg q 8 hours, on day 3 decrease to 4 mg q 8 hours, on day 6 change to prednisone 0.4 mg/kg per day divided TID). Taper steroids after antihelmintics are discontinued. In patients with symptoms of intracranial hypertension: antihelmintic treatment is started after symptoms subside (usually after 3 doses). Any cysticercoidal drug may cause irreversible damage when used to treat ocular or spinal cysts, even with corticosteroid use.

Antiepileptics
Seizures usually respond to a single AED. However, the risk of seizures may be lifelong. Risk factors for recurrent seizures: calcified brain lesions, multiple seizures, multiple brain cysts.

Antihelmintic drugs
Since many lesions resolve on their own, and there are significant side effects to these drugs, their use is controversial.

Praziquantel (Biltricide®) is an antihelmintic with activity against all known species of schistosomes. Several regimens have been published:
- 50 mg/kg/d divided in 3 doses (same dose for pediatrics) for 15 days (doses of 100 mg/kg/d have been recommended because steroids reduce serum concentration by 50%). Produces a significant reduction in symptoms and in number of cysts seen on CT.
- 10–100 mg/kg/d × 3–21 days
- high dose single day regimen: 25–30 mg/kg q 2 hrs × 3 doses
- for intestinal infestation: single oral dose of 5–10 mg/kg

Albendazole (Zentel®) 15 mg/kg per day divided in 2–3 doses, taken with a fatty meal to enhance absorption (same dose for pediatrics), may be given for 3 months, can be stopped sooner if imaging shows resolution. More parasiticidal than praziquantel and may have fewer side effects.

Niclosamide (Niclocide® and others) may be given orally to treat adult tapeworms in the GI tract. 1 gm (2 tablets) chewed PO, repeated in 1 hour (total=2 gm).

Intraventricular disease: There is no consensus on the efficacy of medical treatment for intraventricular cysts.
Surgery may sometimes be necessary to establish the diagnosis. Stereotactic biopsy may be well suited for some cases, especially with deep lesions.

CSF diversion is necessary for patients with symptomatic hydrocephalus, although tubing may become obstructed by granulomatous inflammatory debris. Surgery may be indicated for spinal cysts and for intraventricular cysts which may be less responsive to medical therapy. The latter may sometimes be dealt with using stereotactic techniques and/or endoscopic instrumentation, however, shunting and antihelmintics may suffice. Surgery may also be needed for giant cysts when intracranial hypertension does not respond to steroids. Antihelmintics may be required even after complete surgical removal because of possibility of relapse.

Follow-up
CT or MRI scan every 6 months until lesions disappear or calcify.

Contacts
Both patients with cysticercosis and their personal contacts should be screened for tapeworm infection since a single dose of niclosamide or praziquantel will eliminate the tapeworm. Close contacts of persons with tapeworms should have screening by medical history and serologic testing for cysticercosis; if suggestive of cysticercosis a neurologic exam and CT or MRI should be done.

22.3.3 Echinococcosis
General information
AKA hydatid (cyst) disease. Caused by encysted larvae of the dog tapeworm Echinococcus granulosus in endemic areas (Uruguay, Australia, New Zealand...). The dog is the primary definitive host of the adult worm. Intermediate hosts for the larval stage include sheep and man. Ova are excreted in dog feces and contaminate herbage eaten by sheep. After ingestion, the embryos hatch and the parasite burrows through the duodenal wall to gain hematogenous access to multiple organs (liver, lungs, heart, bone, brain). Dogs eat these infected organs and the parasite enters the intestine where it remains.

Man is infected either by eating food contaminated with ova, or by direct contact with infected dogs. CNS involvement occurs in only ≈ 3% Produces cerebral cysts that are confined to the white matter. Primary cysts are usually solitary, secondary cysts (e.g. from embolization from cardiac cysts that rupture or from iatrogenic rupture of cerebral cysts) are usually multiple. The CT density of the cyst is similar to CSF, it does not enhance (although rim enhancement may occur if there is an inflammatory reaction), and there is little surrounding edema. It contains germinating parasitic particles called “hydatid sand” containing ≈ 400,000 scoleces/ml. The cyst enlarges slowly (rates of ≈ 1 cm per year are quoted, but this is variable and may be higher in children), and usually does not present until quite large with findings of increased ICP, seizures, or focal deficit. Patients often have eosinophilia and may have positive serologic tests for hydatid disease.

Treatment
Treatment is surgical removal of the intact cyst. Every effort must be made to avoid rupturing these cysts during removal, or else the scoleces may contaminate the adjacent tissues with possible recurrence of multiple cysts or allergic reaction. May use adjunctive medical treatment with albendazole (Zentel®) 400 mg PO BID (pediatric dose: 15 mg/kg/d) × 28 days, taken with a fatty meal, repeated as necessary.

The Dowling technique is recommended:
1. the head is positioned so that the cyst points straight up towards the ceiling when the OR table is 30° head up
2. drilling burr holes and performing craniotomy must be done very carefully to avoid rupturing the cyst or tearing the dura which is thin and under tension
3. do not coagulate with anything but low-power bipolar (to avoid cyst rupture)
4. open the dura circumferentially away from the dome of the cyst as it may be adherent to the dura
5. keep the surface of the cyst moist to prevent desiccation and rupture
6. open the thinned overlying cortex gently, separating it from the cyst with irrigation and cotonoids. The cortical opening need only be ≈ 3/4 the cyst diameter but no less
7. Insert a soft rubber catheter between the cyst and the brain, and gently irrigate with saline as the head of the OR table is slowly lowered 45° while the surgeon supports the adjacent cortex with his/her fingers.

8. Continue irrigating more saline and float the cyst out and into a saline filled receptacle.

9. If the cyst is ruptured during the procedure, immediately place a sucker in the cyst to aspirate the contents, remove the capsule, and wash the cavity with saline for 5 minutes. Change instruments and gloves. Placing 10% formalin soaked cottonoids on the cavity for a few minutes is controversial.

22.4 Fungal infections of the CNS

22.4.1 General information

Most are medically treated conditions that do not require neurosurgical intervention. They tend to present either with chronic meningitis or brain abscess. Some of the more common ones or those of particular relevance to neurosurgery include:

1. Cryptococcosis: see below
   a) Cryptococcal meningitis
   b) Cryptococcoma (mucinous pseudocyst): rare

2. Candidiasis: the most common fungal infection of the CNS, but rarely diagnosed before autopsy.
   Very rare in healthy individuals. Most are C. albicans
   a) Candidal meningitis (p.320): the most common CNS infection; see (p.320)
   b) Parenchymal infection: candida brain abscesses are rare
   c) Following ventricular shunt placement: almost all fungal VP shunt infections are due to Candida spp. (p.339)

3. Aspergillosis (p.322): may be associated with cerebral abscess in organ transplant patients

5. Mucormycosis (phycomycosis) (p.568): usually occurs in diabetics

22.4.2 Cryptococcal involvement of the CNS

General information

Cryptococcal CNS involvement with cryptococcus is diagnosed more frequently in living patients than any other fungal disease. Occurs in healthy or immunocompromised patients. In HIV, Cryptococcus neoformans is the typical agent.

1. Cryptococcoma (mucinous pseudocyst): a parenchymal collection which occurs almost exclusively in AIDS patients. Much less common than cryptococcal meningitis. No enhancement of the lesion or the meninges. Usually 3–10 mm in diameter and are frequently located in the basal ganglia (due to spread by small perforating vessels)

2. Cryptococcal meningitis (p.376)
   a) Occurs in 4–6% of patients with AIDS. Typical symptoms: fever, malaise and H/A. Meningeal signs (nuchal rigidity, photophobia…) occur in only 25% of patients. Encephalopathic symptoms (lethargy, altered mentation…) usually from increased ICP occur in a minority
   b) Can also occur without AIDS: gatti variety can infect the brain of immunocompetent hosts
   c) Can be associated with increased ICP (with or without hydrocephalus on CT/MRI), decreased visual acuity, and/or cranial nerve deficits. Dilation of Virchow–Robbins spaces may be seen on imaging; on MRI the signal is similar to CSF on T1WI & T2WI but will be higher signal on FLAIR
   d) Late deterioration in the absence of documented infection may respond to decadron 4 mg q 6 hrs transitioned to prednisone 25 mg p.o. q d

Diagnosis

LP

Opening pressure (OP) should be measured in the lateral decubitus position. OP is usually elevated, and is > 20 cm H2O in up to 75%

CSF: cryptococcal antigen titer is invariably high with cryptococcal meningitis or meningoencephalitis.

Serum cryptococcal antigen: almost always elevated with CNS involvement.

http://e-surg.com
Management

2009 CDC guidelines for CNS cryptoccal infection in HIV-infected adolescents/adults:

1. antifungal agents: the recommended initial standard treatment is amphotericin B deoxycholate (Amphocin®) 0.7 mg/kg IV q d, plus fluconazole (an oral triazole) 100 mg/kg po q d in 4 divided doses

2. patients with clinical signs of increased ICP (confusion, blurred vision, papilledema, LE clonus...) should have LP to measure ICP

3. management of intracranial hypertension (ICHHT) (OP ≥ 25 cm H₂O) with or without hydrocephalus; corticosteroids, acetazolamide and mannitol have not been shown to be effective:
   a) daily LPs: drain enough CSF to reduce ICP by 50% (typically 20–30 ml)
   b) daily LPs may be suspended when pressures are normal for several consecutive days
   c) lumbar drain: occasionally needed for extremely high OPs (>40 cm H₂O) when frequent LPs are required or to fail to control symptoms
   d) CSF shunt: considered when daily LPs are no longer tolerated or when signs and symptoms of ICHT are not being relieved (neither dissemination of infection through the distal shunt nor creation of a nidus of infection refractory to medical therapy has been described). Options:
      - lumboperitoneal shunt
      - VP or VA shunt

4. antifungal treatment is continued for ≥ 2 weeks if renal function is normal (most immunocompetent patients will be successfully treated with 6 weeks of therapy)

5. after 2 weeks of treatment, repeat the LP to look for clearance of the organism from the CSF. Positive CSF cultures after 2 weeks of treatment are predictive of future relapse and are associated with worse outcome

6. treatment failures: defined as lack of clinical improvement after 2 weeks of appropriate therapy including management of ICHT, or relapse after an initial response, defined as either a positive CSF culture and/or rising CSF cryptoccal Ag titer with a compatible clinical picture. Management:
   a) optimal management has not been defined
   b) trials with alternative antifungals (e.g. flucytosine) or higher doses of fluconazole

7. maintenance therapy (secondary prophylaxis): HIV patients who have completed 10 weeks of treatment should be maintained on fluconazole 200 mg q d until immune reconstitution occurs, otherwise lifetime treatment is indicated.

8. the risk of recurrence is low for patient who remain asymptomatic after a complete course of therapy and have sustained increase (>6 months) of CD4+ counts to ≥ 200 cells/mcL. Some experts perform an LP to document negative CSF culture and antigen before stopping maintenance therapy

22.5 Amebic infections of the CNS

22.5.1 General information

Naegleria fowleri: the only ameba (alternative spelling: amoeba) known to cause CNS infection in humans → primary amebic meningoencephalitis (PAM): diffuse encephalitis with hemorrhagic necrosis and purulent meningitis involving brain and spinal cord. Rare (only 95 cases in the U.S. as of 2002, and ≈ 200 cases worldwide as of 2004). The ameba lives in fresh water and soil and typically gains entry to the CNS by invading nasal olfactory mucosa. PAM usually occurs within 5 days of exposure, usually from diving in warm freshwater.

Associated cerebral edema may cause increased ICP and, ultimately, herniation. Fatal in ≈ 95% of cases, usually within 1 week.

CSF: cloudy and often hemorrhagic, ↑ leukocytes, ↑ protein, normal or ↓ glucose, Gram stain negative (no bacteria or fungi), wet prep → motile trophozoites (may be confused with WBCs).

22.5.2 Treatment

Drug of choice: amphotericin B (lipid preparations (Abelcet®) achieve higher MICs (minimal inhibitory concentrations) than other amphotericin preparations). Miconazole may be synergistic with amphotericin B.

Surgical intervention: ventriculostomy with CSF drainage may be indicated when findings are suggestive of increased ICP. In one survivor, surgical drainage of a brain abscess was performed in addition to treatment with a 6-week course of amphotericin B, rifampicin, and chloramphenicol.

Hydrocephalus and Cerebrospinal Fluid (CSF)

23 Cerebrospinal Fluid 382
24 Hydrocephalus – General Aspects 394
25 Treatment of Hydrocephalus 414
23 Cerebrospinal Fluid

23.1 General information
Cerebrospinal fluid (CSF) surrounds the brain and spinal cord, and may function as a shock absorber for the CNS. It may also serve an immunological function analogous to the lymphatic system. It circulates within the subarachnoid space, between the arachnoid and the pial membranes.

CSF is normally a clear colorless fluid with a specific gravity of 1.007 and a pH of ≈ 7.33–7.35.

23.2 Production

23.2.1 Location
80% of CSF is produced by the choroid plexuses, located in both lateral ventricles (accounts for ≈ 95% of CSF produced in the choroid plexuses) and in the 4th ventricle. Most of the rest of intracranial production occurs in the interstitial space. A small amount may also be produced by the ependymal lining of the ventricles. In the spine, it is produced primarily in the dura of the nerve root sleeves.

Table 23.1 shows properties of CSF production, volumes and pressures.

23.2.2 Production rate
In the adult, CSF is produced at a rate of about 0.3 ml/min (Table 23.1). In terms that are clinically relevant, this approximates 450 ml/24hrs, which means that in an adult (where the average total CSF volume in the body is 150 ml), the CSF is “turned over” ≈ 3 times every day. The rate of formation is independent of the intracranial pressure (except in the limiting case when ICP becomes so high that cerebral blood flow is reduced).

23.3 Absorption
CSF is absorbed primarily by arachnoid villi (granulations) that extend into the dural venous sinuses. Other sites of absorption include the choroid plexuses and lymphatics. The rate of absorption is pressure dependent.

23.4 CSF constituents

23.4.1 Cellular components of CSF
In normal adult CSF, there are 0–5 lymphocytes or mononuclear cells per mm³, and no polys (PMNs) or RBCs. In the absence of RBCs, 5–10 WBCs per mm³ is suspicious, and > 10 WBCs per mm³ is definitely abnormal.

23.5 Cranial CSF fistula

**Key concepts**

- suspect in posttraumatic otorrhea/rhinorrhea or recurrent meningitis
- management strategy: 1) confirm the fluid is CSF, 2) identify the site of origin of the leak, 3) determine etiology/mechanism
- most bedside tests are unreliable and include: “reservoir sign”, target/halo sign, qualitative glucose
- most accurate confirmatory test is β2-transferrin
- CT cisternography is the test of choice for localizing site of fistula

23.5.1 General information

AKA CSF leak. CSF fistula should be suspected in patients with otorrhea or rhinorrhea after head trauma, or in patients with recurrent meningitis.

23.5.2 Possible routes of egress of CSF

1. mastoid air cells (especially after p-fossa surgery, e.g. for vestibular schwannoma (VS))
2. sphenoid air cells (especially post-transsphenoidal surgery)
3. cribriform plate/ethmoidal roof (floor of frontal fossa)
4. frontal sinus air cells
5. herniation into empty sella and then into sphenoid air sinus
6. along path of internal carotid artery
7. Rosenmüller’s fossa: located just inferior to cavernous sinus, may be exposed by drilling off anterior clinoids to allow access to ophthalmic artery aneurysms
8. site of the opening of the transient lateral craniopharyngeal canal
9. percutaneously through a surgical or traumatic wound
10. petrous ridge or internal auditory canal: following temporal bone fracture or vestibular schwannoma surgery. Then either:
   a) rhinorrhea: through middle ear → eustachian tube → nasopharynx
   b) otorrhea: via perforated tympanic membrane → external auditory canal

23.5.3 Traumatic vs. nontraumatic etiology

**Description**

Two major subgroups of CSF fistula (omitting the ambiguous category of “spontaneous”):

1. traumatic (or posttraumatic): may occur acutely or may be delayed
   a) post-procedure (iatrogenic). Including: post-transsphenoidal surgery and post skull base surgery
   b) posttraumatic (more common): 67–77% of cases
2. nontraumatic
   a) high pressure
      - hydrocephalus
   b) tumor

b the CSF findings in TB meningitis are almost pathognomonic when they occur in combination; 20–30% have acid-fast bacilli in their CSF sediment smears
c to differentiate traumatic tap from SAH, see Differentiating SAH from traumatic tap (p.1506)
d see more information on the CSF in MS (p.181)
Traumatic fistula

Occur in 2–3% of all patients with head injury, 60% occur within days of trauma, 95% within 3 months.70% of cases of CSF rhinorrhea stop within 1 wk, and usually within 6 mos in the rest. Non-traumatic cases cease spontaneously in only 33% Adult:child ratio is 10:1, rare before age 2 yrs. In children the incidence of CSF leaks is less than 1% of closed head injuries.10 Anosmia is common in traumatic leaks (78%), rare in spontaneous.11 Most (80–85%) CSF otorrhea ceases in 5–10 days.

CSF fistula occurred in 8.9% of 101 cases of penetrating trauma, and increases the infection rate over those penetrating injuries without fistula (50% vs. 4.6%).12 It is reported to occur post-op in up to 30% of cases of skull-base surgery.13

Nontraumatic CSF fistula

General information

Nontraumatic leaks primarily occur in adults >30 yrs. Often insidious. May be mistaken for allergic rhinitis. Unlike traumatic leaks, these tend to be intermittent, the sense of smell is usually preserved, and pneumocephalus is uncommon.14 Sometimes associated with the following15

1. agenesis of the floor of the anterior fossa (cribriform plate) or middle fossa
2. empty sella syndrome (p.773); primary or post transsphenoidal surgery
3. increased ICP and/or hydrocephalus
4. infection of the paranasal sinuses
5. tumor: including pituitary adenomas (p.718), meningoamas
6. a persistent remnant of the craniopharyngeal canal16
7. AVM14
8. congenital anomalies: most involve dehiscence of bone
   a) dehiscence of the footplate of the stapes (a congenital abnormality) which can produce CSF rhinorrhea via the eustachian tube14
   b) dehiscence below foramen rotundum

Spontaneous posterior fossa CSF fistula

1. pediatric: usually presents with either meningitis or hearing loss
   a) preserved labyrinthine function (hearing and balance): these usually present with meningitis.
      3 usual routes of fistula:
      • facial canal: can fistulize into middle ear
      • petromastoid canal: along path of arterial supply to mucosa of mastoid air sinuses
      • Hyrtl’s fissure (AKA tympanomeningeal fissure): links p-fossa to hypotympanum
   b) anomalies of labyrinth (hearing lost): one of several types of Mundini dysplasias, usually presenting with rounded labyrinth/cochlea that permits CSF to erode through oval or round window into auditory canal
2. adult: usually presents with conductive hearing loss with serous effusion, meningitis (often following an episode of otitis media), or cerebral abscess. Occurs most commonly through middle fossa. May be due to arachnoid granulations eroding into air sinus compartment

23.6 Spinal CSF fistula

Often presents with postural headache associated with neck stiffness and tenderness.17

23.7 Meningitis in CSF fistula

Incidence with posttraumatic CSF leak: 5–10% increases as leak persists >7 days. Meningitis is more common with spontaneous fistula. Risk may be higher in fistula following a neurosurgical procedure than in post-traumatic fistula possibly due to elevated ICP common in latter (forces CSF outward).

Meningitis may promote inflammatory changes at the site of the leak, with a resultant cessation of the leak. However, this often proves to be a temporary resolution, providing a false sense of security.

Pneumococcal meningitis is the most common pathogen (83% of cases18), mortality is lower than in pneumococcal meningitis without underlying fistula (<10% vs. 50%), possibly because the latter is frequently seen in elderly debilitated patients. Prognosis in children is worse.9
23.8 Evaluation of the patient with CSF fistula

23.8.1 Determining if rhinorrhea or otorrhea is due to a CSF fistula

1. characteristics of the fluid suggesting the presence of CSF
   a) fluid is as clear as water (unless infected or admixed with blood)
   b) fluid does not cause excoriation within or outside the nose
   c) patients with CSF rhinorrhea describe the taste as salty

2. confirmatory tests
   a) β₂-transferrin: present in CSF, but absent in tears, saliva, nasal exudates and serum (except for newborns and patients with liver disease). The only other source is the vitreous fluid of the eye. It may be detected by protein electrophoresis. A minimum of ≈ 0.5 ml needs to be collected, placed in a sterile urine container, packed in dry ice, and shipped to a lab that can perform this study. Very sensitive & specific
   b) collect fluid and obtain quantitative glucose (urine glucose detection strips are too sensitive, and may be positive even with excess mucus). Test the fluid shortly after collection to minimize fermentation. Normal CSF glucose is >30 mg% (usually lower with meningitis) whereas lacrimal secretions and mucus are usually < 5 mg%. A negative test is more helpful since it rules out CSF (except in hypoglycorrhachia (low glucose in the CSF)), but there is a 45–75% chance of false positive
   c) “ring sign”: when a CSF leak is suspected but the fluid is blood tinged, allow the fluid to drip onto linen (sheet or pillowcase). A ring of blood with a larger concentric ring of clear fluid (so called “double ring” or halo sign) suggests the presence of CSF. An old, but unreliable, sign
   d) reservoir sign: a gush of fluid that occurs with a certain head position. Most commonly when first sitting up after a period of recumbency. Thought to indicate drainage of CSF pooled in the sphenoid sinus. Not reliable

3. radiographic signs: pneumocephalus on CT or skull x-ray. Pneumocephalus occurs in ≈ 20% of patients with CSF leaks

4. cisternogram: intrathecal injection of radionuclide tracer followed by scintigram or injection of radiopaque contrast followed by CT scan (see below)

5. anosmia is present in ≈ 5% of CSF leaks

6. following skull-base surgery (especially involving greater superficial petrosal nerve) there may be a pseudo-CSF rhinorrhea possibly due to nasal hypersecretion from imbalanced autonomic regulation of the nasal mucosa ipsilateral to the surgery. Often accompanied by nasal stuffiness and absent ipsilateral lacrimation, and occasionally by facial flushing

Localizing the site of CSF fistula

90% of the time, localization does not require water-soluble contrast CT cisternography (WS-CTC) (see below).

1. CT: to detect pneumocephalus, fractures, skull base defects, hydrocephalus and obstructive neoplasms. Include thin coronal cuts or reconstructions through anterior fossa all the way back to the sella turcica
   a) non-contrast (optional): to demonstrate bony anatomy
   b) with IV contrast: leak site is usually associated with abnormal enhancement of adjacent brain parenchyma (possibly from inflammation)

2. water-soluble contrast CT cisternography (procedure of choice): see below

3. plain skull x-ray (helpful in only 21%)

4. MRI: may provide additional information for localization and can R/O p-fossa mass, tumor, and empty sella better than CT. Both CT and MRI can R/O hydrocephalus. T2WI fast spin-echo sequences with fat suppression and video image reversal have been used to visualize CSF flow (sensitivity and specificity are 0.87 and 0.57 respectively)

5. older tests (abandoned in favor of above):
   a) radionuclide cisternography (RNC): not a contemporary test. Poor localization. Some of the studied radiopharmaceuticals are no longer available
   b) intrathecal (visible) dye studies: some success with indigo carmine or fluorescein (p. 1426) with little or no complications.
      methylene blue (p. 1426) is neurotoxic and should not be used

Water-soluble contrast CT cisternography

Procedure of choice. This test is performed if:

1. no site identified on plain CT (with coronals)
2. when patient is leaking clinically (the site is only sometimes identified in the absence of an active leak)
3. when multiple bony defects are identified, and it is essential to determine which site is actively leaking
4. if a bony defect seen on plain CT does not have associated changes of abnormal enhancement of adjacent brain parenchyma

**Technique**: 
Use iohexol (p.219) 6–7ml of 190–220 mg/ml injected into lumbar subarachnoid space via 22 gauge spinal needle (or 5 ml via C1–2 puncture). Patient positioned in -70° Trendelenburg x 3 min prone with neck gently flexed, in CT they are kept prone with head hyperextended with 5 mm coronal cuts with 3 mm overlap (use 1.5 mm cuts if necessary). May need provocative maneuvers (coronal scans prone (brow up) or in position of leak, intrathecal saline infusion (requires Harvard pump)26...).

Look for accumulation of contrast in air sinuses. Apparent discontinuity of bone on CT without extravasation of contrast is probably not the site of leakage (bone discontinuities may be mimicked by partial volume averaging on CT).

### 23.9 Treatment for CSF fistula

#### 23.9.1 Initial treatment

Acute after trauma, observation is justified as most cases cease spontaneously. Prophylactic antibiotics: Controversial. There was no difference in the incidence or morbidity of meningitis between treated and untreated patients. Furthermore, the risk of selecting resistant strains appears real and is therefore usually avoided.

#### 23.9.2 For persistent posttraumatic or post-op leaks

**Non-surgical treatment**

1. measures to lower ICP:
   a) bed rest: although recumbency may ameliorate symptoms, there is no other benefit from bed rest28
   b) avoid straining (stool softeners) and avoid blowing nose
   c) acetazolamide (250 mg PO QID) to reduce CSF production
   d) modest fluid restriction; caution post-transsphenoidal because of possible DI (p.120):
      1500 ml/day in adults, 75% of maintenance/day in peds
2. if leak persists (caution: first R/O obstructive hydrocephalus with CT or MRI)
   a) LP: q d to BID (lower pressure to near atmospheric or until H/A) OR
   b) continuous lumbar drainage (CLD): via percutaneous catheter. Two (of many) management options:
      - keep HOB elevated 10–15° and place drip chamber at shoulder level (lower the chamber if leak persists) and leave open to drain (uses pressure to regulate drainage – may be dangerous e.g. if drainage bag falls to floor)
      - allow 15–20 cc to drain, then clamp tubing. Repeat q 1 hour
   c) CLD may require ICU monitoring. If patient deteriorates with drain in place: immediately stop drainage, place patient flat in bed (or slight Trendelenburg), start 100% O2, get CT or bedside cross-table skull x-ray (to R/O tension pneumocephalus due to drawing in of air)
3. surgical treatment in persistent cases (see below)

**Surgical treatment**

**General information**
If the site of leakage is not identified prior to attempted surgical treatment, 30% develop a recurrent leak post-op, with 5–15% of these developing meningitis before leak is stopped.26
Indications for surgical intervention
1. traumatic CSF leak that persists > 2 weeks in spite of non-surgical measures
2. spontaneous leaks and those of delayed onset following trauma or surgery: usually require surgery because of a high incidence of recurrence
3. leaks complicated by recurrent meningitis

Leaks through cribiform plate/ethmoidal roof
Extradural approach: Generally preferred by ENT surgeons.29 If a frontal craniotomy is being performed, an intradural approach should be used since problems may arise in dissecting the dura off the floor of the frontal fossa, wherein the dura almost always tears and then it is difficult to know if an identified tear is the cause of the leak or if it is iatrogenic. Fluorescein dye mixed with CSF injected intrathecally may help demonstrate the leak intraoperatively. CAUTION: must be diluted with CSF to reduce risk of seizures (p.1426).

Intradural approach
- Generally the procedure of choice.30 If the fistula site is unidentified preoperatively, use a bifrontal bone flap.
- General techniques of intradural approach:
  - Close bone defects with fat, muscle, cartilage, or bone.
  - Close dural defect with fascia lata, temporalis muscle fascia, or pericranium. Fibrin glue may be used to help hold tissue in place.
  - If the leak is unidentified pre-op and intra-op, then pack both cribiform plates and sphenoid sinus (incise dura over tuberculum sellae, drill through bone to reach sphenoid sinus, remove mucosa or pack it inferiorly, pack with fat).
  - Post op: lumbar drain after craniotomy is controversial. Some feel CSF pressure may help enhance the seal.31 If used, place the drip chamber at the level of shoulder for 3–5 days (for precautions, see above).
  - Consider shunt (LP or VP) if elevated ICP or hydrocephalus is demonstrated.

Leaks into sphenoid sinus (including post-transsphenoidal surgery leak)
1. LP BID or CLD: as long as pressure >150 mm H2O or CSF xanthochromic
   a) if leak persists >3 days: repack sphenoid sinus and pterygoid recesses with fat, muscle, cartilage and/or fascia lata (must reconstruct floor of sella, packing alone is inadequate). Some recommend against muscle since it putrefies and shrinks. Continue LP or CLD as above for 3–5 days post-op
   b) if leak persists >5 days: lumboperitoneal shunt (first R/O obstructive hydrocephalus)
2. more difficult surgical approach: intracranial (intradural) approach to medial aspect of middle cranial fossa
3. consider transnasal sellar injection of fibrin glue under local anesthesia32

Petrous bone
May present as otorrhea or as rhinorrhea (via the eustachian tube).
1. following posterior fossa surgery: see also treatment following vestibular schwannoma surgery (p.685)
2. following mastoid bone fractures: may be approached via extensive mastoidectomy14
3. due to dehiscence of the footplate of the stapes: may require obliteration of the middle ear and eustachian tube through a tympanomeatal flap14

23.10 Intracranial hypotension (spontaneous)

23.10.1 General information
Intracranial hypotension may be spontaneous or post-traumatic (including iatrogenic, e.g. post-LP). This chapter addresses spontaneous intracranial hypotension (SIH).
Key concepts

- orthostatic headache (headache that is improved in recumbency)
- diagnosed clinically with assistance of LP
- characteristic findings on imaging not required for dx: “SEEPS” (sagging brain, pachymeningeal enhancement, engorged veins, pituitary hyperemia, subdural fluid)
- excludes patients with history of dural puncture, penetrating spinal trauma, spinal surgery or procedures
- epidural blood patch provides relief in the majority of patients

Epidemiology

Incidence 5:100,000, prevalence 1:50,000. More common in females with mean age of presentation in the 40’s.

Clinical

The syndrome of spontaneous intracranial hypotension is characterized by the following in the absence of antecedent trauma or dural puncture:

1. orthostatic headache: dramatically worse when upright, improved in recumbency
2. low CSF pressure
3. diffuse pachymeningeal enhancement (cerebral and/or spinal) on MRI

Most patients have orthostatic headache with sudden onset, but other headaches have been described such as thunderclap, non-positional, exertional headaches, headaches at the end of the day, and even paradoxical headaches with worsening upon lying. Atypical patients have been described without headache, without pachymeningeal enhancement on MRI, with clinical signs of encephalopathy, cervical myelopathy or parkinsonism. Since some patients may have normal intracranial pressure, the term “CSF hypovolemia” has been suggested.

Diagnosis

Diagnostic criteria per IHS Classification (ICHD-III):

1. any headache fulfilling criterion C (see below)
2. low CSF pressure (<6 cm of water) and/or evidence of CSF leakage on imaging
3. headache has developed in temporal relation to the low CSF pressure or CSF leakage, or has led to its discovery
4. not better accounted for by another ICHD-III

Compared to older criteria, current diagnostic criteria exclude the need for the headache to worsen within 15 minutes from sitting or standing, eliminate the need for specific associated symptoms used previously to aid in diagnosis although some of these symptoms are often seen (neck stiffness, tinnitus, hypacusia, photophobia, nausea), exclude the need for MRI as there is no change seen in 20-25% of patients, and exclude the effectiveness of epidural blood patch within 72hrs, as it has no effect in approximately 25% of patients. The median delay from presentation to diagnosis of SIH is 4 months. This delay may be detrimental to patient outcomes. Therefore, brain MRI without and with contrast is recommended in patients with new onset orthostatic headaches.

Pathophysiology

The underlying cause of SIH is a spontaneous CSF leak. Evidence supports an underlying weakness of the meninges as a contributing factor, for instance connective tissue disorders like Marfan syndrome, and Ehlers-Danlos syndrome. Spinal diverticula, at the cervicothoracic junction or thoracic spine, thoracic being more common and excluding lumbar sacral perineural cysts, are thought to be the source of CSF leak in most patients. No relationship has been found between cranial leaks and SIH. Other causes of dural injury are degenerative disc disease, osteophytes and bony spurs. The orthostatic headache is believed to be caused by the descent of the brain, causing strain on intracranial structures sensitive to pain.
Evaluation

1. radiographic studies
   a) MRI Brain: findings (mnemonic SEEPS)
      - Sagging of the brain caused by the loss of buoyancy from low CSF volume. Associated with low lying cerebellar tonsils occurred, seen in 36% of patients, effacement of periaxial and preptontine cisterns, bowing of the optic chiasm, flattening of pons, and ventricular collapse. Associated with low lying cerebellar tonsils occurred, seen in 36% of patients, effacement of periaxial and preptontine cisterns, bowing of the optic chiasm, flattening of pons, and ventricular collapse. Effacement of basal cisterns due to sagging of the brain. Engorgement of veins. Can also see venous distension sign as transverse sinus becomes dilated and convex.
      - Pituitary hyperemia
      - Subdural fluid collections seen in 50% of patients. Can be hygromas versus hematomas, with hygromas being twice as frequent as hematomas. Occasionally may require intervention.
   b) CT Brain is not as conclusive but can help identify these changes. 11% of SIH patients also have pseudo-SAH finding on CT caused by effacement of basal cisterns due to sagging of the brain.
   c) CT Myelogram with iodinated contrast: Study of choice for diagnosis and localization of CSF leak. Timed images immediately after contrast injection or at delayed intervals after injections can help localize intermittent leaks.
   d) MRI with intrathecal gadolinium: Alternative to CT myelogram. Injection of 0.5 ml of gadolinium followed by full spine T1 with fat suppression imaging an hour after injection. Contrast remains for 24 hours, hence it can aid in detection of intermittent leaks. Prospective cohort study localized leak in 67% of patients with SIH. In another study, MRI 15 minutes after gadolinium injection identified CSF leak in 21% of SIH patients with a negative CT myelogram. No side effects were reported, but intrathecal gadolinium is not FDA approved (off-label use).
   e) spinal MRI: May show evidence of CSF leak, but is more likely to help localize extradural fluid collections for patients with local symptoms. If there is focal spine pain, the leak will often be near this location. Other findings include: dural enhancement, dilated veins, deformed dural sac, meningeal diverticula, syringomyelia, and retrospinal fluid collections at C1-C2.
   f) radioisotope cisternography: Poor resolution, may leave as many as one third of leaks unidentified. Can be used especially if CT myelogram fails.

2. lumbar puncture: CSF pressure <6 cm of water is part of the diagnostic criteria. Patients have been identified with normal CSF pressure. Associated CSF findings that have been identified include: lymphocytic pleocytosis, high protein level and xanthochromia.

3. positive response to EBP can also be used to support the diagnosis.

Treatment

None of these treatments have been evaluated by randomized clinical trials.

- conservative medical management: bed rest, hydration, analgesics, caffeine, and abdominal binder. Limited effect has been reported with intravenous caffeine, steroids and theophylline. Epidural blood patch (EBP): see technique (p. 1509). Injection of autologous blood (10-20 ml) into epidural space. Evidence shows patients respond well and usually immediately. However, some patients require more than one EBP and relief in headache may not be permanent. If unsuccessful, can repeat blood patch with same or larger amount of blood. Positioning the patient in Trendelenberg position after injection aides in movement of blood to cover more segments for increased effectiveness. May not be effective in up to 25-33%.

- directed epidural blood patch to site of leak if the above fails
- percutaneous placement of fibrin sealant at site of leak: can provide relief in patients that fail to improve with conservative measures and epidural blood patch.
- surgical intervention: last resource for patients without relief with conservative measures, EBP or fibrin sealant in which the exact site of leak has been identified. Meningeal diverticula can be ligated with suture, aneurysm clips or muscle pledget with gel foam and fibrin sealant, technique that may also be effective if a dural defect is identified.

Outcome

After appropriate treatment, clinical improvement is seen and precedes radiographic improvement. MRI usually takes days to weeks to normalize. Complete resolution of HA was achieved in 70% of...
patients (usually in days to weeks). Resolution was more likely if receiving EBP and less likely if they had multiple sites of CSF leak.\(^{30}\) Patients with MRI changes characteristic of SIH and an identifiable focal CSF leak have better outcomes when compared to patients with multilevel CSF leaks.\(^{37,34,36}\) CSF leak can recur in approximately 10% of patients. An association between longer interval from symptom onset to diagnosis and poorer outcome has been reported.\(^{35}\)

24 Hydrocephalus – General Aspects

24.1 Basic definition
An abnormal accumulation of cerebrospinal fluid within the ventricles of the brain.

24.2 Epidemiology
Estimated prevalence: 1–1.5%
Incidence of congenital hydrocephalus is ≈ 0.9–1.8/1000 births (reported range from 0.2 to 3.5/1000 births1).

24.3 Etiologies of hydrocephalus

24.3.1 General information
Hydrocephalus (HCP) is either due to subnormal CSF reabsorption or, rarely, CSF overproduction.
- subnormal CSF reabsorption. Two main functional subdivisions:
  1. obstructive hydrocephalus (AKA non-communicating): block proximal to the arachnoid granulations (AG) On CT or MRI: enlargement of ventricles proximal to block (e.g. obstruction of aqueduct of Sylvius → lateral and 3rd ventricular enlargement out of proportion to the 4th ventricle, sometimes referred to as triventricular hydrocephalus)
  2. communicating hydrocephalus (AKA non-obstructive): defect in CSF reabsorption by the AG
- CSF overproduction: rare. As with some choroid plexus papillomas; even here, reabsorption is probably defective in some as normal individuals could probably tolerate the slightly elevated CSF production rate of these tumors.

24.3.2 Specific etiologies of hydrocephalus
The etiologies in one series of pediatric patients is shown in Table 24.1.
1. congenital
   a) Chiari Type 2 malformation and/or myelomeningocele (MM) (usually occur together)
   b) Chiari Type 1 malformation: HCP may occur with 4th ventricle outlet obstruction
   c) primary aqueductal stenosis (usually presents in infancy, rarely in adulthood)
   d) secondary aqueductal gliosis: due to intrauterine infection or germinal matrix hemorrhage3
   e) Dandy Walker malformation (p.256): atresia of foramina of Luschka & Magendie. The incidence of this in patients with HCP is 2.4%
   f) X-linked inherited disorder (p.401): rare
2. acquired
   a) infectious (the most common cause of communicating HCP)
      • post-meningitis; especially purulent and basal, including TB, cryptococcus (p.376)
      • cysticercosis
   b) post-hemorrhagic (2nd most common cause of communicating HCP)
      • post-SAH
      • post-intraventricular hemorrhage (IVH): many will develop transient HCP. 20–50% of patients with large IVH develop permanent HCP requiring a shunt

c) secondary to masses
   • non neoplastic: e.g. vascular malformation
   • neoplastic: most produce obstructive HCP by blocking CSF pathways, especially tumors
     around aqueduct, e.g. medulloblastoma. A colloid cyst can block CSF flow at the foramen of
     Monro. Pituitary tumor: suprasellar extension of tumor or expansion from pituitary
     apoplexy

d) post-op: 20% of pediatric patients develop permanent hydrocephalus (requiring shunt) fol-
lowing p-fossa tumor removal. May be delayed up to 1 yr

e) neurosarcoidosis (p.189)
f) “constitutional ventriculomegaly”: asymptomatic. Needs no treatment
g) associated with spinal tumors4: ? due to ↑ protein?, ↑ venous pressure?, previous hemor-
rhage in some?

24.3.3 Special forms of hydrocephalus
These are covered in subsequent sections
• normal pressure hydrocephalus (NPH) (p.403)
• entrapped fourth ventricle (p.402)
• arrested hydrocephalus (p.402)

24.4 Signs and symptoms of HCP
24.4.1 In older children (with rigid cranial vault) and adults
Symptoms are those of increased ICP, including: papilledema, H/A, N/V, gait changes, upgaze and/or
abducens palsy. Slowly enlarging ventricles may initially be asymptomatic.

24.4.2 In young children
Overview
• abnormalities in head circumference (OFC) (see below)
• cranium enlarges at a rate >facial growth
• irritability, poor head control, N/V
• fontanelle full and bulging
• enlargement and engorgement of scalp veins: due to reversal of flow from intracerebral sinuses
due to increased intracranial pressure5
• Macewen’s sign: cracked pot sound on percussing over dilated ventricles
• 6th nerve (abducens) palsy: the long intracranial course is postulated to render this nerve very
  sensitive to pressure
• “setting sun sign” (upward gaze palsy) (p.99): Parinaud’s syndrome (p.99) from pressure on re-
gion of suprapineal recess
• hyperactive reflexes
• irregular respirations with apneic spells
• splaying of cranial sutures (may be seen on plain skull x-ray)

Occipital-frontal circumference
The occipital-frontal circumference (OFC) should be followed in every growing child (as part of a
“well-baby” check-up, and especially in infants with documented or suspected hydrocephalus
(HCP)). As a rule of thumb, the OFC of a normal infant should equal the distance from crown to
rump,6 (rule No. 335) for the differential diagnosis of macrocephaly (p.1403).

Measurement technique7: use a non-stretchable tape, measure the circumference of the head just
above the supraorbital ridge anteriorly and around the most prominent part of the occiput posteri-
orly (keeping above the ears). Pull the tape snug to compress hair (exclude any braids or hairclips).
Take 2 separate measurements (reposition the tape each time), if the measurements are within
2 mm, record the largest value. If the measurements disagree by >2 mm, take a third measurement
and record the average of the 2 closest measures.

Normal head growth: parallels normal curves as seen on the graphs on the inside front cover of
this book, or in Fig. 24.1 and Fig. 24.2 for premies. Any of the following may signify treatable
conditions such as active HCP, subdural hematoma, or subdural effusions, and should prompt an
evaluation of the intracranial contents (e.g. CT, head U/S ...):
1. Progressive upward deviations from the normal curve (crossing curves)
2. Continued head growth of more than 1.25 cm/wk
3. OFC approaching 2 standard deviations (SD) above normal
4. Head circumference out of proportion to body length or weight, even if within normal limits for age (Fig. 24.2)

These conditions may also be seen in the “catch-up phase” of brain growth in premature infants after they recover from their acute medical illnesses, see Catch-up phase of brain growth (p. 1351). Deviations below the curves or head growth in the premature infant in the neonatal period of less than 0.5 cm/wk (excluding the first few weeks of life) may indicate microcephaly (p. 289).

Technique: measure circumference around forehead and occiput (excluding ears) three consecutive times, and use the largest value. OFC is then plotted on a graph of average values as a function of age (Fig. 24.2)

The graph in Fig. 24.1 shows the OFC for premature infants as a function of gestational age up to term.

The graph in Fig. 24.2 shows the relationship of head circumference, weight and length for various gestational ages.

24.4.3 Blindness from hydrocephalus

General information

Blindness is a rare complication of hydrocephalus and/or shunt malfunction. Possible causes include:
1. Occlusion of posterior cerebral arteries (PCA caused by downward transtentorial herniation
2. Chronic papilledema causing injury to optic nerve at the optic disc
3. Dilatation of the 3rd ventricle with compression of optic chiasm

Fig. 24.1 OFC for premature infants as a function of gestational age
Ocular motility or visual field defects are more common with shunt malfunction than blindness. One series found 34 reported cases of permanent blindness in children attributed to shunt malfunction with concomitant increased ICP (these authors were based in a referral center for visually impaired children, thus incidence not estimated). Another series of 100 patients with tentorial herniation (most from acute EDH and/or SDH) proven by CT; 48 patients operated; only 19 of 100 survived >1 month (all were in operated group); 9 of 100 developed occipital lobe infarct (2 died, 3 vegetative state, remaining 4 moderate to severe disability).

Types of visual disturbance
9 of 14 had pregeniculate (anterior visual pathway) blindness with marked optic nerve atrophy (early), and reduced pupillary light reflexes. 5 of 14 had postgeniculate (cortical) blindness with normal light responses and minimal or no optic nerve atrophy (or atrophy late). A few patients had evidence of damage in both sites.

Cortical blindness: due to lesions posterior to lateral geniculate bodies (LGB), may also be seen with hypoxic injuries or trauma. Occasionally associated with Anton’s syndrome (denial of visual deficit) and with Ridoch’s phenomenon (appreciation of moving objects without perception of stationary stimuli).
Pathophysiology

In patients with occipital lobe infarction

Occipital lobe infarctions (OLI) in PCA distribution are seen either bilaterally, or if unilateral are associated with other injuries to optic pathways posterior to LGB. The most often cited mechanism is compression of PCA resulting from brain herniating downward through tentorial notch where the PCA or its branches lie on the surface of the hippocampal gyrus and tend to cross the free edge of the tentorium (some authors implicate parahippocampal gyrus compression in tentorial notch directly injuring LGBs; this may never produce permanent blindness). Alternatively, upward cerebellar herniation (e.g., from ventricular puncture in face of a p-fossa mass) may impinge on PCA or branches with the same results.

OLIs are more likely with a rapid rise in ICP (doesn’t allow compensatory shifts and collateral circulation to develop). Macular sparing is common, possibly due to potential dual blood supply of occipital poles (sometimes filled both by PCA and MCA collaterals), alternatively the calcarine cortex may be supplied by a distinct branch of the PCA that fortuitously escapes compression.

Reported causes of OLI include: post traumatic edema, tumor, abscess, SDH, unshunted hydrocephalus, and shunt malfunction.

The occipital poles are also particularly vulnerable to diffuse hypoxia; attested to by cases of cortical blindness after cardiac arrest. Hypotension superimposed on compromised PCA circulation (from herniation or elevated ICP) may thus increase the risk of postgeniculate blindness.

Both coup and contrecoup trauma may produce OLI. Unlike a PCA occlusion infarct, macular sparing is not expected in traumatic occipital lobe injury.

In patients with pregeniculate blindness

Elevated ICP transmits pressure to retina → bloodflow stasis, as well as mechanical trauma to optic chiasm from enlarging third ventricle (latter more commonly thought to be responsible for bitemporal hemianopia, but could, if unchecked, progress to complete visual loss). Also, if hypotension and anemia were present, consider the possibility of ischemic optic neuropathy which may be anterior, or posterior (the latter of which carries a poorer prognosis).

Presentation

These deficits are frequency unsuspected (altered mental state and the youth of many of these patients makes detection difficult); an examiner must persevere to detect homonymous hemianopsias in an obtunded patient.

Pregeniculate blindness is less often associated with depressed sensorium than is postgeniculate (where direct compression and vascular compromise of midbrain are more likely).

Prognosis

Cortical blindness after diffuse anoxia frequently improves (occasionally to normal); usually slowly (weeks to years quoted; several mos usually adequate). Many reports of blindness after shunt malfunction are pre-CT era, thus the presence or extent of occipital lobe infarction not ascertained. Some optimistic outcomes reported, however, permanent blindness or severe visual handicap are also described; no reliable predictor has been identified. As with infarcts elsewhere, younger patients fare better, but extensive calcarine infarcts are probably incompatible with significant visual recovery.

24.5 CT/MRI criteria for hydrocephalus

24.5.1 General information

In general, hydrocephalus is best demonstrated on CT or MRI (Fig. 24.3). Occasionally, other means of determining the presence of hydrocephalus must be employed. Most experienced clinicians can recognize HCP by its appearance on CT or MRI. Numerous methods have been devised to attempt to quantitatively define radiographic criteria for hydrocephalus (HCP) (most date back to the early CT experience, and some are used definitionally for research purposes). Some are presented here for completeness. See also radiologic features of chronic HCP (p. 400).
24.5.2 Specific imaging criteria for hydrocephalus

HCP is suggested when either:
1. the size of both temporal horns (TH) is \( \geq 2 \) mm in width (Fig. 24.3; in the absence of HCP, the temporal horns should be barely visible), and the sylvian & interhemispheric fissures and cerebral sulci are not visible
   OR
2. both TH are \( \geq 2 \) mm, and the ratio \( \frac{FH}{ID} > 0.5 \) (where FH is the largest width of the frontal horns, and ID is the internal diameter from inner-table to inner-table at this level, Fig. 24.3)

Other features suggestive of hydrocephalus (see Fig. 24.3 for measurements):
1. ballooning of frontal horns of lateral ventricles (“Mickey Mouse” ventricles) and/or 3rd ventricle (the 3rd ventricle should normally be slit-like)
2. periventricular low density on CT, or periventricular high intensity signal on T2WI on MRI suggesting transependymal absorption of CSF (note: a misnomer: CSF does not actually penetrate the ependymal lining, proven with CSF labeling studies; probably represents stasis of fluid in brain adjacent to ventricles)

3. used alone, the ratio
   \[
   \begin{align*}
   &\frac{8}{8} < 40\% & \text{normal} \\
   &\frac{FH}{ID} \leq 40 \text{ Å } 50\% & \text{borderline} \\
   &\frac{FH}{ID} > 50\% & \text{suggests hydrocephalus}
   \end{align*}
   \]

4. Evans ratio (originally described for ventriculography, or index; note: measurements that rely on the frontal horn diameter tend to underestimate hydrocephalus in pediatrics possibly because of disproportionate dilatation of the occipital horns in peds): ratio of FH to maximal biparietal diameter (BPD) measured in the same CT slice: \( \geq 0.3 \) suggests hydrocephalus

5. sagittal MRI may show thinning of the corpus callosum (generally present with chronic HCP) and/or upward bowing of the corpus callosum

24.6 Differential diagnosis of hydrocephalus

For etiologies of HCP, see above.
Conditions that may mimic HCP but are not due to inadequate CSF absorption are occasionally referred to as “Pseudohydrocephalus” and include:

- “hydrocephalus ex vacuo” enlargement of the ventricles due to loss of cerebral tissue (cerebral atrophy), usually as a function of normal aging, but accelerated or accentuated by certain disease processes (e.g. Alzheimer’s disease, Creutzfeldt-Jakob disease, traumatic brain injury). Does not represent altered CSF hydrodynamics, but is rather loss of brain tissue (p.400). See means of differentiating from true hydrocephalus (p.920)

- hydrancephaly (p.288)

- developmental anomalies where the ventricles or portions of the ventricles appear enlarged:
  - agensis of the corpus callosum (p.259): may occasionally be associated with HCP, but more often merely represents expansion of the third ventricle and separation of the lateral ventricles
  - septo-optic dysplasia (p.260)
  - hydrancephaly (p.288): a post-neurulation defect. Total or near-total absence of the cerebrum most commonly due to bilateral ICA infarcts. It is critical to differentiate this from severe (“maximal”) hydrocephalus (HCP) since shunting for true HCP may produce some re-expansion of the cortical mantle; see means to differentiate (p.288)

Conditions that have been dubbed “hydrocephalus” but do not actually mimic the appearance of HCP

- otitic hydrocephalus: obsolete term used to describe the increased intracranial pressure seen in patients with otitis media; see Idiopathic intracranial hypertension (IIH) (p.766)

- external hydrocephalus (p.400): seen in infancy, enlarged subarachnoid space with increasing OFCs and normal or mildly dilated ventricles

24.7 Chronic HCP

Features indicative of chronic hydrocephalus (as opposed to acute hydrocephalus):
1. beaten copper cranium (some refer to beaten silver appearance) on plain skull x-ray. By itself, does not correlate with increased ICP, however when associated with #3 and #4 below, does suggest ↑ ICP. May be seen in craniostenosis; see description (p.252)
2. 3rd ventricle herniating into sella (seen on CT or MRI)
3. erosion of sella turcica (may be due to #2 above) which sometimes produces an empty sella, and erosion of the dorsum sella
4. the temporal horns may be less prominent on imaging than in acute HCP
5. macrocrania: by convention, OFC greater than 98th percentile (p.203)
6. atrophy of corpus callosum: best appreciated on sagittal MRI
7. in infants
   a) sutural diastasis
   b) delayed closure of fontanelles
   c) failure to thrive or developmental delay

24.8 External hydrocephalus (AKA benign external hydrocephalus)

24.8.1 General information

**Key concepts**

- enlarged subarachnoid spaces over the frontal poles in the first year of life
- ventricles are normal or minimally enlarged
- may be distinguished from subdural hematoma by the “cortical vein sign”
- usually resolves spontaneously by 2 years of age

Enlarged subarachnoid space (usually over the cortical sulci of the frontal poles) seen in infancy (primarily in the first year of life) usually accompanied by abnormally increasing head circumference with normal or mildly dilated ventricles. There are often enlarged basal cisterns and widening of the anterior interhemispheric fissure. No other symptoms or signs should be present (although there may be slight delay only in motor milestones due to the large head). Etiology is unclear, but a defect
in CSF resorption is postulated. External hydrocephalus (EH) may be a variant of communicating hydrocephalus.\textsuperscript{36} No predisposing factor may be found in some cases, although EH may be associated with some craniosynostoses\textsuperscript{37} (especially plagiocephaly) or it may follow intraventricular hemorrhage or superior vena cava obstruction.

24.8.2 Differential diagnosis

EH is probably distinct from benign subdural collections (or extra-axial fluid) of infancy (p. 903). EH must be distinguished from symptomatic chronic extra-axial fluid collections (p. 904) (or chronic subdural hematoma), which may be accompanied by seizures, vomiting, headache... and may be the result of child abuse. With EH, MRI or CT may demonstrate cortical veins extending from the surface of the brain to the inner table of the skull coursing through the fluid collection (“cortical vein sign”), whereas the collections in subdural hematomas compress the subarachnoid space which apposes the veins to the surface of the brain.\textsuperscript{38,39}

24.8.3 Treatment

EH usually compensates by 12–18 mos age without shunting.\textsuperscript{40} Recommend: follow serial ultrasound and/or CT to rule out abnormal ventricular enlargement. Emphasize to parents that this does not represent cortical atrophy. Due to increased risk for positional molding, parents may need to periodically reposition the head while the child is sleeping.\textsuperscript{41}

A shunt may rarely be indicated when the collections are bloody (consider the possibility of child abuse) or for cosmetic reasons for severe macrocrania or frontal bossing.

24.9 X-linked hydrocephalus

24.9.1 General information

Inherited hydrocephalus (HCP) with phenotypic expression in males passed on through carrier mothers who are phenotypically normal. Classical phenotypic expression will skip single generations.

Incidence: 1/25,000 to 1/60,000. Prevalence: \( \approx 2 \) cases per 100 cases of hydrocephalus.

Gene located on Xq28.\textsuperscript{42,43,44}

24.9.2 Pathophysiology

L1CAM membrane bound receptor plays a significant role in CNS development for axonal migration to appropriate target locations through Integrin cell adhesion molecules and MAP Kinase signal cascade.\textsuperscript{42,43,44}

Abnormal gene expression results in poor differentiation and maturation of cortical neurons macroscopic anatomical abnormalities (bilateral absence of pyramidal tracts, see below).

Cyttoplasmic domain loss of function mutations result in severe L1 syndrome, whereas mutations retaining expression of some functional protein (component imbedded in cell membrane) leads to mild L1 syndrome.

24.9.3 L1 syndromes

Classical syndromes include CRASH (corpus callosum hypoplasia, retardation, adducted thumbs (clasp thumbs), spastic paralysis, HCP), MSAS (mental handicap, aphasia, shuffling gate, adducted thumbs), HSAS (HCP with stenosis of the aqueduct of sylvius). Spectrum of disease also includes x-linked agenesis of the corpus callosum (ACC), and spastic paraparesis type 1.\textsuperscript{42,43}

Recent delinations\textsuperscript{44}:

- mild L1 syndrome: adducted thumbs, spastic paralysis, hypoplasia of CC
- severe L1 syndrome: as in mild L1 syndrome plus anterior cerebellar vermis hypoplasia, large massa intermedia, enlarged quadrigeminal plate, rippled ventricular wall following VP shunt placement (pathognomonic for X-linked HCP). Profound mental retardation in virtually all cases

Radiographic findings likely present if severe L1\textsuperscript{45}:

1. severe symmetric HCP with predominant posterior horn dilation
2. hypoplastic CC/ACC
3. hypoplastic anterior cerebellar vermis

http://e-surg.com
4. large massa intermedia 5. large quadrigeminal plate 6. rippled ventricular wall following VP shunt placement (pathognomonic)

Treatment: no intervention demonstrates improvement in retardation status in observational papers.
1. VP shunt: main purpose is management of head size for improved care by caregiver. Does not improve neurologic outcome
2. there are no current genetic therapies for L1CAM protein abnormalities
3. prenatal U/S: early (≈ 20–24 weeks gestational age) with frequent repeat scan in known carrier mothers. May allow for medically indicated termination early on
4. male infants with HCP and ≥ 2 clinical/radiographic signs should undergo genetic testing for L1CAM mutation detection for future pregnancy counseling

24.10 “Arrested hydrocephalus”

24.10.1 General information
The exact definition of this term is not generally agreed upon, and some use the term compensated hydrocephalus interchangeably. Most clinicians use these terms to refer to a situation where there is no progression or deleterious sequelae due to hydrocephalus that would require the presence of a CSF shunt. Patients and families should be advised to seek medical attention if they develop symptoms of intracranial hypertension (decompensation) which may include: headaches, vomiting, ataxia or visual symptoms.41

Arrested hydrocephalus satisfies the following criteria in the absence of a CSF shunt:
1. near normal ventricular size
2. normal head growth curve
3. continued psychomotor development

24.10.2 Shunt independence
The concept of becoming independent of a shunt is not universally accepted.46 Some feel that shunt independence occurs more commonly when the HCP is due to a block at the level of the arachnoid granulations (communicating hydrocephalus),47 but others have shown that it can occur regardless of the etiology.48 These patients must be followed closely as there are reports of death as late as 5 years after apparent shunt independence, sometimes without warning.47

24.10.3 When to remove a disconnected or non-functioning shunt?
Note: a disconnected shunt may continue to function by CSF flow through an endothelialized subcutaneous tract. Recommendations on whether or not to repair vs. remove a disconnected or non-functioning shunt:
1. when in doubt, shunt
2. indications for shunt repair (vs. removal)
   a) marginally functioning shunts
   b) the presence of any signs or symptoms of increased ICP (vomiting, upgaze palsy, sometimes H/A alone49…)
   c) changes in cognitive function, ↓ attention span, or emotional changes
   d) patients with aqueductal stenosis or spina bifida: most are shunt dependent
3. because of risks associated with shunt removal, surgery for this purpose alone should be performed only in the situation of a shunt infection50
4. patients with a nonfunctioning shunt should be followed closely with serial CTs, and possibly with serial neuropsychological evaluations

24.11 Entrapped fourth ventricle
24.11.1 General information
AKA isolated fourth ventricle: 4th ventricle that neither communicates with the 3rd ventricle (through sylvian aqueduct) nor with the basal cisterns (through foramina of Luschka or Magendie). Usually seen with chronic shunting of the lateral ventricles, especially with post-infectious
hydrocephalus (fungal, in particular) or in those with repeated shunt infections. Possibly as a result of adhesions forming from prolonged apposition of the ependymal lining of the aqueduct due to the diversion of CSF through the shunt. Occurs in 2–3% of shunted patients. May also occur in Dandy Walker malformation (p. 256) if the aqueduct is also obstructed. The choroid plexus of the 4th ventricle continues to produce CSF which enlarges the ventricle when there is 4th ventricular outlet obstruction or obstruction at the level of the arachnoid granulations.

24.11.2 Presentation
Presentation may include:
1. headache
2. lower cranial nerve palsies: swallowing difficulties
3. pressure on the floor of the 4th ventricle may compress the facial colliculus (p. 576) → facial diplegia and bilateral abducens palsy
4. ataxia
5. reduced level of consciousness
6. nausea/vomiting
7. may also be an incidental finding (NB: some “atypical” findings, such as reduced attention span, may be related)

24.11.3 Treatment
Treatment of the entrapped 4th ventricle may alleviate associated slit ventricles. Most surgeons advocate shunting the ventricle either with a separate VP shunt, or linking into an existing shunt. Options:
1. usual first choice: insertion from below the tonsils under direct vision. The catheter may be brought out at the dural suture line, and may be anchored here by use of an angle adapter sutured to the dura
2. passage through a cerebellar hemisphere: potential complications include delayed injury to the brainstem by the catheter tip as the brainstem moves into its normal position with drainage of the 4th ventricle. This may be avoided by bringing the catheter into the 4th ventricle at a slight angle through the cerebellar hemisphere
3. Torkildsen shunt (ventriculocisternal shunt) is an option for obstructive hydrocephalus if it is certain that the arachnoid granulations are functional (usually not the case with hydrocephalus of infantile onset)
4. an LP shunt may be considered when the 4th ventricle outlets are patent

Cranial nerve palsies may occur with shunting of the 4th ventricle usually as a result of penetration of the brainstem by the catheter either at the time of catheter insertion, or in a delayed fashion as the 4th ventricle decreases in size, but also possibly as a result of overshunting causing traction on the lower cranial nerves as the brainstem shifts posteriorly.

24.12 Normal pressure hydrocephalus (NPH)
24.12.1 General information

Key concepts

- triad (not pathognomonic): dementia, gait disturbance, urinary incontinence
- communicating hydrocephalus on CT or MRI
- normal pressure on random LP
- symptoms may be remediable with CSF shunting

Normal pressure hydrocephalus (NPH), AKA Hakim-Adams syndrome, first described in 1965, is clinically important because it may cause treatable symptoms, including one of the few forms of remediable dementia.

As originally described, the hydrocephalus of NPH was considered to be idiopathic (iNPH). However, in some cases of hydrocephalus with normal pressure, a predisposing condition may be
identified, suggesting that the ICP may have been elevated at some point in time. These patients may also respond to shunting.

Possible etiologies of “secondary NPH” include:
1. post-SAH
2. post-traumatic
3. post-meningitis
4. following posterior fossa surgery
5. tumors, including carcinomatous meningitis
6. also seen in ≈15% of patients with Alzheimer’s disease (AD)
7. deficiency of the arachnoid granulations
8. aqueductal stenosis may be an overlooked cause

To further complicate things, some patients considered to have NPH may actually have episodic elevations in ICP.

Throughout this text, discussion focuses on idiopathic NPH unless stated otherwise.

It is becoming increasingly acknowledged that the ventricular enlargement is likely not the primary underlying pathologic entity. Research continues in an effort to improve the understanding of this complicated condition.

24.12.2 Epidemiology

Incidence for idiopathic NPH (iNPH) may be as high as 5.5 per 100,000 per year.55 The mean age for iNPH is older than that for secondary NPH.

24.12.3 Clinical

Clinical triad

See reference.56

The triad is not pathognomonic, and similar features may also be seen e.g. in vascular dementia.57 Alzheimer’s dementia and Parkinson’s disease.

1. gait disturbance: usually precedes other symptoms. Wide based with short, shuffling steps and unsteadiness on turning. Patients often feel like they are “glued to the floor” (so-called “magnetic gait”) and may have difficulty initiating steps or turns. Absence of appendicular ataxia

2. dementia: primarily memory impairment with bradyphrenia (slowness of thought) and bradykinesia. Table 24.2 shows some differentiating features with Alzheimer’s disease.

3. urinary incontinence: usually unwitting (NB: a patient demented for any reason or with mobility impairment may have incontinence)

Table 24.2 Comparison of cognitive deficits in Alzheimer’s disease (AD) and NPH

Other clinical features

Age usually > 60 yrs. Slight male preponderance. Also below for other clinical information.

True aphasia is unusual, but speech output may be disturbed by impaired motivation or executive dysfunction. As NPH progresses, cognitive impairment may become more generalized and less responsive to treatment. Symptoms identical to those of idiopathic parkinsonism may occur in 11%. Case reports of a variety of psychiatric disturbances associated with NPH include: depression, bipolar disorder, aggressiveness, paranoia.

Symptoms not expected with NPH

Although a variety of clinical features have been demonstrated to occur infrequently (e.g. SIADH, syncope...), clinical features not expected solely as a result of NPH include: papilledema, seizures (prior to shunting), headaches.

24.12.4 Imaging in NPH

CT and MRI

Features on CT and MRI

1. prerequisite: ventricular enlargement without block (i.e. communicating hydrocephalus)
2. features that correlate with favorable response to shunt. These features suggest that the hydrocephalus is not due to atrophy alone. (Note: atrophy / hydrocephalus ex vacuo, as in conditions such as Alzheimer's disease, lessens the chance of, but does not preclude, responding to a shunt (cortical atrophy is a common finding in healthy individuals of advanced age))
   a) periventricular low density on CT or high intensity on T2WI MRI: may represent transependymal absorption of CSF. May resolve with shunting
   b) compression of convexity sulci (note: focal sulcal dilation may sometimes be seen and may represent atypical reservoirs of CSF which may diminish after shunting and should not be considered as atrophy)
   c) rounding of the frontal horns

Although some patients improve with no change in ventricles, clinical improvement most often accompanies reduction of ventricular size.
Radionuclide cisternography

Usefulness remains controversial. One study found that the cisternogram does not increase the diagnostic accuracy of clinical and CT criteria. Use has been abandoned by most researchers.

24.12.5 Ancillary tests for NPH

Lumbar puncture (LP)

Opening pressure

Normal LP opening pressure (OP) in the left lateral decubitus position averages 12.2 ± 3.4 cm H₂O (8.8 ± 0.9 mm Hg) and should be <180 mm H₂O (OP > 24 cm H₂O suggests noncommunicating hydrocephalus rather than NPH). In NPH the average OP is 15 ± 4.5 cm H₂O (11 ± 3.3 mm Hg), slightly higher than, but overlapping with, normal. Based on expert opinion, an upper limit of 24 cm H₂O (17.6 mm Hg) is suggested for the definition of NPH. Patients with an initial OP > 10 cm H₂O have a higher response rate to shunting.

CSF labs

Send CSF for routine labs (p. 1506) to rule out infection, elevated protein (e.g. with tumor), SAH.

“Tap Test”

Consists of lumbar puncture with removal of a specific quantity of CSF and assessment of response.

The tap test has not undergone rigorous prospective evaluation. A positive response to withdrawal of 40–50 ml of CSF has a PPV in the range of 73–100% but sensitivity is low (26–61%). (Note: what constitutes a significant “response” has not been standardized, most experts prefer demonstrating objective improvement in gait, taking into account the fact that NPH patients can have day-to-day fluctuations in symptoms.)

Resistance testing

CSF Ro is considered to be the impedance of CSF absorptive mechanisms. 1/Ro is the conductance. Techniques and thresholds are center-specific. No clinical study has adequately addressed the fact that Ro normally increases with age.

Determination of CSF Ro may have a higher sensitivity (57–100%) but a similar PPV (75–92%) to the tap test.

Methodology

Numerous methods have been devised to measure Ro. Two illustrative methods:

1. bolus method: a known volume (usually 4 ml) is injected via LP at a rate of 1 ml/sec
2. Katzman test: infuse saline through LP at a known rate, Ro is given by Eq (24.1) (up to 19% of patients experience H/A after infusion studies)

\[ Ro = \frac{\text{final steady state pressure} - \text{initial pressure}}{\text{infusion rate}} \]

Ambulatory lumbar drainage (ALD)

See reference.

A lumbar subarachnoid drain is placed with Tuohy needle, connected through a drip chamber to a closed drainage system. The drip chamber is placed at the level of the patient’s ear when they are recumbent, or at the level of the shoulder when sitting or ambulating.

A properly functioning drain should put out ≈ 300 ml of CSF per day. If symptoms of nerve root irritation develop during the drainage, the catheter should be withdrawn several millimeters. Daily surveillance CSF cell counts and cultures should be performed (NB: a pleocytosis of ≈ 100 cells/mm³ can be seen normally just as a result of the presence of a drain).

A 5 day trial is recommended (mean time to improvement: 3 days).

Continuous CSF pressure monitoring

Some patients with a normal OP on LP demonstrate pressure peaks >270 mm H₂O or recurrent B-waves. These patients also, and may have a higher response rate to shunting than those without these findings.
Miscellaneous

Cerebral blood flow (CBF) measurements: Although some studies indicate otherwise, CBF measurements show no specific findings in NPH, and are not helpful in predicting who will respond to shunting. However, increased CBF after shunting correlates with clinical improvement. 

EEG: There are no specific EEG findings in NPH.

24.12.6 Diagnostic criteria

**Practice guideline: Diagnosis of NPH**

*Level II*: Since strict diagnostic criteria cannot be formulated for NPH because of a lack of knowledge of the underlying pathophysiology at this time, it is recommended that the diagnosis be made in terms of Probable, Possible, and Unlikely NPH as described in Table 24.3.

Guidelines for diagnosis of NPH are shown in Table 24.3.

24.12.7 Differential diagnosis of NPH

Table 24.4 shows conditions with presentations similar to findings in NPH in the differential diagnosis. Table 24.5 compares some features of NPH, Alzheimer’s disease, and Parkinson’s disease.

24.12.8 Treatment

**Management algorithm**

1. based on history, physical exam, and imaging studies, categorize the patient as probable, possible, or unlikely NPH based on Table 24.3. For probable and possible NPH, without further testing, the degree of certainty of the diagnosis of NPH is ≥ 50 – 61%. In an otherwise healthy patient in whom the diagnosis of NPH seems highly probable, it is not unreasonable to proceed to shunting.

2. otherwise, to increase the certainty of response to shunting, one or more of the following tests is recommended:
   a) “tap test”: withdrawal of 40–50 ml of CSF via LP
      • positive response (p.407) increases likelihood of responding to a shunt (PPV) to the range of 73–100%
      • due to low sensitivity (26–61%), a negative response does not rule out the possibility of responding, and a subsequent supplemental test should be performed.
      • if OP > 17.6 mm Hg (24 cm H2O), consider further search for cause of secondary hydrocephalus (does not rule-out shunting as a treatment)
   b) resistance testing: sensitivity (57–100%) > tap test, similar PPV (75–92%)
   c) external lumbar drainage

**CSF diversionary procedures**

VP shunt is the procedure of choice. Lumbar-peritoneal shunts have been used, but disadvantages include: tendency to overshunt, difficult to tap, tendency to migrate. For most, use a medium pressure valve (closing pressure 65–90 mm H2O) to minimize the risk of subdural hematomas (see below), although response rate may be higher with a low-pressure valve. Gradually sit patient up over a period of several days; proceed more slowly in patients who develop low-pressure headaches. Alternatively, the risk of developing SDH may be decreased with use of a programmable shunt valve, set initially at a high pressure (to reduce risk of subdural hematoma) and gradually decreasing the pressure setting over a number of weeks.

Follow patients clinically and with CT for ≥ 6–12 months.

Patients who do not improve and whose ventricles do not change on imaging should be evaluated for shunt malfunction. If not obstructed, and if no subdural fluid collections have developed, a lower pressure valve may be tried (or a lower pressure selected on a programmable shunt).

**Potential complications of shunting for NPH**

Complication rates may be as high as ≈ 35% (due in part to the frailty of the elderly brain).
Potential complications include:

1. subdural hematomas or hygroma (p.426): higher risk with low pressure valve and older patients who tend to have cerebral atrophy. Usually accompanied by headache, most resolve spontaneously or remain stable. Approximately one-third require evacuation and tying off of shunt (temporarily or permanently). Risk may be reduced by gradual mobilization post-op

2. shunt infection

3. intracerebral hemorrhage

4. seizures (p.417)

5. delayed complications include: above, plus shunt obstruction or disconnection

**Endoscopic third ventriculostomy (ETV)**

Initially reported for NPH in 1999. Mechanistically, it is difficult to explain why ETV would work for NPH, but it has been advocated by some in highly selected patients, using nonvalidated outcome measures, quoting post-op improvement in 69% of patients. At this time, ETV should not be considered a first line treatment for most cases of NPH.
24.12.9 Outcome

The most likely symptom to improve with shunting is incontinence, then gait disturbance, and lastly dementia. Black et al. give the following markers for good candidates for improvement with shunting:

- clinical: presence of the classic triad (p. 404).
- Also 77% of patients with gait disturbance as the primary symptom improved with shunting. Patients with dementia and no gait disturbance rarely respond to shunting.
- LP: OP > 100 mm H₂O
- isotope cisternogram: typical NPH pattern. The mixed or normal pattern has no correlation with response to shunting.
- continuous CSF pressure recording: pressure > 180 mm H₂O or frequent Lundberg B waves (p. 864)
- CT or MRI: large ventricles with flattened sulci (little atrophy)

Response is better when symptoms have been present for a shorter time.

NB: NPH patients with co-existing Alzheimer’s disease (AD) may still improve with VP shunts, thus AD should not exclude these patients from shunting. However, patients with AD alone (without NPH) did not respond to shunting in a RPDB placebo-controlled trial.

In general, most responders eventually relapse, often after ≈ 5–7 years of good response. Shunt malfunction and subdural collections must be ruled out before ascribing this to the natural course of the underlying condition.

24.13 Hydrocephalus and pregnancy

24.13.1 General information

Patients with CSF shunts may become pregnant, and there are case reports of patients developing hydrocephalus during pregnancy requiring shunting.

Any of the shunt problems discussed in the following sections may occur in a pregnant patient with a shunt. With VP shunts, distal shunt problems may be higher in pregnancy. The following are management suggestions modified from Wisoff et al.

24.13.2 Preconception management of patients with shunts

1. evaluation, including:
   a) evaluation of shunt function: preconception baseline MRI or CT. Further evaluation of shunt patency if any suspicion of malfunction. Patients with slit ventricles may have reduced compliance and may become symptomatic with very small changes in volume
   b) assessment of medications, especially anticonvulsants

| Table 24.5 Comparison of NPH, Alzheimer’s & Parkinson’s disease<sup>a</sup> |
|-----------------------------|------|----|----|
| Feature                    | NPH  | AD  | IPA |
| gait disturbance<sup>b</sup> | +    | ±   | ±  |
| postural instability       | ±    | ±   | ±  |
| urinary disturbance        | ±    | ±   | ±  |
| memory or cognitive impairment | ±  | +   | ±  |
| difficulty performing familiar tasks | ± | +  | ± |
| behavioral changes         | ±    | +   | ±  |
| limb rigidity              | ±    | +   | ±  |
| limb tremor                |      | +   |    |
| bradykinesia               |      | +   |    |

<sup>a</sup> abbreviations: AD=Alzheimer’s disease; IPA=idiopathic paralysis agitans (Parkinson’s disease); + = feature present; ± = feature partial or late

<sup>b</sup> in NPH, the gait is often wide based, in IPA often narrow stance
2. counselling, including:
   a) genetic counselling: if the HCP is due to a neural tube defect (NTD), then there is a 2–3% chance that the baby will have a NTD
   b) other recommendations include early administration of prenatal vitamins, and avoiding teratogenic drugs and excessive heat (e.g. hot-tubs): Neural tube defects, Risk factors (p.290).

24.13.3 Gravid management

1. close observation for signs of increased ICP: headache, N/V, lethargy, ataxia, seizures… Caution: these signs may mimic pre-eclampsia (which must also be ruled out). 58% of patients exhibit signs of increased ICP, which may be due to:
   a) decompensation of partial shunt malfunction
   b) shunt malfunction
   c) some show signs of increased ICP in spite of adequate shunt function, may be due to increased cerebral hydration and venous engorgement
   d) enlargement of tumor during pregnancy
   e) cerebral venous thrombosis: including dural sinus thrombosis & cortical venous thrombosis
   f) encephalopathy related to disordered autoregulation

2. patients developing symptoms of increased ICP should have CT or MRI to compare ventricle size to preconception baseline study
   a) if no change from preconception study, puncture shunt to measure ICP and culture CSF. Consider radioisotope shunt-o-gram
   b) if all studies are negative, then physiologic changes may be responsible. Treatment is bed rest, fluid restriction, and in severe cases steroids and/or diuretics. If symptoms do not abate, then early delivery is recommended as soon as fetal lung maturity can be documented (give prophylactic antibiotics for 48 hrs before delivery)
   c) if ventricles have enlarged and/or shunt malfunction is demonstrated on testing, shunt revision is performed
      • in first two trimesters: VP shunt is preferred (do not use peritoneal trocar method after first trimester) and is tolerated well
      • in third trimester: VA or ventriculopleural shunt is used to avoid uterine trauma or induction of labor

24.13.4 Intrapartum management

1. prophylactic antibiotics are recommended during labor and delivery to reduce the incidence of shunt infection. Since coliforms are the most common pathogen in L&D, Wisoff et al. recommend ampicillin 2 gm IV q 6 hrs, and gentamicin 1.5 mg/kg IV q 8 hrs in labor and 48 hrs post partum. In patients without symptoms: a vaginal delivery is performed if obstetrically feasible (lower risk of forming adhesions or infection of distal shunt). A shortened second stage is preferred since the increase in CSF pressure in this stage is probably greater than during other valsalva maneuvers. In the patient who becomes symptomatic near term or during labor, after stabilizing the patient a C-section under general anesthesia (epidurals are contraindicated with elevated ICP) is performed with careful fluid monitoring and, in severe cases, steroids and diuretics

Hydrocephalus – General Aspects

[References]

http://e-surg.com
25 Treatment of Hydrocephalus

25.1 Medical treatment of hydrocephalus

HCP remains a surgically treated condition. Acetazolamide may be helpful for temporizing (see below).

25.1.1 Diuretic therapy

May be tried in premature infants with bloody CSF (as long as there is no evidence of active hydrocephalus) while waiting to see if there will be resumption of normal CSF absorption. However, at best this should only be considered as an adjunct to definitive treatment or as a temporizing measure.

Satisfactory control of HCP was reported in ≈ 50% of patients of age <1 year who had stable vital signs, normal renal function and no symptoms of elevated ICP (apnea, lethargy, vomiting) using the following regimen:

1. acetazolamide (a carbonic anhydrase inhibitor): 25 mg/kg/day PO divided TID × 1 day, increase 25 mg/kg/day each day until 100 mg/kg/day is reached
2. simultaneously start furosemide: 1 mg/kg/day PO divided TID
3. to counteract acidosis, use tricitrate (Polycitra®):
   a) start 4 ml/kg/day divided QID (each ml is equivalent to 2 mEq of bicarbonate, and contains 1 mEq K+ and 1 mEq Na+)
   b) measure serial electrolytes, and adjust dosage to maintain serum HCO₃ >18 mEq/L
   c) change to Polycitra-K® (2 mEq K+ per ml, no Na+) if serum potassium becomes low, or to sodium bicarbonate if serum sodium becomes low
4. watch for electrolyte imbalance and acetazolamide side effects: lethargy, tachypnea, diarrhea, paresthesias (e.g. tingling in the fingertips)
5. perform weekly U/S or CT scan and insert ventricular shunt if progressive ventriculomegaly occurs. Otherwise, maintain therapy for a 6 month trial, then taper dosage over 2–4 weeks.

Resume 3–4 mos of treatment if progressive HCP occurs

25.2 Spinal taps

HCP after intraventricular hemorrhage may be only transient. Serial taps (ventricular or LP²) may temporize until resorption resumes but LPs can only be performed for communicating HCP. If reabsorption does not resume when the protein content of the CSF is <100 mg/dl, then it is unlikely that spontaneous resorption will occur in the near future (i.e. a shunt will usually be necessary).

25.3 Surgical

25.3.1 Goals of therapy

Normal sized ventricles is not the goal of therapy (some children have a paucity of brain tissue). Goals are optimum neurologic function (which usually requires normal intracranial pressure) and a good cosmetic result.

25.3.2 Surgical options

Options include

- third ventriculostomy: currently, endoscopic method is preferred (see below)
- shunting: various shunts are described below. The techniques of shunt placement are covered for VP shunts (p. 1515), for VA shunt (p. 1516), for ventriculopleural shunts (p. 1515), and for LP shunt (p. 1517)
- eliminating the obstruction: e.g. opening a stenosed sylvian aqueduct. Often higher morbidity and lower success rate than simple CSF diversion with shunts, except perhaps in the case of tumor
- choroid plexectomy: described by Dandy in 1918 for communicating hydrocephalus. May reduce the rate but does not totally halt CSF production (only a portion of CSF is secreted by the choroid plexus, other sources include the ependymal lining of the ventricles and the dural sleeves of spinal nerve roots). Open surgery was associated with a high mortality rate (possibly due to replacement
of CSF by air). Endoscopic choroid plexus coagulation was originally described in 1910 and was recently resurrected.

25.4 Endoscopic third ventriculostomy

25.4.1 Indications

Endoscopic third ventriculostomy (ETV) may be used in patients with obstructive HCP. May also be an option in managing shunt infection (as a means to remove all hardware without subjecting the patient to increased ICP). ETV has also been proposed as an option for patients who developed subdural hematomas after shunting (the shunt is removed before the ETV is performed). ETV may also be indicated for slit ventricle syndrome (p.424).

25.4.2 Contraindications

Communicating hydrocephalus has traditionally been considered a contraindication to ETV. However, it has been occasionally used for NPH. Relative contraindications to ETV would be the presence of any of the conditions associated with a low success rate (see below).

25.4.3 Complications

- hypothalamic injury: may result in hyperphagia
- injury to pituitary stalk or gland: may result in hormonal abnormalities including diabetes insipidus, amenorrhea
- transient 3rd and 6th nerve palsies
- injury to basilar artery, p-comm, or PCA: a fixed endoscope sheath seated just distal to the foramen of Monro within the third ventricle may allow for safe egress of blood extacranially
- uncontrollable bleeding
- cardiac arrest
- traumatic basilar artery aneurysm: possibly related to thermal injury from use of laser in performing ETV

25.4.4 Technique

See dedicated section on technique (p.1517).

25.4.5 Success rate

Overall success rate is \( \approx 56\% \) (range of 60–94\% for nontumoral aqueductal stenosis (AqS)). Highest maintained patency rate is with previously untreated acquired AqS. Success rate in infants may be poor because they may not have a normally developed subarachnoid space. There is a low success rate (only \( \approx 20\% \) of TVs will remain patent) if there is pre-existing pathology including:

1. tumor
2. previous shunt
3. previous SAH
4. previous whole brain radiation (success with focal stereotactic radiosurgery is not known)
5. significant adhesions visible when perforating through the floor of the third ventricle at the time of performance of ETV

The ETV Success Score (see Table 25.1) is a validated means of predicting the likelihood of success of ETV and therefore may assist in selecting appropriate patients for the procedure. Total of the 3 scores (1 from each category: age, etiology and shunt history) expressed as a percent is the approximate chance of an ETV lasting 6 months without failure. Scores <40\% correlated with a very low chance of success. Scores >80\% correlated with a better chance of success compared to shunting from the outset.

Intermediate scores (50–70\%) ETV had a higher initial failure rate compared to shunting, but after 3-6 months the balance shifted in favor of ETV.

In one series, clinical improvement after ETV was achieved in 76\% (72 of 95 patients), including 6 patients requiring second ETVs (three of which had partially functioning shunts that were left in place at the time of ETV).
25.5 Shunts

25.5.1 Types of shunts

1. ventriculoperitoneal (VP) shunt:
   a) most commonly used shunt in modern era
   b) lateral ventricle is the usual proximal location
   c) intraperitoneal pressure: normal is near atmospheric

2. ventriculo-atrial (VA) shunt ("vascular shunt"):
   a) shunts ventricles through jugular vein to superior vena cava, so-called “ventriculo-atrial” shunt because it shunts the cerebral ventricles to the vascular system with the catheter tip in the region of the right cardiac atrium)
   b) treatment of choice when abdominal abnormalities are present (extensive abdominal surgery, peritonitis, morbid obesity, in preemies who have had NEC and may not tolerate VP shunt...)
   c) shorter length of tubing results in lower distal pressure and less siphon effect than VP shunt, however pulsatile pressures may alter CSF hydrodynamics

3. Torkildsen shunt:
   a) shunts ventricle to cisternal space
   b) rarely used
   c) effective only in acquired obstructive HCP, as patients with congenital HCP frequently do not develop normal subarachnoid CSF pathways

4. miscellaneous: various distal projections used historically or in patients who have had significant problems with traditional shunt locations (e.g. peritonitis with VP shunt, SBE with vascular shunts):
   a) pleural space (ventriculopleural shunt): not a first choice, but a viable alternative if the peritoneum is not available. To avoid symptomatic hydrothorax necessitating relocating distal end, it is recommended only for patients >7 yrs age (although some feel that these may be placed as young as 2 yrs age, and that hydrothorax is primarily a sign of infection regardless of age). Pressure in pleural space is less than atmospheric
   b) gall bladder
   c) ureter or bladder: causes electrolyte imbalances due to losses through urine

5. lumboperitoneal (LP) shunt; see insertion technique (p.1517)
   a) only for communicating HCP: primarily pseudotumor cerebri or CSF fistula. Useful in situations with small ventricles
   b) over age 2 yrs, percutaneous insertion with Tuohy needle is preferred
6. cyst or subdural shunt: from arachnoid cyst or subdural hygroma cavity, usually to peritoneum

25.5.2 Disadvantages/complications of various shunts

Complications that may occur with any shunt

1. obstruction: the most common cause of shunt malfunction
   a) proximal: ventricular catheter (the most common site)
   b) valve mechanism
   c) distal: reported incidence of 12–34%\(^{14}\) Occurs in peritoneal catheter in VP shunt (see below), in atrial catheter in VA shunt

2. disconnection at a junction, or break at any point

3. infection: may produce obstruction

4. hardware erosion through skin, usually only in debilitated patients (especially preemies with enlarged heads and thin scalp from chronic HCP, who lay on one side of head due to elongated cranium). May also indicate silicone allergy (see below)

5. seizures (ventricular shunts only): there is \(\approx 5.5\%\) risk of seizures in the first year after placement of a shunt which drops to \(\approx 1.1\%\) after the 3rd year\(^{15}\) (NB: this does not mean that the shunt was the cause of all of these seizures). Seizure risk is questionably higher with frontal catheters than with parieto-occipital

6. act as a conduit for extraneural metastases of certain tumors (e.g. medulloblastoma). This is probably a relatively low risk\(^{16}\)

7. silicone allergy\(^{17}\): rare (if it occurs at all). May resemble shunt infection with skin breakdown and fungating granulomas. CSF is initially sterile but later infections may occur. May require fabrication of a custom silicone-free device (e.g. polyurethane)

Disadvantages/complications with VP shunt

1. inguinal hernia: incidence =17\%(many shunts are inserted while processus vaginalis is patent)\(^{18}\)

2. need to lengthen catheter with growth: may be obviated by using long peritoneal catheter (p.1515)

3. obstruction of peritoneal catheter:
   a) may be more likely with distal slit openings (“slit valves”) due to occlusion by omentum or by trapping debris from the shunt system\(^{14}\)
   b) by peritoneal cyst (or pseudocyst)\(^{19}\), usually associated with infection, may also be due to reaction to talc from surgical gloves (the omentum tends to “wall off” a nidus of irritation). It may rarely be necessary to differentiate a CSF collection from a urine collection in patients with overdistended bladders that have ruptured (e.g. secondary to neurogenic bladder). Fluid can be aspirated percutaneously and analyzed for BUN and creatinine (which should be absent in CSF)
   c) severe peritoneal adhesions: reduce surface area for CSF resorption
   d) malposition of catheter tip:
      - at time of surgery: e.g. in preperitoneal fat
      - tubing may pull out of peritoneal cavity with growth

4. peritonitis from shunt infection

5. hydrocele

6. CSF ascites

7. tip migration
   a) into scrotum\(^{20}\)
   b) perforation of a viscus\(^{21}\): stomach,\(^{22}\) bladder… More common with older spring-reinforced (Raimondi) shunt tubing
   c) through the diaphragm\(^{23}\)

8. intestinal obstruction (as opposed to perforation): rare

9. volvulus\(^{24}\)

10. intestinal strangulation: occurred only in patients in whom attempt was made to remove peritoneal tubing using traction on the catheter applied at the cephalad incision with subsequent breakage of the tubing leaving a residual intraabdominal segment (immediate peritoneal exploration is recommended under these circumstances)\(^{25}\)

11. overshunting (p.424): more likely than with VA shunt. Some recommend LP shunt for communicating hydrocephalus

http://e-surg.com
Disadvantages/comlications with VA shunt
1. requires repeated lengthening in growing child
2. higher risk of infection, septicemia
3. possible retrograde flow of blood into ventricles if valve malfunctions (rare)
4. shunt embolus
5. vascular complications: perforation, thrombophlebitis, pulmonary micro-emboli may cause pulmonary hypertension\(^\text{26}\) (incidence \(\approx 0.3\%\))

Disadvantages/comlications with LP shunt
1. if at all possible, should not be used in growing child unless ventricular access is unavailable (e.g. due to slit ventricles) because of:
   a) laminectomy in children causes scoliosis in 14\(^\text{27}\)%
   b) risk of progressive cerebellar tonsillar herniation (Chiari I malformation)\(^\text{28}\) in up to 70\% of cases\(^\text{29,30}\)
2. overshunting harder to control when it occurs (a special horizontal-vertical (H-V) valve increases resistance when upright, see below)
3. difficult access to proximal end for revision or assessment of patency; see Lumboperitoneal (LP) shunt evaluation (p.1518).
4. lumbar nerve root irritation (radiculopathy)
5. leakage of CSF around catheter
6. pressure regulation is difficult
7. bilateral 6th and even 7th cranial nerve dysfunction from overshunting
8. high incidence of arachnoiditis and adhesions

Programmable shunt valves
A number of externally programmable shunts available in the U.S., including:
- Strata by Medtronic (p. 429)
- Polaris by Sophysa (p.431)
- Codman Hakim (p.429)
- Certas Plus by Codman
- proGav by Aesculap

All are programmed externally with a magnet, and can potentially be inadvertently reprogrammed by external magnetic fields including those encountered during an MRI (the Polaris valve and the Certas Plus valve are promoted as being less susceptible to inadvertent reprogramming. Therefore, valve settings should be rechecked after an MRI scan performed for any reason, or if there is ever a concern about shunt function. The pressure setting on all of these valves can be checked on a plain x-ray taken perpendicular to the shunt valve (see Fig. 25.1 to identify the programmable valve type, then see the corresponding section for that valve to determine the shunt pressure setting). Some can also be checked using a special hand-held compass-like device provided by the manufacturer to most hospitals and clinics that deal with their valves.

In all systems on the market, increasing the programmed number results in higher valve opening pressures and therefore less CSF drainage at any given CSF pressure.

X-ray appearance of some shunt valves
Fig. 25.1 depicts idealized x-ray appearances of some common shunts. It is intended to help differentiate shunt systems on x-ray, and is not to scale. Appearance may vary with orientation relative to the x-ray beam. Manufacturer’s diagrams of these shunts appears in section 25.7.

Miscellaneous shunt hardware
1. tumor filter: used to prevent peritoneal or vascular seeding in tumors that may metastasize through CSF (e.g. medulloblastoma,\(^\text{31}\) PNETs, ependymoma); may eventually become occluded by tumor cells and need replacement; may be able to radiate tumor filter to “sterilize” it. Not often used despite the fact that the risk of “shunt mets” appears to be low\(^\text{16}\)
2. devices to avoid overdrainage when the patient is upright
   a) antisyphon devices (ASD): prevents syphoning effect when patient is erect. Some valves have ASDs integrated into the valve. ASDs always increase the resistance of the shunt
   b) “horizontal-vertical valve” (H-V valve) (p. 433) used primarily with LP shunts

http://e-surg.com
3. with a standard 90 cm long 1.2 mm inner diameter distal catheter, the hydrodynamic resistance of most shunts increases by 2–2.5 mm Hg/(ml/min) \(^{12}\)

### 25.6 Shunt problems

#### 25.6.1 Risks associated with shunt insertion

1. intraparenchymal or intraventricular hemorrhage: risk \(\approx 4\%\) (in the absence of coagulopathy \(^{13}\))
2. seizures

---

*Fig. 25.1 X-ray appearance of common shunts
For x-ray appearance of programmable valves and the corresponding pressures, see the individual valve.*
3. malposition
   a) of ventricular catheter
   b) of distal catheter

4. infection

25.6.2 Problems in patients with established CSF shunt

Shunt “problems” usually involve one or more of the following (undershunting and infection account for most common shunt problems):

1. undershunting (see below): obstruction (rate: \( \approx 10\% \) per year), breakage...
3. Having a shunt infection decrease IQ
4. overshunting:
   a) slit ventricle syndrome
   b) subdural hematomas... (p.424)
   c) “spinal headache"
5. seizures (p.417)
6. problems related to the distal catheter
   a) peritoneal (p.417)
   b) atrial (p.418)
7. skin breakdown over hardware (p.417): may indicate infection or silicone allergy

25.6.3 Evaluation of the patient with a shunt

History and physical

1. history directed at determining presence of shunt-related symptoms
   a) acute symptoms of increased ICP
      - H/A: effect of posture, position, activity, migraine-like symptoms (visual aura...)
      - N/V
      - diplopia
      - lethargy
      - ataxia
      - infants: apnea and/or bradycardia; irritability; poor feeding
      - seizures: either new onset, or if pre-existing, an increase in frequency, or difficulty in control
   b) symptoms of infection: fever, chills, night-sweats, erythema and/or tenderness over shunt tubing. Diarrhea may indicate infection unrelated to shunt. Exposure to other sick individuals

2. physical exam: the following includes signs of increased intracranial pressure
   a) for children: OFC (p.395). Plot on graph of normal curves (use existing chart for that patient if available) loof for OFC crossing curves
   b) fontanelle tension (if open): a soft pulsating fontanelle varying with respirations is normal, a tense bulging fontanelle suggests obstruction, a sunken fontanelle may be normal or may represent overshunting
   c) upward gaze palsy: “setting sun sign”, Parinaud’s syndrome (p.99)
   d) abducens palsy (p.567): false localizing sign
   e) field cut, or blindness; see Blindness from hydrocephalus (p.396)
   f) swelling around shunt tubing: caused by CSF dissecting along tract of an obstructed shunt

3. shunt history
   a) type of shunt: VP, VA, pleural, LP
   b) initial insertion of shunt: reason (MM, post-meningitis, etc.) and patient age
   c) date of last revision and reason for revision
   d) presence of accessory hardware in system (e.g. antisiphon device, etc.)

4. ability of shunt to pump and refill
   a) caution: may exacerbate obstruction, especially if shunt is occluded by ependyma due to overshunting: controversial
   b) difficult to depress: suggests distal occlusion
   c) slow to refill (generally, any valve should refill in 15–30 secs): suggests proximal (ventricular) occlusion or slit ventricles

5. evidence of CSF dissecting along tract outside of shunt tubing

6. in children presenting only with vomiting, especially those with cerebral palsy and feeding gastrostomy tubes, rule-out gastroesophageal reflux
Radiographic evaluation

1. “shunt series” (plain x-rays to visualize entire shunt)
   a) Purpose: R/O disconnection/breakage or migration of tip (NB: a disconnected shunt may continue to function by CSF flow through a subcutaneous fibrous tract)
   b) For a VP shunt: AP & lateral skull, CXR and abdominal x-ray
   c) the following hardware may be radiolucent and can mimic disconnection:
      - the central silastic part of older Holter style valves
      - connectors (“Y” & “T” as well as straight)
      - antisiphon devices
      - tumor filters
   d) obtain most recent x-rays available to compare for breaks (essential for “complicated” shunts involving multiple ventricular or cyst ends or accessory hardware)

2. in infants with open fontanelles, ultrasound is optimal method of evaluation (especially if previous U/S available)

3. CT required if fontanelles closed, may be desirable in complicated shunt systems (e.g. cyst shunts). Minimize the number of CTs in pediatric patients

4. MRI: shunt hardware is difficult to see. May show transependymal absorption of CSF, loculations... Programmable valves must be evaluated and reprogrammed after MRI

5. “shunt-o-gram” if it is still unclear if shunt is functioning
   a) radionuclide: see below
   b) x-ray: using iodinated contrast: see below

“Shunt-o-gram”

Indications
When shunt function cannot be reliably ascertained using other methods.

Procedure
Shave hair over reservoir & prep (e.g. with Betadine). With patient supine tap the shunt by inserting a 25 gauge butterfly needle into the reservoir. Measure the pressure with a manometer. Patients with multiple ventricular catheters need to have each injected to verify its patency.

Radionuclide “shunt-o-gram” AKA radionuclide shuntography: after tapping the shunt, drain 2–3 ml of CSF and send 1 ml of CSF for C&S. Inject radio-isotope (e.g. for VP shunt in an adult, use 1 mCi of 99m-Tc (technetium) pertechnetate (usable range: 0.5 to 3 mCi) in 1 cc of fluid) while occluding distal flow (by compressing valve or occluding ports). Flush in isotope with remaining CSF.

Immediately image the abdomen with the gamma camera to rule out direct injection into distal tubing. Image the cranium to verify flow into ventricles (proximal patency). for diffusion of the isotope within the abdomen to rule out pseudocyst formation around catheter.

Interpretation: If spontaneous flow into abdomen occurs within 20 minutes, the shunt is patent. If there is no flow on delayed imaging, it is occluded. The valve can be pumped to look for diffusion of isotope within the abdomen to rule out pseudocyst formation around the catheter tip. If it takes > 20 minutes, or if the patient has to be stood up to get flow, this is indeterminate and you should use other information to decide whether or not to revise the shunt.

X-ray “shunt-o-gram”: after tapping the shunt, drain ≈ 1 ml of CSF and send for C&S. Inject e.g. iohexol (Omnipaque 180) (p.219) while occluding distal flow (by compressing valve or occluding ports).

Pseudocyst (peritoneal) with VP shunt
An abdominal pseudocyst is usually an indication of infection.

Treatment algorithm
One of many viable surgical protocols to deal with this:
1. open abdominal incision over tubing, and divide tubing at this site
2. verify which cut end is the peritoneal end and which is the distal shunt (with a working shunt, pumping the valve should cause CSF to come out the distal shunt)
3. attempt to drain the cyst through the remaining peritoneal end
   a) when you can’t draw any more fluid, or if you don’t get any to begin with, withdraw the catheter a little at a time and aspirate at each step
   b) send any fluid obtained for culture
   c) if tubing does not pull out smoothly, the abdomen may need to be opened (consider consulting general surgeon)
4. verify function of remaining shunt
   a) if the remaining shunt is functioning
      - connect it to sterile collection system
      - monitor output volumes & send surveillance cultures of CSF qod
      - after 3 consecutive cultures are negative, internalize distal end of shunt (using fresh distal catheter). The choice of target for distal end (peritoneum, pleura, vein) depends on whether abdominal cyst fluid is infected and if the peritoneal cavity still seems suitable
   b) if the shunt is not functioning, a new external ventricular catheter should be inserted and connected to a collection system
      - monitor output volumes & send surveillance cultures of CSF qod
      - after 3 consecutive cultures are negative, remove the old shunt and place a totally new shunt. The choice of target for distal end (peritoneum, pleura, vein) depends on whether abdominal cyst fluid is infected and if the peritoneal cavity still seems suitable

5. shunt tap: indications vary, generally performed if occlusion suspected or if surgical exploration is considered or if infection is strongly suspected; see Tapping a shunt (p.422)

6. shunt exploration: sometimes even after thorough evaluation the only means to definitively prove or disprove the functioning of various shunt components is to operate and isolate and test each part of the system independently. Even when infection is not suspected, CSF and any removed hardware should be cultured.

**Tapping a shunt**

**Indications**

Indications to tap a shunt or ventricular access device (e.g. Ommaya reservoir) include:

1. to obtain CSF specimen
   a) to evaluate for shunt infection
   b) for cytology: e.g. in PNET to look for malignant cells in CSF
   c) to remove blood: e.g. in intraventricular hemorrhage
2. to evaluate shunt function
   a) measuring pressures
   b) contrast studies:
      - proximal injection of contrast (iodinated or radio-labeled)
      - distal injection of contrast
3. as a temporizing measure to allow function of a distally occluded shunt
4. to inject medication
   a) antibiotics: for shunt infection or ventriculitis
   b) chemotherapeutic (antineoplastic) agents
5. for catheters placed within tumor cyst (not a true shunt):
   a) periodic withdrawal of accumulated fluid
   b) for injection of radioactive liquid (usually phosphorous) for ablation

**Technique**

For LP shunt, see Lumboperitoneal (LP) shunt evaluation (p.1518). There is a risk of introducing infection with every entry into the shunt system. With care, this may be kept to a minimum.

1. shave area
2. prep: e.g. povidone iodine solution × 5 minutes
3. use 25 gauge butterfly needle or smaller (ideally a noncoring needle should be used): for routine taps, the needle should only be introduced into shunt components specifically designed to be tapped

To measure pressures
A 25 Ga butterfly needle and an LP tray (with manometer, specimen tubes, 3-way stopcock valve...) are helpful. Steps are outlined in Table 25.2.

**25.6.4 Undershunting**

**General information**

The shunt malfunction rate is ≈ 17% during the first year of placement in the pediatric population.
May be due to one or a number of the following:

1. blockage (occlusion)
   a) possible causes of occlusion:
      - proximal obstruction by choroid plexus
      - buildup of proteinaceous accretions
      - blood
      - cells (inflammatory or tumor)
      - secondary to infection
   b) site of blockage
      - blockage of ventricular end (most common): usually by choroid plexus, may also be due to glial adhesions, intraventricular blood
      - blockage of intermediate hardware (valves, connectors, etc., tumor filters may become blocked by tumor cells, antisiphon devices may close due to variable overlying subcutaneous tissue pressures37)
      - blocked distal end, also see VP shunt (p.417)
   c) disconnection, kinking or breakage of system at any point: with age, silicone elastomers used in catheters calcify and break down, and become more rigid and fragile which may promote subcutaneous attachment.38 Barium impregnation may accelerate this process. Tube fractures often occur near the clavicle, presumably due to the increased motion there

2. disconnection, kinking or breakage of system at any point: with age, silicone elastomers used in catheters calcify and break down, and become more rigid and fragile which may promote subcutaneous attachment.38

Table 25.2 Steps in tapping a shunt

<table>
<thead>
<tr>
<th>Step</th>
<th>Information provided</th>
</tr>
</thead>
</table>
| • After shave and prep, insert 25 Ga butterfly needle into the reservoir and look for spontaneous flow into butterfly tubing | • spontaneous flow indicates proximal end not completely occluded  
• pressure is that of ventricular system (normal is <15 cm of CSF in relaxed recumbent patient) |
| • then measure the pressure with distal occluder compressed (if present) | • rise in pressure indicates some function of valve and distal shunt |
| • if no spontaneous flow, try to aspirate CSF with syringe | • if CSF is easily aspirated, it may be that pressure seen by ventricular system is very low. There should be spontaneous flow after that when the end of the tubing is lowered  
• if no CSF obtained or if difficult to aspirate, indicates proximal occlusion |
| • if still no flow, carefully inject 1–2 ml of preservative free saline into ventricular catheter and see if spontaneous flow of more than the amount injected occurs | • may dislodge clot or debris from catheter  
• if only the 1–2 ml that were injected returns, indicates there is not a patent catheter in an open CSF space (possibilities include: occluded catheter, tip lodged in brain, slit ventricles) |
| • send any CSF for: C&S, protein/glucose, cell count | • checks for infection |
| • fill manometer with sterile saline with the valve turned off to the shunt  
• compress proximal (inlet) occluder if present  
• Open valve to shunt and measure runoff pressure after ≈60 seconds | • measures forward transmission pressure (through valve and peritoneal catheter in valves with a proximal occluder); forward pressure should be less than ventricular pressure (and absolute pressure should be <8 cm H2O) |
| • if no distal flow, keep inlet occluder compressed and inject 3–5 ml of saline into distal shunt and recheck distal runoff pressure  
• do not inject more than ≈1–2 ml into ventricles to avoid increasing ICP | • if peritoneal catheter is in a loculated compartment the pressure will be considerably higher after injection |

Etiologies

May be due to one or a number of the following:

1. blockage (occlusion)

2. site of blockage

3. disconnection, kinking or breakage of system at any point: with age, silicone elastomers used in catheters calcify and break down, and become more rigid and fragile which may promote subcutaneous attachment.

Signs and symptoms of undershunting

Signs and symptoms are those of active hydrocephalus. See “Evaluation of patient with shunt” (p.420).
25.6.5 Shunt infection

See Shunt infection (p.339) for evaluation and treatment.

25.6.6 “Overshunting”

General information

Possible complications of overshunting include:
1. slit ventricles: including slit ventricle syndrome (see below)
2. intracranial hypotension: see below
3. subdural hematomas (p.426)
4. craniosynostosis and microcephaly (p.427): controversial
5. stenosis or occlusion of sylvian aqueduct

10–12% of long-term ventricular shunt patients will develop one of the above problems within 6.5 yrs of initial shunting. Some experts feel that problems related to overshunting could be reduced by utilizing LP shunts for communicating hydrocephalus, and reserving ventricular shunts for obstructive HCP. VP shunts may also be more likely to overdrain than VA shunts because of the longer tubing →greater siphoning effect.

Intracranial hypotension

AKA low ICP syndrome. Very rare. Symptoms similar to those of spinal H/A (postural in nature, relieved by recumbency). Although usually not associated with the following symptoms, they may occur: N/V, lethargy, or neurologic signs (e.g. diplopia, upgaze palsy). Sometimes the symptoms resemble those of high ICP except that they are relieved when prostrate. Acute effects that may occur include: tachycardia, loss of consciousness, other brain stem deficits due to a rostral shift of the intracranial contents or to low ICP.

Etiology is a siphoning effect due to the column of CSF in the shunt tube when the patient is erect. Ventricles may be slit-like (as in slit ventricle syndrome (SVS)) or may be normal in appearance. Sometimes it is necessary to document a drop in ICP when going from supine to erect to diagnose this condition. These patients may also develop shunt occlusion and then the distinction from SVS blurs (see below).

With short-term symptoms, an antisiphon device (ASD) is the treatment of choice. However, patients with long-standing overshunting may not tolerate efforts to return intraventricular pressures to normal levels.

Slit ventricles

“Slit ventricles” refers to complete collapse of the ventricles. In a survey, a frontal-occipital horn ratio \(<0.2\) was most often interpreted as representing SVS. May be seen in:
1. overshunting
2. with entrapped (isolated) fourth ventricle (p.402)
3. some patients with idiopathic intracranial hypertension (AKA pseudotumor cerebri) (p.766) have slit-like ventricles with consistently elevated ICP

Slit ventricles may be:
1. asymptomatic:
   a) slit ventricles (totally collapsed lateral ventricles) may be seen on CT in 3–80% of patients after shunting; most are asymptomatic
   b) these patients may occasionally present with symptoms unrelated to the shunt, e.g. true migraine
2. slit ventricle syndrome (SVS): seen in <12% of all shunted patients. Subtypes:
   a) intermittent shunt occlusion: overshunting leads to ventricular collapse (slit ventricles) which causes the ependymal lining to occlude the inlet ports of the ventricular catheter (by coaptation) producing shunt obstruction. With time, many of these patients develop low ventricular compliance, where even minimal dilatation results in high pressure which produces symptoms. Expansion then eventually reopens the inlet ports allowing resumption of drainage (hence the intermittent symptoms). Symptoms may resemble shunt malfunction: intermittent headaches unrelated to posture, often with N/V, drowsiness, irritability and impaired
m entation. Signs may include 6th cranial nerve palsy. Incidence in shunted patients: 2–5%\textsuperscript{40}, \textsuperscript{46} CT or MRI scans may also show evidence of transependymal absorption of CSF

b) total shunt malfunction (AKA normal volume hydrocephalus\textsuperscript{45}): may occur and yet ventricles remain slit-like if the ventricles cannot expand because of subependymal gliosis, or due to the law of Laplace (which states that the pressure required to expand a large container is lower than the pressure required to expand a small container)

c) venous hypertension with normal shunt function: may result from partial venous occlusion that occurs in some conditions (e.g. at the level of the jugular foramen in Crouzon’s syndrome). Usually subsides by adulthood

3. intracranial hypotension: symptoms often relieved by recumbency (see above)

Evaluation of slit ventricles

The shunt valve fills slowly if pumped when the ventricles are collapsed.

Monitoring CSF pressure: either via lumbar drain, or with a butterfly inserted into the shunt reservoir (with this method, pressure can be followed during postural changes to look for negative pressure when upright; possibly higher risk of infection with this). These patients are also monitored for pressure spikes, especially during sleep.

Alternatively, these patients may be evaluated by “shunt-o-gram” (see above).

Treatment

In treating a patient with slit ventricles in imaging studies, it is important to ascertain into which of the categories (see above) the patient falls. If the patient can be categorized, then the specific treatment listed below should be employed. Otherwise, it is probably most common to initially treat the patient empirically as intracranial hypotension, and then to move on to other methods for treatment failures.

Treatment of asymptomatic slit ventricles

Propylactic upgrading to a higher pressure valve or insertion of an antisiphon device as initially advocated has largely been abandoned. However, this may be appropriate at the time of shunt revision when done for other reasons.\textsuperscript{44}

Treatment of intracranial hypotension

Postural H/A due to intracranial hypotension (true overshunting) is usually self limited, however, if symptoms persist after \(\approx\) 3 days of bed-rest and analgesics and a trial with a tight abdominal binder, the valve should be checked for proper closing pressure. If it is low, replace with a higher pressure valve. If it is not low, an ASD (which, by itself, also increases the resistance of the system) alone or together with a higher pressure valve may be needed.\textsuperscript{47}

Treatment of slit ventricle syndrome

Patients with symptoms of SVS are actually suffering from intermittent high pressure. If total shunt malfunction is the cause, then shunt revision is indicated. For intermittent occlusion, treatment options include:

1. if symptoms occur early after shunt insertion or revision, initial expectant management may be indicated since symptoms will spontaneously resolve in many patients as they equilibrate to the new intracranial pressure
2. revision of the proximal shunt. This may be difficult due to the small size of the ventricles. One can attempt to follow the existing tract and insert a longer or shorter length of tubing based on the pre-op imaging studies. Some advocate the placement of a second ventricular catheter, leaving the first one in place
3. patients may “respond” (fortuitously) to either of the following interventions because the slight ventricular enlargement elevates the ependyma off of the inlet ports (this may not always be the therapy of choice):
   a) valve upgrade\textsuperscript{48} or
   b) ASD insertion\textsuperscript{40,47}: the procedure of choice in some opinions.\textsuperscript{39} First described in 1973\textsuperscript{49}
4. subtemporal decompression\textsuperscript{50,51,52} sometimes with dural incision.\textsuperscript{50} This results in dilatation of the temporal horns (evidence for elevated pressure) in most, but not all cases
5. third ventriculostomy (p. 415)\textsuperscript{53}

25.6.7 Problems unrelated to shunting

For H/A consistent with migraine that are not postural, a trial with migraine-specific medications is warranted (Fiorinal®). See treatment of idiopathic intracranial hypertension (pseudotumor cerebri) (p. 771).
25.6.8 Subdural hematomas

General information

May be due to collapse of brain with tearing of bridging veins. Incidence: 4–23% in adults, 2.8–5.4% in children, and is higher with normal pressure hydrocephalus (20–46%) than with “hypertensive hydrocephalus” (0.4–5%). The risk of SDH is higher in the setting of longstanding hydrocephalus with a large head and little brain parenchyma (craniocerebral disproportion) with a thin cerebral mantle, as usually occurs in children with macrocephaly and large ventricles on initial evaluation. These patients have an “extremely delicate balance between subdural and intraventricular pressure.” By the same token, SDH can also follow shunting in elderly patients who have severe brain atrophy. The development of SDH may also be facilitated by negative pressures in the ventricles as a result of a siphoning effect when the patient is upright. There is also a low risk of epidural hematoma following CSF shunting.

Characteristics of the fluid

The collections may be on the same side as the shunt in 32% on the opposite side in 21% and bilateral in 47%. At the time of discovery, the SDHs are usually subacute to chronic, and the previously large ventricles are usually collapsed. Only 1 of 19 cases showed colorless fluid. In all cases tested (even the 1 with clear fluid), the protein was elevated compared to CSF.

Treatment

Indications for treatment

Small (<1–2 cm thick) asymptomatic collections in patients with closed cranial sutures may be followed with serial imaging studies. SDH were symptomatic in ≈ 40% of cases (symptoms often resemble those of shunt malfunction), and these require treatment. Treatment of SDH in children with open sutures has been advocated to prevent later symptoms and/or development of macrocrania. The controversy arises with large asymptomatic SDH in older children or adults. Many authors recommend not treating asymptomatic lesions regardless of appearance, whereas others vary their recommendations based on diverse criteria including size, appearance (chronic, acute, mixed…), etc.

Treatment techniques

A number of techniques have been described. Most involve evacuation of the SDHs by any of the usual methods (e.g. burr holes for chronic collections, craniotomy for acute collections) together with:

1. reducing the degree of shunting (i.e. to establish a lower pressure in the subdural space than in the intraventricular space, to cause the ventricles to re-expand and to prevent reaccumulation of the SDH)
   a) in shunt dependent cases
      • replacing the valve with a higher pressure unit (upgrading the valve)
      • increasing the pressure on a programmable pressure valve
      • using a Portnoy device that can be turned off and on externally. Be sure that care providers can reliably open the device in an emergency
   b) in non-shunt dependent cases
      • any of the methods outlined above for shunt dependent cases, or
      • temporarily tying off the shunt
   c) insertion of an anti-siphon device
2. drainage of the subdural space to
   a) the cisterna magna
   b) to the peritoneum (subdural peritoneal shunt) with a low pressure valve (or no valve). Some authors have the care-giver frequently pump the subdural valve

The goal is to achieve a delicate balance between undershunting (producing symptoms of active hydrocephalus) and overshunting (promoting the return of the SDH). Following surgery the patient should be mobilized slowly to prevent recurrence of the SDH.
25.6.9 Miscellaneous shunt issues

Craniosynostosis, microcephaly and skull deformities

See also Craniosynostosis (p. 252). A number of skull changes have been described in infants after shunting, including\(^62\): thickening and inward growth of the bone of the skull base and cranial vault, decrease in size of the sella turcica, reduction in size of the cranial foramina, and craniosynostosis. The most common skull deformity was dolichocephaly from sagittal synostosis.\(^63\) Microcephaly accounted for \(\approx 6\%\) of skull deformities after shunting (about half of these had sagittal synostosis). Some of these changes were reversible (except when complete synostosis was present) if intracranial hypertension recurred.

Laparoscopic surgery in patients with VP shunts

Issues regarding safety of laparoscopic surgery in patients with VP shunts:

1. laparoscopic surgery: abdominal insufflation with CO\(_2\) is used to create a pneumoperitoneum permitting the general surgeon to work. Typical insufflation pressure: 15 mm Hg (see conversion factors between mm Hg and cm of water (p. 861)). In thin patients, 10 mm Hg may suffice. Transient additional increases in pressure may occur, e.g. when the surgeon leans on the patient’s abdomen.

2. concerns for patients with VP shunts:
   a) in some cases insufflation \(\rightarrow\) \(\uparrow\) ICP\(^64\) which may be due to:
      - compression of vena cava \(\rightarrow\) reduced venous return from head, as in valsalva maneuver (independent of presence of a shunt)
      - absorption of CO\(_2\) from the peritoneum \(\rightarrow\) \(\uparrow\) in arterial CO\(_2\) causing cerebral arterial dilatation thereby increasing ICP
      - \(\downarrow\) CSF drainage due to \(\uparrow\) pressure against which CSF must flow
      - retrograde passage of air/debris into intracranial compartment through an incompetent shunt valve (this also has potential for infection in the presence of peritonitis). This risk is minimal even with in vitro back-pressures up to 80 mm Hg.\(^65\) Retrograde flow may also occur with a valveless shunt (rarely used)
      - in one case report monitoring TCDs,\(^66\) there was no change during laparoscopic surgery in a patient with a VP shunt (except during periods of very high pressure)
   b) occlusion of the distal catheter by air, debris\(^67\) or soft tissue
   c) extremely high intraabdominal pressures (>80 mm Hg in vitro) may damage the valve,\(^65\) which could cause malfunction after the laparoscopy

Prophylactic management options:

1. very controversial, special precautions may not be necessary\(^68\)
2. one can temporarily occlude the peritoneal catheter (e.g. by a hemoclip applied by the general surgeon through the laparoscope under minimal initial insufflation pressure; the clip is removed at the end of the procedure), or, temporary externalization of the shunt by the neurosurgeon, with internalization at the end of the procedure (this engenders an increased risk of infection)
3. ICP monitoring during laparoscopy
4. using low insufflation pressures (e.g. <10 mm Hg)

25.7 Specific shunt systems

The following describes the salient features of some commonly used shunt systems. Diagrams are for general information only, and are not to scale.

25.7.1 Comparison of nonprogrammable shunt valves

Fig. 25.2 compares opening pressures for some common nonprogrammable shunt valves. Symbols superimposed on the pressure bars show the x-ray markings on the valves.

25.7.2 Comparison of programmable shunt valves

Fig. 25.3 shows a comparison of operating pressures of some common programmable shunt valves.

25.7.3 PS Medical/Medtronic CSF flow controlled valve

Manufactured by Medtronic Inc.

Fig. 25.2 Opening pressures of nonprogrammable shunt valves.

Fig. 25.3 Operating pressures of programmable shunt valves. Modified from figure courtesy of Codman Neuro, used with permission.
A single one-way membrane valve design. The radio-opaque arrowhead points in the direction of flow (Fig. 25.4).

**Pumping the valve**

To pump the shunt in the “forward” direction, first occlude the inlet port (Fig. 25.5) with pressure from one finger on the “inlet occluder” (prevents back-flow into the ventricle during the next step). Then while maintaining this pressure, depress the reservoir dome with a second finger. Release both fingers, and repeat. The one-way valve regulates shunt pressure and prevents reflux of CSF during normal use and during the release phase of shunt pumping.

**X-ray characteristics**

The three available valve pressures are indicated by radio-opaque dots on the valve (allows x-ray identification of valve pressure): one dot = low pressure, two dots = medium, three dots = high.

**25.7.4 Strata® programmable valve**

The Medtronic Strata valve is an externally adjustable valve that is programmed (using a magnet) to one of five performance level (“P/L”) settings (Fig. 25.6).

Also, see general information regarding programmable valves (p.418).

**25.7.5 Codman Hakim programmable valve**

Manufactured by Codman Inc.

18 pressure settings. Programmed by an AC-powered programming unit that requires confirmatory x-ray after re-programming. Newer programming units with acoustic monitoring may obviate...
the need for x-ray. The manufacturer advises not to increase the pressure by >40 mm H$_2$O in a 24-hour period.

X-ray appearance for various settings are shown in Fig. 25.7. (note: settings of 70, 120 & 170 mm H$_2$O align with an arm of the central cross of the valve). NB: when x-rayed correctly, the x-ray beam passes first through the valve and then the patient, which causes the radio-opaque marker to appear as a solid circle to the right of center as shown in Fig. 25.7. If the marker is on the left side, the beam is passing from the bottom of the valve, and the actual pressure reading should be based on a mirror image of the x-ray.

**25.7.6 Certas Plus programmable valve**

Manufactured by Codman Inc.

The x-ray appearance is shown in Fig. 25.8, and the pressure settings appear in Table 25.2.
25.7.7 Polaris programmable valve

Manufactured by Sophysa.

The Polaris valve is an externally programmable valve that uses two attracting Samarium-Cobalt magnets to lock the pressure setting and to resist inadvertent reprogramming by environmentally encountered magnets such as MRI scanners, cell phones, headphones...

Available in 4 models (different pressure ranges, each identified by a unique number of radio-opaque dots), each with 5 externally adjustable positions. The x-ray appearance and corresponding pressures are shown in Fig. 25.9.

25.7.8 Heyer-Schulte

Distributed by Integra Neurosciences.

The LPV® II valve is shown in Fig. 25.10. To pump the shunt, occlude inlet port with one finger, then depress reservoir with another finger (as for the PS Medical valve, see above). This valve may be injected in either direction by depressing the appropriate occluder while injecting into the reservoir.

25.7.9 Hakim (Cordis) shunt

Distributed by Integra Neurosciences.

Fig. 25.8 Certas Plus Valve, x-ray appearance
A dual ball-valve mechanism (Fig. 25.11). To pump shunt, depress the indicated portion of the valve. NB: do not tap here, as the silicone elastomer housing is not self-sealing. The antechamber is provided for this type of access.

### 25.7.10 Integra (Cordis) horizontal-vertical lumbar valve

Fig. 25.12. May be used in lumbo-peritoneal shunt to increase the transmission pressure when the patient is upright to prevent overshunting. Markings used to orient the device during implantation:

1. an arrow on the inlet side of the unit indicates direction of flow
2. inlet tubing is clear
3. inlet tubing has smaller diameter than outlet tubing
4. outlet tubing is white
5. before positioning the valve and fastening it to the fascia with permanent suture, the valve should be connected to both the subarachnoid catheter (inlet) and the peritoneal catheter (outlet). The arrow on the inlet valve should point towards the patient’s feet

25.7.11 Holter valve

A dual slit valve mechanism (Fig. 25.13). Usually used in combination with a Rickham or Salmon-Rickham reservoir (Fig. 25.14).
To pump the shunt, simply depress the indicated portion of the valve.
X-ray characteristics
The silastic tube between the two one-way valves is radiolucent (Fig. 25.1).
25.7.12 Salmon-Rickham reservoir

Similar to standard Rickham reservoir except for lower profile (Fig. 25.14).

25.8 Surgical insertion techniques

For surgical techniques, refer to the section on insertion of Ventricular shunts (p. 1514).

25.9 Instructions to patients

All patients and families of patients with hydrocephalus should be instructed regarding the following:

1. signs and symptoms of shunt malfunction or infection
2. not to pump the shunt unless instructed to do so for a specific purpose
3. prophylactic antibiotics: for the following situations (mandatory in vascular shunts, sometimes recommended in other shunts)
   a) dental procedures other than routine cleaning
   b) instrumentation of the bladder: not practical for patients who catheterize to void. Important for cystoscopy, CMG, etc. where septicemia may occur
4. in a growing child: the need for periodic evaluation, including assessment of distal shunt length

26 Seizure Classification and Anti-Convulsant Pharmacology

26.1 Seizure classification

Definition of a seizure: an abnormal paroxysmal cerebral neuronal discharge that results in alteration of sensation, motor function, behavior or consciousness. Seizures may be classified by type, etiology, and by epileptic syndromes.

26.1.1 Classification of major seizure types

Generalized seizures

1. Tonic–clonic (in any combination)
2. Absence
   - Typical
   - Atypical
   - Absence with special features: Myoclonic absence, Eyelid myoclonia
3. Myoclonic
   - Myoclonic
   - Myoclonic atonic
   - Myoclonic tonic
4. Clonic
5. Tonic
6. Atonic
7. Focal seizures
8. Unknown
   - Epileptic spasms

Primary generalized seizures

Primary generalized: bilaterally symmetrical and synchronous involving both cerebral hemispheres at the onset, no local onset, consciousness lost from the start. Represents ≈ 40% of all seizures

1. generalized tonic-clonic (GT C) (née: grand-mal seizure): generalized seizure that evolves from tonic to clonic motor activity. This is a specific type and does NOT include partial seizures that generalize secondarily
2. clonic seizures: fairly symmetric, bilateral synchronous semirhythmic jerking of the UE & LE, usually with elbow flexion and knee extension
3. tonic seizures: sudden sustained increased tone with a characteristic guttural cry or grunt as air is forced through adducted vocal cords
4. absence (née: petit-mal seizure): impaired consciousness with mild or no motor involvement (see below)
   a) typical absences
   b) atypical absences: more heterogeneous with more variable EEG pattern then typical absence. Seizures may last longer
5. myoclonic seizures: shocklike body jerks (1 or more in succession) with generalized EEG discharges
6. atonic seizures (AKA astatic seizures or “drop attacks”): sudden brief loss of tone that may cause falls

Partial seizures

Partial (née focal seizure): implies one hemisphere involved at onset. About 57% of all seizures. A new onset of partial seizure represents a structural lesion until proven otherwise

1. simple partial seizure (no impairment of consciousness)
   a) with motor signs (including Jacksonian)
   b) with sensory symptoms (special sensory or somatosensory)
   c) with autonomic signs or symptoms
   d) with psychic symptoms (disturbance of higher cerebral function)
2. complex partial seizure (many used to be classified as psychomotor seizure, often attributed to temporal lobe but they can arise from any cortical area): any alteration of consciousness, usually LOC or automatisms (including lip smacking, chewing, or picking with the fingers) with autonomic aura (usually an epigastric rising sensation)
   a) simple partial onset followed by impairment of consciousness (may have premonitory aura)
      • without automatisms
      • with automatisms
   b) with impairment of consciousness at onset
      • without automatisms (impairment of consciousness only)
      • with automatisms
   c) partial seizure with secondary generalization
      • simple partial evolving to generalized
      • complex partial evolving to generalized
      • simple partial evolving to complex partial evolving to generalized

Unclassified epileptic seizures
≈ 3% of all seizures

26.1.2 Epileptic syndromes

General information
This list is not all inclusive (see reference1-2).
1. symptomatic (AKA “secondary”): seizures of known etiology (e.g. stroke, tumor…)
   a) temporal lobe epilepsies:
      • mesial temporal sclerosis: see below
2. idiopathic (AKA “primary”): no underlying cause. Includes:
   a) juvenile myoclonic epilepsy: see below
3. cryptogenic: seizures presumed to be symptomatic but with unknown etiology
   a) West syndrome (infantile spasms, Blitz-Nick-Salaam Krämpfe): see below
   b) Lennox-Gastaut syndrome: see below
4. special syndromes: situation-related seizures
   a) febrile seizures (p.467)
   b) seizures occurring only with acute metabolic or toxic event: e.g. alcohol

KEY distinctions (having therapeutic implications)
In generalized tonic-clonic seizures: primary generalized vs. partial with secondary generalization (often, local onset may not be observed).
In staring spells: absence vs. complex partial.

Epilepsy
A disorder, not a single disease. Characterized by recurrent (2 or more), unprovoked seizures.

Absence seizure
Formerly called petit-mal seizure. Impaired consciousness with mild or no motor involvement (automatisms occur more commonly with bursts lasting >7 secs). No post-ictal confusion. Aura rare. May be induced by hyperventilation × 2–3 mins. EEG shows spike and wave at exactly 3 per second.

Uncinate seizures
Obsolete term: “uncal fits.” Seizures originating in the inferior medial temporal lobe, usually in the hippocampal region. May produce olfactory hallucinations (kakosmia or cacosmia: the perception of bad odors where none exist).

Mesial temporal sclerosis
See references.3-4
The most common cause of intractable temporal lobe epilepsy. Specific pathologic basis: hippocampal sclerosis (cell loss in hippocampus on one side). Characteristics are shown in Table 26.1. See also differential diagnosis (p.1386).
Table 26.1 Syndrome of mesial temporal-lobe epilepsy⁵

Juvenile myoclonic epilepsy

See reference.⁶ Sometimes called bilateral myoclonus. 5–10% of cases of epilepsy. An idiopathic generalized epilepsy syndrome with age-related onset consisting of 3 seizure types:
1. myoclonic jerks: predominantly after waking
2. generalized tonic-clonic seizures
3. absence

EEG → polyspike discharges. Strong family history (some studies showing linkage to the HLA region on the short arm of chromosome 6).
Most are responsive to depakene.

West syndrome

This term is being used less frequently as it appears not to be a homogeneous group and as specific etiologies for infantile spasms are identified. Classically a seizure disorder that usually appears in first year of life, and consists of recurrent, gross flexion and occasionally extension of the trunk and limbs (massive myoclonus, AKA infantile spasms, AKA salaam seizures, AKA jackknife spasms). Seizures tend to diminish with age, often abating by 5 yrs. Usually associated with mental retardation. 50% may develop complex-partial seizures, some of the rest may develop Lennox-Gastaut syndrome (see below). An associated brain lesion may be found in some.

EEG → the majority show either interictal hypersynchrony (huge spike/wave plus slow wave resembling muscle artifact) or modified hypersynchrony at some point.
Usually dramatic response of seizures and EEG findings to ACTH or corticosteroids.
Lennox-Gastaut syndrome

Rare condition that begins in childhood as atonic seizures (“drop attacks”). Often develops into tonic seizures with mental retardation. Seizures are often polymorphic, difficult to treat medically, and may occur as often as 50 per day. May also present with status epilepticus. Approximately 50% of patients have reduced seizures with valproic acid. Corpus callosotomy may reduce the number of atonic seizures.

26.1.3 Miscellaneous seizure information

Factors that lower the seizure threshold

Factors that lower the seizure threshold (i.e. make it easier to provoke a seizure) in individuals with or without a prior seizure history include many items listed under Etiologies of New onset seizures (see below) as well as:
1. sleep deprivation
2. hyperventilation
3. photic stimulation (in some)
4. infection: systemic (febrile seizures (p.467)), CNS (meningitis…)
5. metabolic disturbances: electrolyte imbalance (especially profound hypoglycemia), pH disturbance (especially alkalosis), drugs… (see below)
6. head trauma: closed head injury, penetrating trauma (p.463)
7. cerebral ischemia: stroke (see below)
8. “kindling”: a concept that repeated seizures may facilitate the development of later seizures

Todd’s paralysis

A post-ictal phenomena in which there is partial or total paralysis usually in areas involved in a partial seizure. More common in patients with structural lesions as the source of the seizure. The paralysis usually resolves slowly over a period of an hour or so. Thought to be due to depletion of neurons in the wake of the extensive electrical discharges of a seizure. Other similar phenomena include post-ictal aphasia and hemianopsia.

26.2 Antiepileptic drugs

26.2.1 General information

The goal of antiepileptic drugs (AEDs) is seizure control (a contentious term, usually taken as reduction of seizure frequency and severity to the point to permit the patient to live a normal lifestyle without epilepsy-related limitations) with minimal or no drug toxicity. ≈ 75% of epileptics can achieve satisfactory seizure control with medical therapy. 7

26.2.2 Classification of AEDs

AEDs can be grouped as shown in Table 26.2.

The following agents are considered “broad spectrum” (treat a variety of seizure types):
1. valproic acid
2. lamotrigine (Lamictal®)
3. levetiracetam (Keppra®)

These agents are not considered broad spectrum:
1. phenytoin (Dilantin® and others)
2. carbamazepine (Tegretol®)

Agents that interfere with platelet function and may increase the risk of bleeding complications:
1. valproic acid
2. phenytoin (Dilantin® and others)
Table 26.2 Classification of AEDs

¹Indications for seizure types (does not include other uses, e.g. for chronic pain). FDA approved indications are in bold, off-label indications appear in plain text. Abbreviations: ABS = absence, adj = adjunctive therapy, CP = complex partial, GTC = generalized tonic-clonic, PHT = phenytoin, Sz = seizure, status = status epilepticus
26.2.3 Choice of antiepileptic drug

Antiepileptic drugs (AED) for various seizure types

Boldface drugs are drug of choice (DOC).

1. primary generalized
   a) GTC (generalized tonic-clonic):
      - valproic acid (VA) (p. 451): if no evidence of focality some studies show fewer side effects and better control than PHT
      - carbamazepine (p. 449)
      - phenytoin (PHT) (p. 446)
      - phenobarbital (PB) (p. 451)
      - primidone (PRM) (p. 452)
   b) absence:
      - ethosuximide
      - valproic acid (VA)
      - clonazepam
      - methsuximide (p. 453)
   c) myoclonic → benzodiazepines
   d) tonic or atonic:
      - benzodiazepines
      - felbamate (p. 453)
      - vigabatrin (p. 456)

2. partial (simple or complex, with or without secondary generalization): the well controlled Veterans Administration Cooperative Study8 ranked the following drugs (based on seizure control and side effects) in this order (VA may compare favorably with CBZ for secondarily GTC, but is less effective for complex partial seizures9):
   a) carbamazepine (CBZ): most effective, least side effects
   b) phenytoin (PHT): ↓
   c) phenobarbital (PB): ↓
   d) primidone (PRM): slightly less effective, more side effects

3. second line drugs for any of the above seizure types:
   a) valproate
   b) lamotrigine (p. 456): effective for many types of generalized seizures, but are not FDA approved for this yet
   c) topiramate (p. 456): effective for many types of generalized seizures, but are not FDA approved for this yet

26.2.4 Anticonvulsant pharmacology

See reference.10

General guidelines

Monotherapy versus polytherapy

1. increase a given medication until seizures are controlled or side effects become intolerable (do not rely solely on therapeutic levels, which is only the range in which most patients have seizure control without side effects)

2. try monotherapy with a different drugs before resorting to two drugs together. 80% of epileptics can be controlled on monotherapy, however, failure of monotherapy indicates an 80% chance that the seizures will not be controllable pharmacologically. Only ≈ 10% benefit significantly from the addition of a second drug.5 When >2 AEDs are required, consider nonepileptic seizures (p. 464)

3. when first evaluating patients on multiple drugs, withdraw the most sedating ones first (usually barbiturates and clonazepam)
Generally, dosing intervals should be less than one half-life. Without loading dose, it takes about 5 half-lives to reach steady state.

Many AEDs affect liver function tests (LFTs), however, only rarely do the drugs cause enough hepatic dysfunction to warrant discontinuation. Guideline: discontinue an AED if the GGT exceeds twice normal.

### Specific anticonvulsants

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

Pharmacokinetics: Unless otherwise specified, numbers are given for oral dosing form.

| $t_{1/2}$ | half-life |
| $t_{\text{PEAK}}$ | time to peak serum level |
| $t_{\text{SS}}$ | time to steady state (approximately $5 \times t_{1/2}$) |
| $t_{\text{D/C}}$ | time to discontinue (recommended withdrawal period over which drug should be tapered) |
| MDF | minimum dosing frequency. “Therapeutic level” is the average therapeutic range. |

---

**Drug info: Phenytoin (PHT) (Dilantin®)**

**Indications**
GTC, S/C-P, occasionally in ABS.

**Pharmacokinetics**
Pharmacokinetics are complicated: at low concentrations, kinetics are 1st order (elimination proportional to concentration), metabolism saturates near the therapeutic level resulting in zero-order kinetics (elimination at a constant rate). ≈ 90% of total drug is protein bound. Oral bioavailability is ≈ 90% whereas IV bioavailability is ≈ 95%; this small difference may be significant when patients are near limits of therapeutic range (due to zero-order kinetics).
**Table 26.4 Pharmacokinetics of phenytoin**

<table>
<thead>
<tr>
<th>Parameter</th>
<th>t½ (half-life)</th>
<th>tₚ (peak serum levels)</th>
<th>tₚₛ (steady state)</th>
<th>tᵩC (discontinue)</th>
<th>Therapeutic level[^a]</th>

</tr>
</tbody>
</table>

[^a]: therapeutic level as measured in most labs: 10–20 mcg/ml (NB: it is the free PHT that is the important moiety; this is usually ≈ 1% of total PHT, thus therapeutic free PHT levels are 1–2 mcg/ml, some labs are able to measure free PHT directly).

[^b]: t½ for phenytoin

Renal failure: dosage adjustment not needed. However, serum protein binding may be altered in uremia which can obfuscate interpretation of serum phenytoin levels. Eq (26.1) may be used to convert serum PHT concentration in a uremic patient C (observed), to the expected PHT level in nonuremic patients C (nonuremic).

\[
C_{\text{nonuremic}} = \frac{C_{\text{observed}}}{0.1 \times \text{albumin} + 0.1} 
\]

Oral dose

Adult: usual maintenance dose = 300–600 mg/d divided BID or TID (MDF=q d, for single daily dosing, either the phenytoin-sodium capsules or the extended release form should be used). Oral loading dose: 300 mg PO q 4 hrs until 17 mg/kg are given. Peds: oral maintenance: 4–7 mg/kg/d (MDF=BID). Supplied: (oral forms): 100 mg tablets of phenytoin-sodium (sodium-salt); 30 & 100 mg Kapseals® (extended release); 50 mg chewable Infatabs® (phenytoin-acid); oral suspension 125 mg/5-ml in 8 oz. (240 ml) bottles or individual 5 ml unit dose packs; pediatric suspension 30 mg/5-ml. Phenytek® 200 & 300 mg capsules.

**Dosage changes**

**Table 26.5 Guidelines for changing phenytoin dosage**

<table>
<thead>
<tr>

</tr>
<tr>
<td>&gt;8</td>
<td>25–30 mg/day</td>
</tr>
</tbody>
</table>

Because of zero-order kinetics, at near-therapeutic levels a small dosage change can cause large level changes. Although computer models are necessary for a high degree of accuracy, the dosing change guidelines in Table 26.5 or the nomogram in Fig. 26.1[^1] may be used as a quick approximation.

[^1]: Fig. 26.1
### Fig. 26.1 Nomogram for adjusting phenytoin dose.

Directions for using nomogram (assumes steady state)

(a) draw line connecting serum level on line A with current dose on line B
(b) mark point where this line intersects line C
(c) connect point on C to the desired serum level on A
(d) read new dosage on line B

---

GI absorption of phenytoin suspension or capsules may be decreased by up to 70% when given with nasogastric feedings of Osmolyte® or Isocal®, and the suspension has been reported to have erratic absorption. Hold NG feeding for 2 hrs before and 1 hour after phenytoin dose.

### Parenteral dose

Phenytoin is a negative inotrope and can cause hypotension.

Conventional phenytoin may be given slow IVP or by IV drip (see below). The IM route should NOT be used (unreliable absorption, crystallization and sterile abscesses may develop). IV must be given
slowly to reduce risk of arrhythmias and hypotension, viz. Adult: <50 mg/min, Peds: <1–3 mg/kg/min. The only compatible solution is NS, inject at site nearest vein to avoid precipitation.

loading. Adult: 18 mg/kg slow IV. Peds: 20 mg/kg slow IV.
maintenance. Adult: 200–500 mg/d (MDF=q d). Most adults have therapeutic levels on 100 mg
PO TID. Peds: 4–7 mg/kg/d (MDF=BID).

Drip loading method:
Requires cardiac monitoring, and BP check q 5 minutes.
Add 500 mg PHT to 50 ml NS to yield 10 mg/ml, run at 2 ml/min (20 mg/min) long enough to give 18 mg/kg (for 70 kg patient: 1200 mg over 60 mins). For more rapid administration, up to 40 mg/min may be used, or use fosphenytoin (see below). Decrease rate if hypotension occurs.

Fosphenytoin sodium injection
Fosphenytoin sodium (FOS) injection (Cerebyx®) is a newer formulation for administering IV phenytoin, and is indicated for short term use (<5 days) when the enteral route is not usable. It is completely converted in vivo to phenytoin by organ and blood phosphatases with a conversion half-life of 10 minutes. Product labeling is given in terms of phenytoin equivalents (PE). Safety in pediatric patients has not been established. Supplied: 50 mg PE/ml in 2 & 10 ml vials (100 mg PE and 500 mg PE respectively).

Advantages of FOS (over conventional IV phenytoin):
1. less venous irritation (due to lower pH of 8.6–9 compared to 12 for phenytoin) resulting in less pain and IV extravasation
2. FOS is water soluble and therefore may be infused with dextrose or saline
3. tolerated well by IM injection (however, the IM route should not be used for status epilepticus)
4. does not come combined with propylene glycol (which can cause cardiac arrhythmias and/or hypotension itself)
5. the maximum administration rate is 3× as fast (i.e. 150 mg PE/min)

Side effects of phenytoin
May interfere with cognitive function. May produce SLE-like syndrome, hepatic granulomas, megaloblastic anemia, cerebellar degeneration (chronic doses), hirsutism, gingival hypertrophy, hemorrhage in newborn if mother on PHT, toxic epidermal necrolysis (Stevens-Johnson variant). PHT antagonizes vitamin D → osteomalacia and rickets. Most hypersensitivity reactions occur within 2 months of initiating therapy. In cases of maculopapular erythematous rash, the drug may be stopped and the patient may be rechallenged; often the rash will not recur the second time. Teratogenic (fetal hydantoin syndrome).

Signs of phenytoin toxicity may develop at concentrations above 20 mcg/ml (toxicity is more common at levels >30 mcg/ml) and include nystagmus (may also occur at therapeutic levels), diplopia, ataxia, asterixis, slurred speech, confusion, and CNS depression.

Drug-drug interactions: fluoxetine (Prozac®) results in elevated phenytoin levels (ave: 161% above baseline). Phenytoin may impair the efficacy of: corticosteroids, warfarin, digoxin, doxycycline, estrogens, furosemide, oral contraceptives, quinidine, rifampin, theophylline, vitamin D.

Drug info: Carbamazepine (CBZ) (Tegretol®)

Indications
Partial seizures with or without secondary generalization. Trigeminal neuralgia. An IV form for use in e.g. status epilepticus is in development.

Dose
oral route. Adult range: 600–2000 mg/d. Peds: 20–30 mg/kg/d. MDF=BID.
Before starting, check: CBC & platelet count (consider reticulocyte count) & serum Fe. Package insert says “recheck at frequent intervals, perhaps q week × 3 mos, then q month × 3 yrs.”
Do not start CBZ (or discontinue it if patient already on CBZ) if: WBC <4K, RBC <3×106, Hct <32%, platelets <100K, reticulocytes <0.3%, Fe >150 mcg%.
Start low and increment slowly: 200 mg PO q d ×1 wk, BID × 1 wk, TID × 1 wk. As an inpatient, dosage changes may be made every 3 days, monitoring for signs of side effects. As an outpatient, changes should be made only ≈ weekly, with levels after each change. Carbamul® (extended release CBZ) is usually dosed BID.
Supplied: oral form. Scored tabs 200 mg. Chewable scored tabs 100 mg. Suspension 100 mg/5-ml. IV form: not available in the U.S. at the time of this writing. Carbatrol® (extended release CBZ): 200 & 300 mg tablets.

Caveats with oral forms: oral absorption is erratic, and smaller more frequent doses are preferred. Oral suspension is absorbed more readily, and also should not be administered simultaneously with other liquid medicinal agents as it may result in the precipitation of a rubbery, orange mass. May aggravate hyponatremia by SIADH-like effect.

*may be misleading since the active metabolite carbamazepine-10,11-epoxide may cause toxicity and must be assayed separately

CBZ induces hepatic enzymes that result in increased metabolism of itself (autoinduction) as well as other drugs over a period of ≈ 3–4 weeks.

Side effects

Drug-drug interaction: caution, cimetidine, erythromycin and isoniazid may cause dramatic elevation of CBZ levels due to inhibition of hepatic cytochrome oxidase that degrades CBZ. Side effects include:

1. drowsiness and GI upset: minimized by slow dose escalation
2. relative leukopenia in many: usually does not require discontinuing drug
3. transient diplopia
4. ataxia
5. less effect on cognitive function than PHT
6. hematological toxicity: rare. May be serious → agranulocytosis & aplastic anemia
7. Stevens-Johnson syndrome
8. SIADH
9. hepatitis (occasionally fatal) reported

Drug info: Oxcarbazepine (Trileptal®)

Very similar efficacy profile to carbamazepine with the following differences:

1. there is no autoinduction (C-P450 is not involved in metabolism) and therefore minimal drug-drug interactions
2. no blood testing is required since:
   a) there is no liver toxicity
   b) there is no hematologic toxicity
   c) there is no need to check drug levels
3. dosing is BID
4. kinetics are linear
5. more expensive

Dose:

: starting dose for pain control is 150 mg PO BID, for seizures it is 300 mg PO BID. Maximum dose 2400 mg/day total. Supplied: 150, 300 & 600 mg scored tablets, 300 mg/5 ml oral suspension.
**Drug info: Valproate**

*Available as valproic acid (Depakene®) and divalproex sodium (Depakote®).*

**Indications**

Effective in primary GTC. Also useful in AES with GTC, juvenile myoclonic epilepsy, and partial seizures (not FDA approved for latter). Also FDA approved for migraine prophylaxis. Note: severe GI upset and short half-life make valproic acid much less useful than Depakote® (divalproex sodium).

**Dose**

Adult range: 600–3000 mg/d. Peds range: 15–60 mg/kg/d. MDF=q d.

Start at 15 mg/kg/d, increment at 1 wk intervals by 5–10 mg/kg/d. Max recommended adult dose: 60 mg/kg/d. If daily dose >250 mg is required, it should be divided. Supplied: Oral: capsules 250 mg, Syrup 250 mg/5-ml; Depakote® (enteric coated) tabs: 125, 250, & 500 mg; sprinkle capsules 125 mg. IV: Depacon® for IV injection 500 mg/5 mL vial.

**Pharmacokinetics**

</tr>
</tbody>
</table>

Valproic acid (VA) is 90% protein bound. ASA displaces VA from serum proteins.

**Side effects**

Serious side effects are rare. Pancreatitis has been reported, sometimes life-threatening. Fatal liver failure has occurred especially if age <2 yrs and in combination with other AEDs. Teratogenic (below). Drowsiness (temporary), minimal cognitive deficits, N/V (minimized with Depakote), liver dysfunction, hyperammonemia (even without liver dysfunction), weight gain, mild hair loss, tremor (dose related; similar to benign familial tremor; if severe and valproic acid is absolutely necessary, the tremor may be treated with beta blockers). May interfere with platelet function, caution with surgery on these patients.

**Contraindications**

Pregnancy: causes neural tube defects (NTD) in ≈ 1–2% of patients. Since a correlation between peak VA levels and the risk of NTDs has been found, if VA must be used, some experts recommend changing from BID to TID dosing. Patients ≤ 2 yrs age (risk of hepatotoxicity).

**Drug info: Phenobarbital**

*Used as alternative in GTC and partial (not DOC). Had been DOC for febrile seizures, dubious benefit. About as effective as PHT, but very sedating. Also used for status epilepticus (p. 469).*

**Dose**

Same dose PO, IV, or IM. MDF=q d. Start slowly to minimize sedation.

Adult loading: 20 mg/kg slow IV (administer at rate <100 mg/min). Maintenance: 30–250 mg/d (usually divided BID-TID). Peds loading: 15–20 mg/kg. Maintenance: 2–6 mg/kg/d (usually divided BID). Supplied: tabs 15 mg, 30 mg, 60 mg, 100 mg; elixir 20 mg/5-mL.

**Pharmacokinetics**

Table 26.8 Pharmacokinetics of phenobarbital

<table>

</tbody>
</table>

Phenobarbital is a potent inducer of hepatic enzymes that metabolize other AEDs.
Side effects
Cognitive impairment (may be subtle and may outlast administration of the drug by at least several months\(^1\)), thus avoid in peds; sedation; paradoxical hyperactivity (especially in peds); may cause hemorrhage in newborn if mother is on phenobarbital.

**Drug info: Primidone (Mysoline®)**

**Indications**
Same as phenobarbital (not DOC). NB: when used in combination therapy, low doses (50–125 mg/day) may add significant seizure control to the primary AED with few side effects.

**Dose**
- Adult: 250–1500 mg/d. Peds: 15–30 mg/kg/d; MDF = BID.
- Start at 125 mg/d × 1 wk, and inc. slowly to avoid sedation. Supplied: (oral only): scored tabs 50 mg, 250 mg; suspension 250 mg/5-ml.

**Pharmacokinetics**
Metabolites include phenylethylmalonamide (PEMA) and phenobarbital. Therefore always check phenobarbital level at same time as primidone level.

<table>
<thead>
<tr>

</tbody>
</table>

**Side effects**
Same as phenobarbital, plus: loss of libido, rare macrocytic anemia.

**Drug info: Ethosuximide (Zarontin®)**

**Indications**
DOC in AEDs.

**Dose**
- Adult: 500–1500 mg/d. Peds: 10–40 mg/kg/d; MDF = q d. Supplied: oral only; capsules 250 mg; syrup 250 mg/5-ml.

**Pharmacokinetics**

<table>

</tbody>
</table>

**Side effects**
N/V; lethargy; hiccups; H/A; rarely: eosinophilia, leukopenia, erythema multiforme, Stevens-Johnson syndrome, SLE-like syndrome. Toxic levels → psychotic behavior.
Drug info: Methsuximide (Celontin®)

Indications
Indicated for absence seizures refractory to other drugs.

Dose
Optimum dose must be determined by trial. Start with 300 mg PO q.d, increase by 300 mg at weekly intervals PRN to a maximum of 1200 mg/d. Supplied: 150 & 300 mg capsules.

Drug info: Felbamate (Felbatol®)

CAUTION: Due to an unacceptably high rate of aplastic anemia and hepatic failure, felbamate (FBM) should not be used except in those circumstances where the benefit clearly outweighs the risk; then, hematologic consultation is recommended by the manufacturer. See Side effects below (also for drug-drug interactions).

FBM is efficacious for monotherapy and adjunctive therapy for partial seizures (complex and secondary generalization), and reduces the frequency of atonic and GTC seizures in Lennox-Gastaut syndrome.

</tbody>
</table>

: CAUTION see above. Felbamate is not to be used as a first-line drug. Patient or guardian should sign informed consent release. Start with 1200 mg/d divided BID, TID, or QID, and decrease other AEDs by one-third. Increase felbamate biweekly in 600 mg increments to usual dose of 1600–3600 mg/d (max: 45 mg/kg/d). Slow down increments and/or reduce other AEDs further if side effects become severe. Administer at upper end of range when used as monotherapy. Supplied: (oral only) 400 & 600 mg scored tablets; suspension 600 mg/5-ml.

Side effects
Felbamate has been associated with aplastic anemia (usually discovered after 5–30 wks of therapy) in ≈ 2–5 cases per million persons per yr, and hepatic failure (some fatal, necessitating baseline and serial LFTs every 1–2 wks). Other side effects: insomnia, anorexia, N/V, H/A. Felbamate is a potent metabolic inhibitor, thus it is necessary to reduce the dose of phenytoin, valproate or carbamazepine when used with felbamate22 (Table 26.12, general rule: drop dose by one third).
Drug info: Levetiracetam (Keppra®)

No identified drug-drug interactions. Less than 10% protein bound. Linear pharmacokinetics, no level monitoring needed.

Indications
Adjunctive therapy for partial onset Sz with secondary generalization in patients 4 years of age and older. Myoclonic seizures (juvenile myoclonic epilepsy). Generalized tonic-clonic.

Dose
start with 500 mg PO BID. Increment by 1000 mg/d q 2 weeks PRN to a maximum of 3000 mg/d. Keppra XR: the same dose of levetiracetam can be converted to Keppra XR for q d dosing.

IV: 500–1500 mg diluted in 100 ml of diluent (LR, D5 W, normal saline) infused over 15 minutes BID.

Supplied: 250, 500, 750 & 1000 mg scored film-coated tabs; 100 mg/ml oral solution. Keppra XR (extended release) 500 mg.

IV: 1 vial (5 ml) contains 500 mg.

Side effects
PO or IV: somnolence and fatigue in 15%. Dizziness in 9%. Asthenia 15% and infection 13% (nasopharyngitis and influenza may or may not have been related).

Keppra XR: somnolence 8%, irritability 6%.

Drug info: Clonazepam (Klonopin®)

A benzodiazepine derivative.

Indications
Not a recommended drug for seizures (see below). Used for myoclonic, tonic, and absence seizures (in absence, less effective than valproate or ethosuximide, and tolerance may develop).

NB clonazepam usually works very well for several months, and then tends to become less effective, leaving only the sedating effects. Also, many cases have been reported of patients having seizures during withdrawal, including status epilepticus (even in patients with no history of status). Thus, may need to taper this drug over 3–6 months.

Dose
Adult: start at 1.5 mg/d DIV TID, increase by 0.5–1 mg q 3 d, usual dosage range is 1–12 mg/d (max 20 mg/d); MDF = q d. Peds: start at 0.01–0.03 mg/kg/d DIV BID or TID, increase by 0.25–0.5 mg/kg/q 3 d; usual dosage range is 0.01–0.02 mg/kg/d; MDF = q d. Supplied: oral only; scored tabs: 0.5 mg, 1 mg, 2 mg.

<td>≈ 3–6 months*</td>
<td>0.013–0.072</td>
</tr>
</tbody>
</table>

*CAUTION: withdrawal seizures are common, see text above.

Side effects
Ataxia; drowsiness; behavior changes.
Drug info: Zonisamide (Zonegran®)

Indications
Adjunctive therapy for partial Sz in adults.

Drug info: Acetazolamide (Diamox®)

The anti-epileptic effect may be either due to direct inhibition of CNS carbonic anhydrase (which also reduces CSF production rate) or due to the slight CNS acidosis that results.

Indications
Centricphalic epilepsies (absence, nonfocal seizures). Best results are in absence seizures; however benefit has also been observed in GTC, myoclonic jerk.

Side effects
Do not use in first trimester of pregnancy (may be teratogenic). The diuretic effect causes renal loss of HCO₃ which may lead to an acidotic state with long-term therapy. A sulfonamide, therefore any typical reaction to this class may occur (anaphylaxis, fever, rash, Stevens-Johnson syndrome, toxic epidermal necrolysis…). Paresthesias: medication should be discontinued.

Dose
Adult: 8–30 mg/kg/d in divided doses (max 1 gm/d, higher doses do not improve control). When given with another AED, the suggested starting dose is 250 mg once daily, and this is gradually increased. Supplied: tablets 125, 250 mg. Diamox sequels® are sustained release 500 mg capsules. Sterile cryodessicated powder is also available in 500 mg vials for parenteral (IV) use.

Drug info: Gabapentin (Neurontin®)

Although developed to be a GABA agonist, it does not interact at any known GABA receptor. Efficacious for primary generalized seizures and partial seizures (with or without secondary generalization). Ineffective for absence seizures. Very low incidence of known side-effects. No known drug interactions (probably because it is renally excreted). Also used for central pain.

Dose
Adult: 300 mg PO × 1 day 1; 300 mg BID day 2; 300 mg TID day 3; then increase rapidly up to usual doses of ≈ 800–1800 mg per day. Doses of 1800–3600 may be needed in intractable patients. Dosage must be reduced in patients with renal insufficiency or on dialysis, see Eq (7.1) to estimate. Supplied: 100, 300, 400, 600, 800 mg capsules. 50 mg/ml suspension.

Pharmacokinetics
Gabapentin is not metabolized, and 93% is excreted unchanged renally with plasma clearance directly proportional to creatinine clearance. Does not affect hepatic microsomal enzymes, and does not affect metabolism of other AEDs. Antacids decrease bioavailability by ≈ 20% therefore give gabapentin >2 hrs after the antacid.

Table 26.14 Pharmacokinetics of gabapentin

*with normal renal function

Side effects
Somnia, dizziness, ataxia, fatigue, nystagmus; all reduce after 2–3 weeks of drug therapy. Increased appetite. Not known to be teratogenic.
Drug info: Lamotrigine (Lamictal®)

Anticonvulsant effect may be due to presynaptic inhibition of glutamate release. Efficacious as adjunctive therapy for partial seizures (with or without secondary generalization) and Lennox-Gastaut syndrome. Preliminary data suggest it may also be useful as an adjunct for refractory generalized seizures, or as monotherapy for newly diagnosed partial or generalized seizures. Also FDA approved for bipolar disorder.

Side effects
Somnolence, dizziness, diplopia. Serious rashes requiring hospitalization and discontinuation of therapy have been reported (rash usually begins 2 weeks after initiating therapy and may be severe and potentially life-threatening, including Stevens-Johnson syndrome (more of a concern with simultaneous use of valproate), and rarely, toxic epidermal necrolysis (TEN)). Incidence of significant epidermal reaction may be decreased by a slow ramping-up of dosage. May increase seizure frequency in some patients with severe myoclonic epilepsy of infancy. Metabolism of lamotrigine is affected by concurrent use of other AEDs.

Dose
Adult: In adults receiving enzyme-inducing AEDs (PHT, CBZ, or phenobarbital), start with 50 mg PO q d × 2 wks, then 50 mg BID × 2 wks, then ↑ by 100 mg/d q week until the usual maintenance dose of 200–700 mg/d (divided into 2 doses) is reached. For patients on valproic acid (VA) alone, the maintenance dose was 100–200 mg/d (divided into 2 doses), and VA levels drop by ≈ 25% within a few weeks of starting lamotrigine. For patients on both enzyme-inducing AEDs and VA, the starting dose is 25 mg PO qod × 2 wks, then 25 mg qd × 2 wks, then ↑ by 25–50 mg/d q 1–2 wks up to a maintenance of 100–150 mg/d (divided into 2 doses). Instruct patients that rash, fever or lymphadenopathy may herald a serious reaction and that a physician should be contacted immediately. Peds: not indicated for use in patients <16 yrs old due to higher incidence of potentially life-threatening rash in the pediatric population. Supplied: 25, 100, 150 & 200 mg tablets. 2, 5 & 25 mg chewable dispersible tablets.

</tbody>
</table>

*half-life is shortened to ≈ 15 hrs by PHT and CBZ, whereas valproic acid increases it to 59 hrs

Drug info: Vigabatrin

Indications
Effective in treating partial seizures. Less so for generalized seizures.

Dose
Adult: 1500–3000 mg/d.

Drug info: Topiramate (Topamax®)

May block voltage-sensitive sodium channels and enhance GABA activity at GABA receptors and attenuate some glutamate receptors.

Indications
As an oral adjunct to other drugs in treating refractory partial onset seizures.
Dose
Adult: start with 50 mg/d and increase slowly up to 200–400 mg/d, with no significant benefit noted at dosages >600 mg/d. Supplied: 25, 100, & 200 mg tabs.

Pharmacokinetics
30% is metabolized in the liver, the rest is excreted unchanged in the urine.

<table>
<thead>

</tr>
</thead>
<tbody>
<tr>
<td>t1/2 (half-life)</td>
</tr>
<tr>
<td>19–25 hrs</td>
</tr>
</tbody>
</table>

Side effects
May increase phenytin concentration by up to 25%. Levels of topiramate are reduced by other AEDs (phenytoin, carbamazepine, valproic acid and possibly others).
Cognitive impairment (word finding difficulty, problems with concentration…), weight loss, dizziness, ataxia, diplopia, paresthesias, nervousness and confusion have been troublesome. ≈ 1.5% incidence of renal stones which usually pass spontaneously.
Oligohidrosis (reduced sweating) and hyperthermia, primarily in children in association with elevated environmental temperatures and/or vigorous physical activity.

Drug info: Tiagabine (Gabitril®)
A GABA uptake inhibitor, with cognitive problems of a similar frequency to that with topiramate. Adult: start with 4 mg/d, increase weekly by 4–8 mg to a maximum of 32–56 mg (divided BID to QID). Supplied: 4, 12, 16 & 20 mg tablets.

Drug info: Lacosamide (Vimpat®)
Enhances slow inactivation of voltage gated sodium channels, affecting only neurons that are depolarized of active over a prolonged period (as in a seizure).

Indications
Partial onset seizures. Painful diabetic neuropathy.

Dose
Adult: 200–400 mg. Supplied: mg tabs.

26.2.5 Withdrawal of antiepileptic drugs

General information
Most seizure recurrences develop during the first 6 months after AED withdrawal.

Indications for AED withdrawal
There is no agreement on how long a patient should be seizure-free before withdrawal of anticonvulsants, nor is there agreement on the prognostic value of EEGs and on the best time period over which to withdraw AEDs.
The following is based on a study of 92 patients with idiopathic epilepsy, who had been free of seizures for two years. Generalization, e.g. to posttraumatic seizures, may not be appropriate. Taper was by 1 “unit” q 2 weeks (where a unit is defined as 200 mg for CBZ or valproic acid, or 100 mg for PHT). Follow-up: mean = 26 mos (range: 6–62).
31 patients (34%) relapsed, with the average time to relapse being 8 mos (range: 1–36). Using actuarial methods, the risk for recurrence is 5.9%/month for 3 months, then 2.7%/month for 3 months, then 0.5%/month for 3 months. Factors found to affect the likelihood of relapse include:

1. seizure type: 37% relapse rate for generalized seizures; 16% for complex or simple partial; 54% for complex partial with secondary generalization
2. number of seizures before control attained: those with ≥100 seizures before control had statistically significant higher relapse rate than those with <100
3. the number of drugs that had to be tried before single drug therapy successfully controlled seizures: 29% if 1st drug worked, 40% if a change to a 2nd drug was needed, and 80% if a change to a 3rd drug was required
4. EEG class (Table 26.17): class 4 had worst prognosis for relapse. Epileptiform discharges on EEG serves to discourage AED withdrawal

In a larger randomized study,35 the most important factors identified to predict freedom from recurrent seizures were:

1. longer seizure-free period
2. use of only one AED (vs. multiple AEDs)
3. seizures other than tonic-clonic seizures

Withdrawal times
The recommended withdrawal times in Table 26.18 should be used only as guidelines.

### 26.2.6 Pregnancy and antiepileptic drugs

#### General information
Women of childbearing potential with epilepsy should undergo counseling regarding pregnancy.36

#### Birth control
AEDs that induce liver microsomal cytochrome P450 enzymes (Table 26.19) increase the failure rate of oral contraceptives up to fourfold.37 Patients desiring to use BCPs should employ barrier contraceptive measures until ovulation is consistently suppressed, and they should watch for breakthrough bleeding which may indicate a need for a change in the hormone dosage.32 Non-oral hormonal contraceptives (e.g. levonorgestrel implant (Norplant®)) circumvents first pass liver degradation but should combined with a barrier method because of declining effectiveness with time.

Complications during pregnancy

Women with epilepsy have more complications with pregnancy than mothers without epilepsy, but >90% of pregnancies have a favorable outcome.\(^\text{32}\) There is an increase in the number of gravid seizures in ≈ 17% (reported range: 17–30%) of epileptic women, which may be due to noncompliance or to changes of free drug levels of AEDs during pregnancy (Table 26.20). Isolated seizures can occasionally be deleterious, but usually cause no problem. Status epilepticus poses serious risk to mother and fetus during pregnancy and should be treated aggressively.

There is also a slightly increased risk of toxemia (HTN of pregnancy) and fetal loss.

Birth defects

The incidence of fetal malformations in offspring of patients with a known seizure disorder is ≈ 4–5% or approximately double that of the general population.\(^\text{40}\) The degree to which this is due to the use of AEDs vs. genetic and environmental factors is unknown. All AEDs have the potential to cause deleterious effects on the infant. Polytherapy is associated with an increased risk over monotherapy in a more than additive manner.

Generally, the risk of seizures (with possible concomitant maternal and fetal hypoxia and acidosis) is felt to outweigh the teratogenic risk of most AEDs, but this must be evaluated on a case-by-case basis. Occasionally patients may be weaned off AEDs.

Specific drugs

Carbamazepine (CBZ) produced an increased incidence of “minor” malformations (but not of “major” malformations) in one study\(^\text{41}\) (this study may have had methodologic problems), and may increase the incidence of neural tube defects (NTD).\(^\text{42}\) In utero exposure to phenytoin may lead to the fetal hydantoin syndrome\(^\text{14,43}\) and a child with an IQ lower by ≈ 10 points.\(^\text{44}\) Phenobarbital produced the highest incidence of major malformations (9.1%) in one prospective study\(^\text{43}\) and was also associated with most of the increase in fetal death or anomalies in another study.\(^\text{46}\) Valproate (VA) causes the highest incidence of NTD (1-2%)\(^\text{18}\), which can be detected with amniocentesis and allow an abortion if desired. TID dosing may reduce the risk of NTD (p. 451). Benzodiazepines given shortly before delivery can produce the “floppy infant syndrome”.\(^\text{47}\) Similar effects may occur with other sedating AEDs such as phenobarbital.

Drug recommendations

A general consensus is that for most women of childbearing potential who require AEDs, that monotherapy with the lowest dose of CBZ that is effective is the method of choice if the seizure disorder is responsive to it.\(^\text{48}\) If ineffective, then monotherapy with valproic acid (with TID dosing) is currently the recommended second choice. Folate supplementation (after confirming normal B12 levels) should be used in all.
References

27 Special Types of Seizures

27.1 New onset seizures

27.1.1 General information

The age adjusted incidence of new onset seizures in Rochester, Minnesota was 44 per 100,000 person years.1

27.1.2 Etiologies

In patients presenting with a first-time seizure, etiologies include (modified2):

1. following neurologic insult: either acutely (i.e. <1 week) or remotely (>1 week, and usually <3 mos from insult)
   a) stroke: 4.2% had a seizure within 14 days of a stroke. Risk increased with severity of stroke3
   b) head trauma: closed head injury, penetrating trauma (p.463)
   c) CNS infection: meningitis, cerebral abscess, subdural empyema
   d) febrile seizures (p.467)
   e) birth asphyxia

2. underlying CNS abnormality
   a) congenital CNS abnormalities
   b) degenerative CNS disease
   c) CNS tumor: metastatic or primary
   d) hydrocephalus
   e) AVM

3. acute systemic metabolic disturbance
   a) electrolyte disorders: uremia, hyponatremia, hypoglycemia (especially profound hypoglycemia), hypercalceemia
   b) drug related, including:
      ● alcohol-withdrawal (p.464)
      ● cocaine toxicity (p.207)
      ● opioids (narcotics)
      ● phenothiazine antiemetics (p.143)
      ● with administration of flumazenil (Romazicon®) to treat benzodiazepine (BDZ) overdose (especially when BDZs are taken with other seizure lowering drugs such as tricyclic antidepressants or cocaine
      ● phencyclidine (PCP): originally used as an animal tranquilizer
      ● cyclosporine: can affect Mg^{2+} levels
   c) eclampsia

4. idiopathic

In 166 pediatric patients presenting to an emergency department with either a chief complaint of, or a discharge diagnosis of a first-time seizure:

1. 110 were found to actually have either a recurrent seizure or a non-ictal event
2. of the 56 patients actually thought to have had a first-time seizure
   a) 71% were febrile seizures
   b) 21% were idiopathic
   c) 7% were “symptomatic” (hyponatremia, meningitis, drug intoxication…)

In a prospective study of 244 patients with a new-onset unprovoked seizure, only 27% had further seizures during follow-up.2,5 Recurrent seizures were more common in patients with a family seizure history, spike-and-waves on EEG, or a history of a CNS insult (stroke, head injury…). No patient seizure-free for 3 years had a recurrence. Following a second seizure, the risk of further seizures was high.

27.1.3 Evaluation

Adults

A new-onset seizure in an adult in the absence of obvious cause (e.g. alcohol withdrawal) should prompt a search for an underlying basis (the onset of idiopathic seizures, i.e. epilepsy, is most
common before or during adolescence). A CT or MRI (without and with enhancement) should be performed. A systemic work-up should be done to identify the presence of any factors listed previously (see above). If all this is negative, then an MRI should be performed if not already done. If this is negative also, a repeat study (CT or MRI) should be done in ≈ 6 months and at 1 and possibly 2 years to rule out a tumor which might not be evident on the initial study.

**Pediatrics**

Among pediatric patients with first-time seizures, laboratory and radiologic evaluations were often costly and not helpful. A detailed history and physical exam were more helpful.

**Management**

Management of an adult with the new onset of idiopathic seizures (i.e. no abnormality found on CT or MRI, no evidence of drug withdrawal) is controversial. In one study, an EEG was performed, which if normal was followed by a sleep deprived EEG with the following observations:

1. there is substantial interobserver variation in interpreting such EEGs
2. if both EEGs were normal, the 2-yr recurrence rate of seizures was 12%
3. if one or both EEGs showed epileptic discharges, the 2-yr recurrence rate was 83%
4. the presence of nonepileptic abnormalities in one or both EEGs had a 41%-2-yr recurrence rate
5. the recurrence rate with focal epileptic discharges (87%) was slightly higher than for generalized epileptic discharges (78%)

The conclusion is that EEGs thus obtained have moderate predictive value, and may be factored into the decision of whether or not to treat such seizures with AEDs.

### 27.2 Posttraumatic seizures

#### 27.2.1 General information

**Key concepts**

- 2 categories: early (≤ 7 days) and late (> 7 days) after head trauma
- anticonvulsants (AEDs) may be used to prevent early posttraumatic seizures (PTS) in patients at high risk for seizures
- prophylactic AEDs do NOT reduce the frequency of late PTS
- discontinue AEDs after 1 week except for cases meeting specific criteria (see text)

Posttraumatic seizures (PTS) are often divided (arbitrarily) into: early (occurring within 1 week of injury) and late (thereafter). There may be justification for a third category: “immediate”, i.e. within minutes to an hour or so.

#### 27.2.2 Early PTS (≤ 7 days after head trauma)

30% incidence in severe head injury (“severe” defined as: LOC>24 hrs, amnesia>24 hrs, focal neuro deficit, documented contusion, or intracranial hematoma) and ≈ 1% in mild to moderate injuries. Occurs in 2.6% of children <15 yrs age with head injury causing at least brief LOC or amnesia.

Early PTS may precipitate adverse events as a result of elevation of ICP, alterations in BP, changes in oxygenation, and excess neurotransmitter release.

#### 27.2.3 7 days after head trauma)"3,7,2,0,0mm,0mm,0mm,0mm>Late onset PTS (> 7 days after head trauma)

Estimated incidence 10–13% within 2 yrs after “significant” head trauma (includes LOC>2 mins, GCS<8 on admission, epidural hematoma…) for all age groups. Relative risk: 3.6 times control population. Incidence in severe head injury ► moderate ► mild.

The incidence of early PTS is higher in children than adults, but late seizures are much less frequent in children (in children who have PTS, 94.5% develop them within 24 hrs of the injury). Most patients who have not had a seizure within 3 yrs of penetrating head injury will not develop
seizures. Risk of late PTS in children does not appear related to the occurrence of early PTS (in adults: only true for mild injuries). Risk of developing late PTS may be higher after repeated head injuries.

27.2.4 Penetrating trauma

The incidence of PTS is higher with penetrating head injuries than with closed head injuries (occurs in 50% of penetrating trauma cases followed 15 yrs).}

27.2.5 Treatment

General information

Some early retrospective studies suggested that early administration of PHT prevents early PTS, and reduces the risk of late PTS even after discontinuation of the drug. Later prospective studies disputed this but were criticized for not maintaining satisfactory levels and for lacking statistical power. A prospective double blind study of patients at high risk of PTS (excluding penetrating trauma) showed a 73% reduction of risk of early PTS by administering 20 mg/kg loading dose of PHT within 24 hrs of injury and maintaining high therapeutic levels; but after 1 week there was no benefit in continuing the drug (based on intention to treat). Carbamazepine (Tegretol®) has also been shown to be effective in reducing the risk of early PTS.

Phenytoin has adverse cognitive effects when given long-term as prophylaxis against PTS.

Treatment guidelines

Based on available information (see above) it appears that:
1. no treatment studied effectively impedes epileptogenesis (i.e. neuronal changes that ultimately lead to late PTS)
2. in high-risk patients (Table 27.1), AEDS reduces the incidence of early PTS
3. however, no study has shown that reducing early PTS improves outcome
4. once epilepsy has developed, continued AEDs reduces the recurrence of further seizures

The following are therefore offered as guidelines.

Initiation of AEDs

AEDs may be considered for short term use especially if a seizure could be detrimental. Early post-traumatic seizures were effectively reduced when phenytoin was used for 2 weeks following head injury with no significant increased risk of adverse effects. Acutely, seizures may elevate ICP, and may adversely affect blood pressure and oxygen delivery, and may worsen other injuries (e.g. spinal cord injury in the setting of an unstable cervical spine). There may also be negative psychological effects on the family, loss of driving privileges, and possibly deleterious effects of excess neurotransmitters.

Option: begin AEDs (usually levetiracetam, phenytoin or carbamazepine) within 24 hrs of injury in the presence of any of the high risk criteria shown in Table 27.1 (modified). When using PHT, load with 20 mg/kg and maintain high therapeutic levels. Switch to phenobarbital if PHT not tolerated.

Discontinuation of AEDs

1. taper AEDs after 1 week of therapy except in the following:
   a) penetrating brain injury
   b) development of late PTS (i.e. a seizure >7 days following head trauma)

Table 27.1 High risk criteria for PTS

| 1. acute subdural, epidural, or intracerebral hematoma SDH, EDH or ICH |
| 2. open-depressed skull fracture with parenchymal injury |
| 3. seizure within the first 24 hrs after injury |
| 4. Glasgow Coma Scale score <10 |
| 5. penetrating brain injury |
| 6. history of significant alcohol abuse |
| 7. ± cortical (hemorrhage) contusion on CT |
c) prior seizure history
d) patients undergoing craniotomy

2. for patients not meeting the criteria to discontinue AEDs after 1 week (see above):
   a) maintain ≈ 6–12 mos of therapeutic AED levels
   b) recommend EEG to rule-out presence of a seizure focus before discontinuing AEDs (shown to have poor predictive value is poor, however probably advisable for legal purposes) for the following:
      • repeated seizures
      • presence of high risk criteria shown in Table 27.1.

27.3 Alcohol withdrawal seizures

27.3.1 General information

Also, see Alcohol withdrawal syndrome (p. 204). The withdrawal syndrome may begin hours after the EtOH peak; see also prevention and treatment (p. 205). Ethanol withdrawal seizures are classically seen in up to 33% (some say 75%) of habituated drinkers within 7–30 hours of cessation or reduction of ethanol intake. They typically consist of 1–6 tonic-clonic generalized seizures without focality within a 6 hour period. Seizures usually occur before delirium develops. They may also occur during intoxication (without withdrawal).

The seizure risk persists for 48 hrs (risk of delirium tremens (DTs) continues beyond that), thus a single loading dose of PHT is frequently adequate for prophylaxis. However, since most EtOH withdrawal seizures are single, brief, and self-limited, PHT has not been shown to be of benefit in uncomplicated cases and is thus usually not indicated. Chlordiazepoxide (Librium®) or other benzodiazepines (p. 205) administered during detoxification reduces the risk withdrawal seizures.

27.3.2 Evaluation

The following patients should have a CT scan of the brain, and should be admitted for further evaluation as well as for observation for additional seizures or for DTs:
1. those with their first EtOH withdrawal seizure
2. those with focal findings
3. those having more than 6 seizures in 6 hrs
4. those with evidence of trauma

Other causes of seizure should also be considered, e.g. a febrile patient may require an LP to rule-out meningitis.

27.3.3 Treatment

A brief single seizure may not warrant treatment, except as outlined below. A seizure that continues beyond 3–4 minutes may be treated with diazepam or lorazepam, with further measures used as in status epilepticus (p. 468) if seizures persist. Loading with phenytoin (18 mg/kg = 1200 mg/70 kg) and long-term treatment is indicated for:
1. a history of previous alcohol withdrawal seizures
2. recurrent seizures after admission
3. history of a prior seizure disorder unrelated to alcohol
4. presence of other risk factors for seizure (e.g. subdural hematoma)

27.4 Nonepileptic seizures

27.4.1 General information

AKA pseudoseizures (some prefer not to use this term since it may connote voluntary feigning of seizures), with the term psychogenic seizures being preferred for nonepileptic seizures (NES) with a psychologic etiology (psychogenic seizures are real events and may not be under voluntary control).

One of the hazards of NES is that patients may end up needlessly taking AEDs, which in some cases may worsen NES. Possible etiologies of NES are given in Table 27.2. Most NES are psychogenic.
DDx for seizures:
1. psychogenic: 20–90% of patients with intractable seizures referred to epilepsy centers. These patients carry the diagnosis of seizures from 5–7 years. Up to 50% of these may have legitimate seizures at some time as well.24
2. tic: can be suppressed, is not repetitive (if repetitive, may be hemifacial spasm)
3. movement disorder: myoclonus (can be epileptic or non-epileptic)
   a) cataplexy: e.g. with narcolepsy often provoked by laughter or other emotional stimulus (can rarely be caught on EEG, when it is it shows REM intrusion into wakefulness)
   b) parasomnia: a sleep movement disorder (occurs during sleep). Includes: night terrors (occurs in slow wave sleep, vs. nightmare which occurs in REM), sleep walking, REM behavior disorders (usually occurs in older men, and there is a high probability they will go on to have degenerative brain disease (used to be called paroxysmal nocturnal PNT). Head banging is a benign parasomnia
4. syncope: 90% of the time people who faint have myoclonic jerks or shaking25
5. TIA

27.4.2 Differentiating NES from epileptic seizures

General information
Distinguishing between epileptic seizures (ES) and NES is a common clinical dilemma. There are unusual seizures that may fool experts.26 Some frontal lobe and temporal lobe complex partial
seizures may produce bizarre behaviors that do not correspond to classic ES findings and may not produce discernible abnormalities with scalp-electrode EEG (and therefore may be misdiagnosed even with video-EEG monitoring, although this is more likely with partial seizures than with generalized). A multidisciplinary team approach may be required.

Table 27.3 contrasts some features of true seizures vs. NES, and Table 27.4 lists some features often associated with NES, however, no characteristics are definitively diagnostic of NES since a number of them may also occur with ES.

Features common to both true seizures and NES: verbal unresponsiveness, rarity of automatisms and whole-body flaccidity, rarity of urinary incontinence. Reminder: some seizures can be bizarre and can resemble NES (sometimes called pseudo-pseudoseizures). 10% of patients with psychogenic seizures actually have epilepsy.

</table>

Table 27.4 Features often associated with NES

- frequent seizures despite therapeutic AEDs
- multiple different-physician visits
- lingering prodrome or gradual ictal onset (over minutes)
- prolonged duration (>5 mins)
- manifestations altered by distraction
- suggestible or inducible seizures
- intermittent arrhythmic and out-of-phase convulsive activity
- fluctuating intensity and severity during Sz
- side-to-side rolling, pelvic thrusting, wild movements
- bilateral motor activity with preserved consciousness
- nonphysiologic spread of neurologic signs
- absence of labored breathing or drooling after generalized convulsion
- expression of relief or indifference
- crying or whimpering
- no postictal confusion or lethargy
- disproportionate postictal mental status changes
- absence of stereotypy
Features suggestive of non-epileptic seizures:
1. arching of the back: 90% specific for NES
2. asynchronous movement
3. stop & go: seizures usually build and then gradually subside
4. forced eye closing during entire seizure
5. provoked with stimuli that would not cause a seizure (e.g. tuning fork to the head, alcohol pad to the neck, IV saline...)
6. bilateral shaking with preserved awareness. Exception: supplementary motor area seizures (mesial frontal area) these seizures are usually tonic (not clonic)
7. weeping (whining): highly specific
8. multiple or variable seizure types (ES is usually stereotypical), fluctuating level of consciousness, denial of correlation of Sz with stress

If any two of the following are demonstrated, 96% of time this will be NES:
1. out-of-phase clonic UE movement
2. out-of-phase clonic LE movement
3. no vocalization or vocalization at start of event

Lateral tongue laceration is very specific for seizures.

History
Attempt to document: prodromal symptoms, precipitating factors, time and environment of Sz, mode and duration of progression, ictal and postictal events, frequency and stereotypy of manifestations. Determine if patient has history of psychiatric conditions, and if they are acquainted with individuals who have ES.

Psychological testing
May help. Differences occur in ES and NES on the Minnesota Multiphasic Personality Inventory (MMPI) scales in hypochondriasis, depression hysteria, and schizophrenia.\(^\text{27}\)

Prolactin levels after seizures
Transient elevations in human serum prolactin (HSP) levels occur following 80% of generalized motor, 45% of complex partial, and only 15% of simple partial seizures.\(^\text{28}\) Peak levels are reached in 15–20 minutes, and gradually return to baseline over the subsequent hour.\(^\text{29,30,31}\) It has been suggested that drawing a serum prolactin level shortly after a questionable seizure may be helpful in differentiating NES (which may have elevated cortisol levels but normal HSP levels\(^\text{32}\)).

Repetitive seizures are associated with progressively smaller HSP elevations,\(^\text{33}\) and no rise follows absence seizures or status epilepticus (whether convulsive or absence).\(^\text{34}\) Greater than twofold HSP elevations consistently follow seizures that produce intense widespread high frequency mesial temporal lobe discharges; whereas such elevations do not occur in seizures not involving these limbic structures.\(^\text{35}\) Furthermore, there may be higher baseline HSP levels in cases with right-sided interictal EEG discharges compared to those with left-sided,\(^\text{36}\) and the presence of psychopathology may affect postictal HSP elevations.\(^\text{37}\)

Therefore, the presence of HSP peaks may be strongly indicative of true seizures, but the absence may be due to a variety of complex phenomena.\(^\text{38}\) The overall classification accuracy is \(\approx 72\%\).\(^\text{31}\)

27.5 Febrile seizures

27.5.1 Definitions
See reference.\(^\text{39}\)

Febrile seizure. A seizure in infants or children associated with fever with no defined cause and unaccompanied by acute neurologic illness (includes seizures during vaccination fevers)

Complex febrile seizure. A convolution that lasts longer than 15 minutes, is focal, or multiple (more than one convolution per episode of fever)

Simple febrile seizure. Not complex

Recurrent febrile seizure. More than one episode of fever associated with seizures
27.5.2 Epidemiology

See reference.39

Febrile convulsions are the most common type of seizure. Excluding children with pre-existing neurologic or developmental abnormalities, the prevalence of febrile seizures is ≈ 2.7% (range: 2–5% in U.S. children aged 6 mos-6 yrs). The risk for developing epilepsy after a simple febrile seizure is ≈ 1% and for a complex febrile seizure is 6% (9% for prolonged seizure, 29% for focal seizure). An underlying neurologic or developmental abnormality or a family history of epilepsy increases the risk of developing epilepsy. The notion that the younger the child with a febrile seizure the greater the risk of epilepsy is unproven.

27.5.3 Treatment

In one study, the IQ in the group treated with phenobarbital was 8.4 points lower (95% confidence interval) than the placebo group, and there remained a significant difference several months after discontinuing the drug.40 Furthermore, there was no significant reduction in seizures in the phenobarbital group. And yet, no other drug really appears well suited to treating this entity: carbamazepine and phenytoin appear ineffective, valproate may be effective but has serious risks in the <2 yrs age group. Given the low incidence (1%) of having afebrile seizures (i.e. epilepsy) after a simple febrile seizure and the fact that AEDs probably do not prevent this development, there is little support for prescribing anticonvulsants in these cases. The recurrence rate of febrile seizures in children with a history of one or more febrile seizure can be reduced by administering diazepam 0.33 mg/kg PO q 8 hrs during a febrile episode (temp >38.1° C) and continuing until 24 hrs after the fever subsides.41

27.6 Status epilepticus

27.6.1 General information

<table>
<thead>
<tr>
<th>Key concepts</th>

</thead>
<tbody>
<tr>
<td>● definition: Sz&gt;5 mins, or persistent Sz after 1st &amp; 2nd line AEDs</td>
</tr>
<tr>
<td>● morbidity and mortality are high in untreated status epilepticus (SE)</td>
</tr>
<tr>
<td>● most common etiology: patient with known Sz disorder with low AED levels</td>
</tr>
<tr>
<td>● de novo SE in acute illness is considered a manifestation of the illness which should be treated at the same time as the SE</td>
</tr>
<tr>
<td>● see Table 27.5 for treatment measures</td>
</tr>
</tbody>
</table>

Definition. A seizure lasting >5 minutes or persistent seizure activity after sequential administration of appropriate first and second-line AEDs.42

Features important to management:

- 61% of seizures that persist >5 mins will continue >1 hour43
- in patients with no prior Sz history, status epilepticus (SE) is usually a manifestation of illness-related cortical irritation or injury42 and treatment of the underlying disorder (in addition to treating the SE) is critical
- a relapse of Sz. in a patient with a known Sz. disorder and subtherapeutic AED levels usually responds to a bolus of the maintenance AEDs. However, SE should be treated by the standard protocol42
- most cases of convulsive status in adults start as partial seizures that generalize secondarily
- the choice of 1st and 2nd-line AEDs is arbitrary, dose42 and starting treatment in <30 minutes44 are more important determinants of success in aborting SE

27.6.2 Types of status epilepticus

See reference.45

- generalized status
  1. convulsive (tonic-clonic, tonic-clonic-tonic, or clonic): generalized convulsive tonic-clonic status epilepticus (SE) is the most frequent type.46 A medical emergency
  2. absence (note: in status, this may present in twilight state)
3. secondarily generalized: accounts for \( \approx 75\% \) of generalized SE
4. myoclonic
5. atonic (drop attack): especially in Lennox-Gastaut syndrome (p. 443)
   - partial status (usually related to anatomic abnormality)
     1. simple (AKA epilepsy partialis continua)
     2. complex (note: in status, this may present in twilight state) most often from frontal lobe focus.
     
     **Urgent treatment is required** (several case reports of permanent deficits following this)
   3. secondarily generalized
   4. non-convulsive SE
      1. benign variants (typical absence SE, complex partial SE)
      2. electrical SE during sleep
      3. atypical absence SE
      4. tonic SE (associated with learning disability in children) SE in coma

Alternatively, SE can be broken down as follows:
- with prominent motor effects
- without prominent motor effects

---

<tr>
<td>- Propofol: 2 mg/kg IV loading dose followed by 2-5 mg/kg/hr</td>
</tr>
<tr>
<td>If Sz persist, ensure that correctable conditions have been ruled-out and/or treated</td>
</tr>
</tbody>
</table>
| **novel therapeutic options** (not systematically studied): shock therapy...
• boundary syndromes (syndromes which combine encephalopathy, behavioral disturbances, delirium, or psychosis with SE-like EEG findings)

27.6.3 Epidemiology

Incidence is \( \approx 150,000 \) new cases/year in the U.S. in the outpatient setting.\(^42\) Most cases occur in young children (among children, 73\% were < 5 yrs old\(^47\)), the next most affected group is patients > 60 yrs age. In > 50\% of cases, SE is the patient’s first seizure.\(^46\) One out of six patients presenting with a first time seizure will present in SE.

27.6.4 Etiologies

Most common causes: low level of AED (34\%), remote symptomatic cause (24\%), cerebrovascular accident (22\%), metabolic disturbances (15\%), and hypoxia (13\%).

A more comprehensive list:

1. a patient with a known seizure disorder having low AED levels for any reason (non-compliance, intercurrent infection preventing PO intake of meds, drug-drug interactions → lowering effectiveness of AEDs…)
2. febrile seizures: a common precipitator in young patients. 5–6\% of patients presenting with SE have a history of prior febrile seizures
3. stroke: the most commonly identified cause in the elderly
4. CNS infection: in children, most are bacterial, the most common organisms were H. influenzae and S. pneumoniae
5. idiopathic: accounts for \( \approx one-third \) (in children, usually associated with fever)
6. epilepsy: is present or is subsequently diagnosed in \( \approx 50\% \) of patients presenting with SE. About 10\% of adults ultimately diagnosed as having epilepsy will present in SE
7. electrolyte imbalance: hyponatremia (most common in children, usually due to water intoxication\(^43\)), hypoglycemia, hypocalcemia, uremia, hypomagnesemia...
8. illicit drug intoxication: especially cocaine, amphetamines
9. precipitous drug withdrawal: barbiturates, benzodiazepines, alcohol or narcotics
10. proconvulsant drugs, including: \( \beta \)-lactam antibiotics (penicillins, cephalosporins), certain antidepressants (bupropion), clonazapine, bronchodilators, immunosuppressants
11. traumatic brain injury: acute as well as old
12. hypoxia/ischemia
13. tumor

In children < 1 yr age, 75\% had an acute cause: 28\% were secondary to CNS infection, 30\% due to electrolyte disorders, 19\% associated with fever.\(^45\) In adults, a structural lesion is more likely. In an adult, the most common cause of SE is subtherapeutic AED levels in a patient with a known seizure disorder.

27.6.5 Morbidity and mortality from SE

Outcomes are related to underlying cause and duration of SE. Mean duration of SE in patients without neurologic sequelae is 1.5 hrs (therefore, proceed to pentobarbital anesthesia before \( \approx 1 \) hour of SE). Recent mortality: < 10–12\% (only \( \approx 2\% \) of deaths are directly attributable to SE or its complications; the rest are due to the underlying process producing the SE). Mortality in lowest amongst children (< 6\%), patients with SE related to subtherapeutic AEDs, and patients with unprovoked SE.\(^48\) The highest mortality occurs in elderly patients and those with SE resulting from anoxia or stroke.\(^48\) 1\% of patients die during the episode itself.

Morbidity and mortality is due to:\(^59\): 1. CNS injury from repetitive electric discharges: irreversible changes begin to appear in neurons after as little as 20 minutes of convulsive activity. Cell death is very common after 60 mins
2. systemic stress from the seizure (cardiac, respiratory, renal, metabolic)
3. CNS damage by the acute insult that provoked the SE

27.6.6 Treatment

General treatment measures for status epilepticus

Treatment success, like morbidity/mortality, may be time dependent. One review showed that first-line AED therapy aborted SE in 60\% of patients if initiated within the first 30 minutes, and efficacy
decreased as seizure duration increased [Lowenstein 1993]. As such, treatment should be initiated as soon as possible and be directed at stabilizing the patient, stopping the seizure, and identifying the cause (determining if there is an acute insult to the brain) and if possible also treating the underlying process. Treatment often must be initiated prior to the availability of test results to confirm the diagnosis and may even be initiated in the pre-hospital setting.

1. “ABCs”
   a) Airway: oral airway if feasible. Turn patient on their side to avoid aspiration
   b) Breathing: O₂ by nasal cannula or bag-valve-mask. Consider intubation if respirations compromised or if seizure persists >30 min
   c) Circulation: CPR if needed. Large bore proximal IV access (2 if possible; 1 for phenytoin (PHT) (Dilantin®), not necessary if fosphenytoin is available): start with NS KVO

2. Simultaneous with ABCs, AEDs should be prepared and/or given if SE suspected
3. neurologic exam
4. monitor: EKG & baseline vital signs. Pulse oximeter. Frequent blood pressure checks
5. bloodwork: STAT capillary blood (fingerstick) glucose (to R/O hypoglycemia), electrolytes (including glucose), CBC, LFTs, Mg ++ , Ca ++ , AED levels, ABG
6. head CT (usually without contrast)
7. correct any electrolyte imbalance (SE due to electrolyte imbalance responds more readily to correction than to AEDs)
8. if CNS infection is a major consideration, perform LP for CSF analysis (especially in febrile children) unless contraindicated (p.1504). WBC pleocytosis up to 80 × 10⁶/L can occur following SE (benign postictal pleocytosis), and these patients should be treated with antibiotics until infection can be ruled out by negative cultures
9. general meds for unknown patient:
   a) glucose:
      ● in patients with poor nutrition (e.g. alcoholics): giving glucose in thiamine deficiency can precipitate Wernicke’s encephalopathy (p.206) prior to glucose bolus give thiamine 50–100 mg IV
      ● if fingerstick glucose can be obtained immediately and it shows hypoglycemia, or if no fingerstick glucose can be done: give 25–50 ml of D50 IV push for adults (2 ml/kg of 25% glucose for peds). If at all possible, draw blood for definitive serum glucose first
   b) naloxone (Narcan®) 0.4 mg IVP (in case of narcotics)
   c) ± bicarbonate to counter acidosis (1–2 amps depending on length of seizure)
   d) for neonate <2 years: consider pyridoxine 100 mg IV push (pyridoxine-dependent seizures constitute a rare autosomal recessive condition that generally presents in the early neonatal period)

10. administer specific anticonvulsants for seizures lasting >5-10 mins (see below)
11. EEG monitor if possible
12. if paralytics are used (e.g. to intubate), use short acting agents and be aware that muscle paralysis alone may stop visible seizure manifestations, but does not stop the electrical seizure activity in the brain, which can lead to permanent neurologic damage if prolonged (see above).

Medications for generalized convulsive status epilepticus

General information
There are no randomized trials for refractory status epilepticus, although there is published data regarding specific treatment options. Numerous protocols exist. Table 27.5 shows a summary of medications for a status epilepticus protocol that is outlined in further detail below (adapted 52,45,56, 51). “Peds dosing” refers to patients <40 kg or approximately 12 yrs of age. Rapid treatment is indicated as delays are associated with neuronal injury and reduced response to medications.

Prehospital phase
1. impending SE: may be heralded by a crescendo in Sz. A 1–3 d course of lorazepam may preempt the development of SE
2. SE treatment may be initiated in the home setting with buccal midazolam or rectal diazepam

Hospital phase
Start IV drugs at half the maximal rate, and titrate up to maximal rate if VS stable.
1. First line drugs
   a) benzodiazepine (main side effect: respiratory depression in ≈ 12% be prepared to intubate).
      Onset of action is rapid (1–2 mins):
      ● lorazepam (Ativan®) 4 mg IV for adults, 2 mg IV for children @<2 mg/min
• OR midazolam (Versed®) 10 mg IM for adults, 5 mg IM for children >13 kg—Repeat dose of benzodiazepine if necessary after 10 min.
• If no IV access or if midazolam injections not available, diazepam can be given rectally in Diastat® gel formulation (0.2-0.5 mg/kg)

2. If seizures persist after first dose of benzodiazepine, initiate second line agent in a different IV.
   a) load with fosphenytoin (Cerebyx®) or phenytoin (Dilantin®) as listed below. Do not worry about acutely overdosing, but do follow dosing rates, monitor BP for hypotension and EKG for arrhythmias. After giving the following loading dose, start on maintenance. Fosphenytoin has the advantage of being less irritating and able to infuse at a faster rate, but phenytoin is less expensive and does not need to be metabolized.
   • fosphenytoin: 15-20 mg PE/kg IV @ 150 mg PE/min
   • OR phenytoin: 15-20 mg/kg IV @ 50 mg/min
      - if no response to loading dose, an additional 10 mg/kg IV may be given after 20 min.
      - if pt is on PHT and a recent level is known: a rule of thumb is giving 0.74 mg/kg to an adult raises the level by ≈1 mcg/ml
   b) There are several good alternatives to fosphenytoin/phenytoin as second-line AEDs:
      • Sodium valproate: 20-30 mg/kg IV bolus (max rate: 100 mg/min) – has been shown to be equal or superior to phenytoin in a few small studies
      • Phenobarbital: 20 mg/kg IV (start infusing @ 50-100 mg/min) – commonly used 2nd or 3rd line AED. A repeat dose of 25-30 mg/kg can be given 10 min after first dose.
      • Levetiracetam (Keppra®): 20 mg/kg IV bolus of over 15 minutes – evidence for Keppra as a first or second line drug is less clear

3. Traditionally, a third line agent was given prior to continuous infusion therapy (CIT), however was successful in only 7%52. As such, most new protocols proceed directly to anesthetic administration. If seizures are continuing after above therapies have been administered (15-30 min after initial presentation), begin CIT as follows:
   • Midazolam: 0.2 mg/kg IV loading dose followed by 0.2-0.6 mg/kg/hr
   • OR Propofol: 2 mg/kg IV loading dose followed by 2-10 mg/kg/hr

4. At this time, lab results and tests should be available. Ensure that all reversible etiologies have been addressed and that a CT head has been performed.

5. Pentobarbital is often reserved for SE that is refractory to all of the above interventions. If necessary, Pentobarbital is administered as follows:
   • Pentobarbital: 5 mg/kg IV followed by 1-5 mg/kg/hr

6. While some practitioners will try additional drugs (carbamazepine, oxcarbazepine, topiramate, levetiracetam, lamotrigine, gabapentin), these are likely to be of limited utility.

7. Experimental interventions include: lidocaine infusion, inhalational anesthesia, direct brain stimulation, transcranial magnetic stimulation, electroconvulsive therapy (shock therapy), surgical intervention if a seizure focus is identified

Remember: Paralytics stop the visible manifestations of the seizure and they may be useful for intubation and/or in order to obtain head imaging; however, they do not stop the abnormal electrical brain activity or the neurological damage that results.

Efficacy of drug therapy
Studies vary widely, but it appears that approximately 2/3 of patients will respond to initial therapy with the other 1/3 progressing to refractory SE.50

Medications to avoid in status epileptics
1. narcotics
2. phenothiazines: including promethazine (Phenergan®)
3. neuromuscular blocking agents in the absence of AED therapy: seizures may continue and cause neurologic injury but would not be clinically evident

27.6.7 Medications for non-convulsive status epilepticus
In non-convulsive status epilepticus, the first and second line AEDs listed in Table 27.5 should be utilized. However, many practitioners avoid escalating to the anesthetic options (CIT, pentobarbital) instead opting for trials of additional AEDs first (carbamazepine, oxcarbazepine, topiramate, lamotrigine, etc).
27.6.8 Miscellaneous status epilepticus

Myoclonic status

Treatment: valproic acid (drug of choice). Place NG, give 20 mg/kg per NG loading dose. Maintenance: 40 mg/kg/d divided.

Can add lorazepam (Ativan®) or clonazepam (Klonopin®) to help with acute control.

Absence status epilepticus

Almost always responds to diazepam.

References

28 Pain

28.1 General information
For pain medication, see Analgesics (p. 136).

Major types of pain:
1. nociceptive
   a) somatic: well localized. Described as sharp, stabbing, aching or cramping. Results from tissue injury or inflammation, or from nerve or plexus compression. Responds to treating the underlying pathology or by interrupting the nociceptive pathway
   b) visceral: poorly localized. Poor response to primary pain medications
2. deafferentation: poorly localized. Described as crushing, tearing, tingling or numbness. Also causes burning dysesthesia numbness often with lancinating pain, and hyperpathia. Unaffected by ablative procedures
3. “sympathetically maintained” pain and the likes, e.g. causalgia (p. 497)

28.2 Neuropathic pain syndromes

28.2.1 General information

Definition: Neuropathic pain: pain caused by a lesion of the peripheral and/or central nervous system manifesting with sensory symptoms and signs (Backonja modified from the International Association for the Study of Pain).

Neuropathic pain syndromes (NPS) are typified by painful diabetic neuropathy (PDN) and postherpetic neuralgia (PHN). Common chronic NPSs are shown in Table 28.1, divided into central or peripheral nervous system origin of the pain. The pain of PDN and PHN is typically burning and aching, and is continuous. and is characteristically refractory to medical and surgical treatment.

28.2.2 Medical treatment of neuropathic pain

General information

Treatment traditionally includes narcotic analgesics, and tricyclic antidepressants (see below). For further details and other treatment measures, see PHN (p.494).

Tricyclic antidepressants

Use is often limited by anticholinergic and central effects and by limited pain relief. Possibly because serotonin potentiates the analgesic effect of endorphins and elevates pain thresholds, serotonin re-uptake blockers are more effective than norepinephrine re-uptake blockers, e.g. trazodone (Desyrel®) blocks only serotonin. Also useful: amitriptyline (Elavil®) 75 mg daily; desipramine (Norpramin®) 10–25 mg/d; doxepin (Sinequan®) 75–150 mg/d. Some benefit may also derive from the fact that many patients with chronic pain are depressed. Side effects: anticholinergic effects and orthostatic hypotension, especially in the elderly. Not recommended for use in patients with ischemic heart disease.

Gabapentin

Effective in postherpetic neuralgia (PHN) (p.495) and painful diabetic neuropathy. Benefit also reported in pain associated with: trigeminal neuralgia, cancer, multiple sclerosis, HIV-related sensory neuropathy, CRPS, spinal cord injury, post-operative state, migraine (a number of these studies may have been sponsored by the manufacturer). See also side effects, dosing & availability...

Lidocaine patch (Lidoderm®)

May be effective: apply patch for up to 12 hrs/day up to a maximum of 3 patches at a time to the intact skin over the most painful area (may trim patch to appropriate size). Supplied: 5% lidocaine (p.496).

Tramadol (Ultram®)

A centrally acting analgesic (p.140).

28.3 Craniofacial pain syndromes

28.3.1 General information

Possible pathways for facial pain include: trigeminal nerve (portio major as well as portio minor (motor root)), facial nerve (usually deep facial pain), and eighth nerve. Etiologies (adapted (p.2328),

1. cephalic neuralgias
   a) trigeminal neuralgia (see below)
      • vascular compression of Cr. N. Vat root entry zone: the most common cause
      • MS: plaque within Cr. N. V nucleus
   b) glossopharyngeal neuralgia (p.492): pain usually in base of tongue and adjacent pharynx
   c) geniculate neuralgia (p.493): otalgia and deep prosopalgia
   d) tic convulsif (p.493): geniculate neuralgia with hemifacial spasm
   e) occipital neuralgia (p.515)
   f) superior laryngeal neuralgia: a branch of the vagus, results primarily in laryngeal pain and occasionally pain on the auricle
   g) sphenopalatine neuralgia
   h) herpes zoster: pain is continuous (not paroxysmal). Characteristic vesicles and crusting usually follow pain, most often in distribution of V1 (isolated V1 TGN is rare). In rare cases without vesicles, diagnosis may be difficult
      i) postherpetic neuralgia (Ramsay-Hunt syndrome) (p.493)
      j) supraorbital neuralgia (SON) (p.491)
   k) trigeminal deafferentation pain (AKA trigeminal deafferentation pain): may follow injuries from sinus or dental surgery, head trauma
   l) trigeminal deafferentation pain: follows trigeminal denervation including therapeutic measures to treat trigeminal neuralgia

http://e-surg.com
m) short-lasting unilateral neuralgiform headache with conjunctival injection and tearing (SUNCT); rare. Usually affects males 23–77 years old. Brief (<2 minutes) pain (burning, stabbing or shock-like) usually near the eye, occurring multiple times per day. Associated autonomic findings (the “hallmark of SUNCT”): ptosis, conjunctival injection, lacrimation, rhinorrhea, hyperemia. May be due to CPA AVM. Microvascular decompression or trigeminal rhizotomy may be effective in some cases refractory to medical treatment with AEDs or corticosteroids. Note: lacrimation (the most common) or other autonomic signs may occur in V1 trigeminal neuralgia but are usually mild, and appear only in the later stages of the condition and with long lasting attacks. Dramatic lacrimation and conjunctival injection from the onset of symptoms with SUNCT are the best characteristics to distinguish this from trigeminal neuralgia. May also occur in cluster headache (p.175).

2. ophthalmic pain
   a) Tolosa-Hunt syndrome (p.569): painful ophthalmoplegia
   b) (Raeder’s) paratrigeminal neuralgia (p.569): unilateral Horner’s syndrome + trigeminal neuralgia
   c) orbital pseudotumor (p.569): proptosis, pain, and EOM dysfunction
   d) diabetic (oculomotor) neuritis
   e) optic neuritis
   f) iritis
   g) glaucoma
   h) anterior uveitis

3. otalgia (see below)

4. masticatory disorders
   a) dental or periodontal disease
   b) nerve injury (inferior and/or superior alveolar nerves)
   c) temporo-mandibular joint (TMJ) dysfunction
   d) elongated styloid process
   e) temporal & masseter myositis

5. vascular pain syndromes
   a) migraine headaches: see Migraine (p.175)
      • simple migraine: includes classic migraine, common migraine
      • complicated migraine: includes hemiplegic migraine, ophthalmoplegic migraine
   b) cluster H/A (p.175); subtypes: episodic, chronic, chronic paroxysmal hemicrania
   c) giant cell arteritis (p.195) (temporal arteritis). Tenderness over STA
   d) toxic or metabolic vascular H/A (fever, hypercapnia, EtOH, nitrates, hypoxia, hypoglycemia, caffeine withdrawal)
   e) hypertensive H/A
   f) aneurysm or AVM (due either to mass effect or hemorrhage)
   g) carotidynia: e.g. with carotid dissection (p.1324)
   h) basilar dolichoectasia with fifth n. compression or indentation of the pons

6. sinusitis (maximally, frontal, ethmoidal, sphenoidal)

7. dental disease

8. neoplasm: may cause referred pain or fifth nerve compression
   a) extracranial
   b) intracranial tumor: primarily posterior fossa lesions, neoplastic compression of trigeminal nerve usually causes sensory deficit (p.481)

9. atypical facial pain (AFP) (prosopalgia): traditionally a “wastebasket” category used for many things. It has been proposed to reserve this term for a psychogenic disorder. May be suspected by

10. primary (nonvascular) H/A: including
   a) tension (muscle contraction) H/A
   b) post-traumatic H/A

28.3.2 Otalgia

General information

Because of redundant innervation of the region of the ear, primary otalgia may have its source in the 5th, 7th, 9th, or 10th cranial nerves or the occipital nerves. As a result, sectioning of the 5th, 9th or 10th nerve or a component of the 7th (nervus intermedius, chorda tympani, geniculate ganglion) has been performed with varying results. Also, microvascular decompression (MVD) of the corresponding nerve may also be done.
Work-up includes: neurotologic evaluation to rule out causes of secondary otalgia (otitis media or externa, temporal bone neoplasms...). CT or MRI should be done in any case where no cause is found.

**Primary otalgia**

Primary otalgia is unilateral in most (≈ 80%). Trigger mechanisms are identified in slightly more than half, with cold air or water being the most common. About 75% have associated aural symptoms: hearing loss, tinnitus, vertigo. Pain relief upon cocainization or nerve block of the pharyngeal tonsils suggests glossopharyngeal neuralgia (p.492), however, the overlap of innervation limits the certainty.

An initial trial with medications used in trigeminal neuralgia (carbamazepine, phenytoin, baclofen…) (p.481) is the first line of defense. In intractable cases not responding to pharyngeal anesthesia, suboccipital exploration of the 7th (nervus intermedius) and lower cranial nerves may be indicated. If significant vascular compression is found, one may consider MVD alone. If MVD fails, or if no significant vessels are found, Rupa et al. recommend sectioning the nervus intermedius, the 9th and upper 2 fibers of 10th nerve, and a geniculate ganglionectomy (or, if glossopharyngeal neuralgia is strongly suspected, just 9th and upper 2 fibers of 10th).

28.3.3 **Trigeminal neuralgia**

**General information**

<table>
<thead>
<tr>
<th>Key concepts</th>
</tr>
</thead>
<tbody>
<tr>
<td>• sharp, electric shock-like paroxysmal lancinating pain in the distribution of one or more branches of the trigeminal nerve on one side</td>
</tr>
<tr>
<td>• characterized by periods of remission and initial response to carbamazepine</td>
</tr>
<tr>
<td>• neurologic exam must be intact (only exception: mild sensory loss)</td>
</tr>
<tr>
<td>• 80–90% of cases are caused by compression of the trigeminal nerve at the root entry zone by the superior cerebellar artery. In MS patients, may be due to MS plaque (MS patients are usually less responsive to procedures)</td>
</tr>
<tr>
<td>• 75% will ultimately fail medical therapy and require a procedure (main options: microvascular decompression, percutaneous rhizotomy or radiosurgery). Choice of modality depends on patient age, location of symptoms, prior treatment and the side effect profile of the treatment modality</td>
</tr>
</tbody>
</table>

Trigeminal neuralgia (TGN) (aka tic douloureux): paroxysmal lancinating electric-like pain lasting a few seconds, often triggered by sensory stimuli, confined to the distribution of one or more branches of the trigeminal nerve (Fig. 28.1) on one side of the face, with no neurologic deficit. The term “atypical facial pain” (AFP) is sometimes used to describe any other type of facial pain.

Rarely, TGN manifests as status trigeminus, a rapid succession of tic-like spasms triggered by seemingly any stimulus. IV carbamazepine (where available) or phenytoin may be effective for this.

**Epidemiology**

See Table 28.2. Annual incidence 4/100,000. There is no correlation with herpes simplex infection. There is a tendency for spontaneous remission with pain free intervals of weeks or months being characteristic, regardless of treatment. 2% of patients with MS have TGN, whereas ≈ 18% of patients with bilateral trigeminal neuralgia have MS.

**Pathophysiology**

Probably due to ephaptic transmission in trigeminal nerve from large-diameter partially demyelinated A fibers to thinly myelinated A-delta and C (nociceptive) fibers. Pathogenesis may be due to:

1. vascular compression of the trigeminal nerve at the root entry zone (NB: compression may be seen in up to 50% of autopsies in patients without TGN):
   a) most commonly (80%) by the SCA; see Neurovascular compression syndromes (p.1534) for more details
   b) persistent primitive trigeminal artery (p.83)
   c) dolichoectatic basilar artery (p.1108)
Table 28.2  Epidemiology of trigeminal neuralgia\textsuperscript{23,24}

greater occipital nerve (dorsal rami C2 & 3)
lesser occipital nerve (ventral ramus C2)
transverse cutaneous nerve of neck (ventral rami C2 & 3)
supraclavicular nerves (ventral rami C3 & 4)
dorsal rami C3, 4 & 5
2. posterior fossa tumor (below)
3. in MS, plaque within brainstem may cause TGN that is often poorly responsive to microvascular decompression

In addition to the sensory division of the trigeminal nerve, other possible pain pathways include:
- the motor branch of the 5th nerve (portio minor), or the 7th or 8th nerve.

**Tumors and trigeminal neuralgia**

In > 2000 patients with facial pain seen over 10 yrs, only 16 harbored tumor (<0.8% incidence). In 3 tumors outside cranial vault included nasal carcinoma and skull base mets; all had hypalgesia and atypical facial pain (AFP). 6 middle fossa tumors included 2 meningiomas, 2 schwannomas (1 primary tumor of Gasserian ganglion), and 1 pituitary adenoma. Posterior fossa tumors are the most likely to cause symptoms that most closely resemble true TGN; of these, vestibular schwannoma (VS) is most common. 2 of 7 VSs had tumors contralateral to the neuralgia (presumably due to brainstem shift). Patients with true TGN initially responded to carbamazepine, none with AFP did.

When facial pain is caused by tumor, especially with peripheral tumors, the pain is frequently atypical (usually constant), neurologic abnormalities are often present (usually sensory loss, although some are neurologically normal at first), and the age is often younger than typical TGN.

**Differential diagnosis**

See Craniofacial pain syndromes (p.477).

**Evaluation**

History and physical (in addition to routine)

1. history
   a) accurate description of pain localization to determine which divisions of trigeminal nerve need to be treated
   b) determine time of onset of TGN, trigger mechanisms
   c) ascertain presence and length of pain-free intervals (lack of any pain-free interval is atypical for TGN)
   d) determine duration, side-effects, dosages, and responses to medications tried
   e) inquire about symptoms that may indicate the presence of conditions other than TGN: e.g. history of herpetic vesicles, excessive tearing of the eye (may indicate SUNCT (p.478), facial twitching (tic convulsif), tongue pain (glossopharyngeal neuralgia), sensory loss (tumor…), progressive relentless pain (tumor, herpes…), symptoms that suggest MS

2. physical exam: the exam should be normal in TGN, any neurologic deficit (except very mild sensory loss) in previously unoperated patient should prompt search for structural cause, e.g. tumor (see below). This exam also serves as a baseline for post-op comparison
   a) assess sensation in all 3 divisions of trigeminal nerve bilaterally (including corneal reflexes)
   b) assess masseter function (bite) and pterygoid function (on opening mouth, chin deviates to weak side)
   c) assess EOM function

**Imaging**

MRI is often used to evaluate these patients for possible intracranial tumors or MS plaques, especially in cases with atypical features. The yield in typical cases is low.

**Medical therapy for trigeminal neuralgia**

Drug info: Carbamazepine (Tegretol®)

Complete or acceptable relief in 69% (if 600–800 mg/d are tolerated and give no relief, diagnosis of TGN is suspect). Side effects: Drowsiness. Rash in 5–10% Possible Stevens-Johnson syndrome. Relative leukopenia is common (usually does not require discontinuing drug). See precautions under carbamazepine (CBZ, Tegretol®) (p.450).
100 mg PO BID, increase by 200 mg/d up to maximum of 1200 mg/d divided TID. Supplied: See supply information (p. 450).

**Drug info: Carbamazepine (Tegretol®)**

Rapidly metabolized to carbamazepine, similar efficacy, often tolerated at higher doses than carbamazepine. Side effects: symptomatic hyponatremia.

For trigeminal neuralgia: 300 mg PO BID, increase by 600 mg/d q week. Usual dose: 450–1200 mg. Maximum of 2400 mg/d. Supplied: 150, 300, 600 mg tablets; 500 mg/5-ml suspension.

**Drug info: Baclofen (Lioresal®)**

2nd DOC (not as effective as carbamazepine, but fewer side-effects). Caution: teratogenic in rats. Avoid abrupt withdrawal (can cause hallucinations and seizures). May be more effective if used in conjunction with low dose carbamazepine.

Start low, 5 mg PO TID, increase q 3 d by 5 mg/dose; not to exceed 20 mg QID (80 mg/d); use smallest effective dose.

**Drug info: Gabapentin (Neurontin®)**

An anticonvulsant, may act synergistically with carbamazepine and baclofen. Side effects: include ataxia, sedation and rash.

Start with 100 mg PO BID, titrate to 5–7 mg/kg/day (3600 mg/d max).

**Miscellaneous drugs**

Also possibly effective:
1. phenytoin (Dilantin®): may be useful IV in patients in too much pain to open their mouths to take carbamazepine orally
2. capsaicin (Zostrix®): 1 gm applied TID for several days resulted in remission of symptoms in 10 of 12 patients (4 relapsed in <4 mos, but remained pain free for 1 yr after 2nd course)\(^{29}\)
3. clonazepam (Klonopin®) (p.454): works in 25%\(^{\phantom{29}}\)
4. lamotrigine (Lamictal®)
5. amitriptyline (Elavil®): more commonly used for atypical facial pain
6. botulinum toxin (Botox®): reduces transmission of CGRP producing a direct effect on the sensory nerve fibers

**Surgical therapy for trigeminal neuralgia**

**Indications for surgery**

Reserved for cases refractory to medical management, or when side effects of medications exceed risks and drawbacks of surgery.

**Surgical options**

1. peripheral trigeminal nerve branch procedures to block or ablate the division involved with pain, or can be used to block the trigger\(^{10}\):
   a) means of blocking
      • local blocks (phenol, alcohol)
      • neurectomy of trigeminal branch involved
   b) nerve branches:
      • V1 (ophthalmic division) at the supraorbital, supratrochlear, or infraorbital nerves
      • V2 (maxillary division) at the foramen rotundum
      • V3 (mandibular division) block at the foramen ovale, or neurectomy of inferior dental nerve

http://e-surg.com
2. blocking the trigger: either via percutaneous rhizotomy or alcohol block

3. percutaneous trigeminal rhizotomy (PTR): AKA percutaneous (stereotactic) rhizotomy (PSR) of trigeminal (Gasserian) ganglion (see below) (not truly a stereotactic procedure in the current sense of the word, therefore the term percutaneous trigeminal rhizotomy is preferred). Objective is to selectively destroy A-delta and C fibers (nociceptive) while preserving A-alpha and beta fibers (touch). Ideally, a retrogasserian lesion (not a ganglionic lesion). May also be used to block trigger. Lesioning techniques include (see below for comparison of techniques):

a) radiofrequency rhizotomy (RFR) (originated by Sweet and Wespic31). Uses radiofrequency energy to thermocoagulate the pain fibers. Requires the patient to be awake at intervals during the procedure

b) glycerol injection into Meckel's cave32,33: possibly lower incidence of sensory loss and anesthesia dolorosa than with radiofrequency lesion. Water soluble contrast cisternography was recommended in original description, may not be essential35

c) mechanotrauma (percutaneous microcompression (PMC) rhizolysis): via inflation of No. 4 Fogarty catheter balloon. Does not require the patient to be awake

d) injection of sterile boiling water

4. Spiller-Frazier subtemporal extradural approach with retrogasserian rhizotomy (rarely used today). Original Spiller-Frazier technique involved avulsion of the nerve, which was met with unacceptably high risk of bleeding. The approach may be used to expose the ganglion and then mildly traumatize it

5. intradural retrogasserian trigeminal nerve section (sensory portion ± motor root, see below): may be performed during MVD if no vascular compression is identified

6. cutting descending trigeminal tract in lower medulla (99.5% success): rarely used

7. microvascular decompression (MVD)39: (see below) microsurgical exploration of root entry zone, usually via posterior fossa craniectomy, and displacement of vessel impinging on nerve (if such a vessel is found). Usually with the placement of a non-absorbable “insulator” (Ivalon® sponge or shredded Teflon felt; see relative merits of Ivalon® vs. Teflon felt (p.1536)

8. complete section of the nerve proximal to the ganglion via a p-ossa crani

9. stereotactic radiosurgery: see below

10. motor cortex stimulation40: (somewhat analogous to spinal cord stimulation for spinal or extremity pain). Better for neuropathic trigeminal pain (as distinct from trigeminal neuralgia)

Selection of surgical option

Some pearls that influence treatment option choices (expert opinion41):

1. V3 neuralgia: RF. Can selectively treat V3 without involving other divisions

2. V1 or V2: balloon compression. Causes numbness in all 3 divisions, but unlike the lesion with RF the corneal numbness is better tolerated and the corneal reflex is often preserved

3. bilateral pain: glycerol. It has the shortest duration of effect, which is an advantage if you think you may need to treat the other side at some point

4. SRS: due to latency until pain relief, suboptimal for patients who need immediate pain relief

Peripheral nerve ablation and neurectomies

Limited to pain or trigger points in territory of supraorbital/supratrochlear, infraorbital, or inferior dental nerves. Neurectomy may be a consideration especially for elderly patients who are not candidates for MVD (neurectomy may be done under local anesthesia) with pain in the forehead (to avoid anesthesia of the eye, as could occur with RFR). Disadvantages include sensory loss in the distribution of the nerve and a high rate of pain recurrence due to nerve regeneration (usually in 18–36 months) which often requires repeat neurectomy.42 May also be used following PTR.

Supraorbital and supratrochlear nerve: See also information on supraorbital neuralgia (SON) or supratrochlear neuralgia (STN) (p.491). SON may be treated with rhizotomy (e.g. with alcohol or radiofrequency) or with neurectomy. Alcohol injection is used with caution for STN because of risk of injury to the superior oblique muscle. For neurectomy, these nerves are exposed through a 2 cm incision parallel to and just above the medial portion of the eyebrow (never through the eyebrow as this can create an unsightly “bi-brow”; shaving the eyebrow is also discouraged since it occasionally does not grow back). The incision is carried down to the bone and the periosteum is elevated caudally towards the supraorbital foramen or notch. The nerves will be visible on the undersurface of the periosteal flap. The supraorbital nerve is freed in its foramen/notch, and is then avulsed by grasping it with a mosquito hemostat and twisting the clamp. The nerve avulses “like pulling a worm out of a hole.” The distal portion of the nerve should be located at the site were the periosteum was incised and it, too, should be avulsed. The process can be repeated for the more medially situated supratrochlear nerve.
Other nerves: Not covered here, other nerve branches that may be cut or avulsed include: infra-trochlear, lacrimal (the branch of V1 at the lateral edge of the orbit), infraorbital nerve, inferior alveolar, lingual and mental nerves.43 (p 290)

Percutaneous trigeminal rhizotomy (PTR)
Recommended for patients who: are poor risk for general anesthesia (elderly or those with increased risk for general anesthesia), wish to avoid "major" surgery, have unresectable intracranial tumors, have MS, have impaired hearing on the other side, or have limited life expectancy (<5 yrs).44 For "atypical facial pain", denervating the painful region of the face benefits <20% of patients, and worsens 20%.44 Recurrences are easily treated by repeat procedures. May be used to treat failures of peripheral nerve ablation.

Choice of lesion technique. Recurrence rates and incidence of dysesthesias are comparable among the various lesioning techniques. Incidence of intraoperative hypertension is less with PMC than with radiofrequency rhizotomy (RFR) lesion38 (no reports of intracerebral hemorrhage). Bradycardia occurs regularly with PMC which may not be harmful (some prophylax with atropine45). RFR requires a patient who is able to cooperate; PMC can be done with the patient asleep. Paralysis of ipsilateral trigeminal motor root (e.g. pterygoids) is more common after PMC (usually temporary) than RFR, and so PMC should not be done if there is already contralateral paralysis from a previous procedure. See also description of technique (p.486).

Complications with percutaneous radiofrequency (note: some “numbness” is actually expected in most successful PTRs and occurs in 98% of cases,24 and is not considered a complication here)
1. mortality: only 17 deaths in over 22,000 procedures (includes lesser experienced neurosurgeons and patients often considered poor surgical risks)21
2. dysesthesias24 (sometimes called “annoying paresthesias”): higher rate in more complete lesions
   a) minor: 9%
   b) major (requiring medical treatment): 2%
   c) anesthesia dolorosa (severe, constant, burning aching pain that is refractory to all treatment): 0.2–4%
3. meningitis23: 0.3%
4. alterations in salivation46: 20% (increased in 17% decreased in 3%)
5. partial masseter weakness (usually not perceived by patient, Table 28.3)
6. oculomotor paresis (usually temporary, Table 28.3)
7. reduced hearing (secondary to paresis of tensor tympani, Table 28.3)
8. neuroparalytic keratitis (keratitis due to fifth nerve deficit which impairs sensation, Table 28.3)
9. intracranial hemorrhage: personal report of 7 cases (6 fatal) in >14,000 procedures, probably due to transient HTN (SBP up to 300 torr)
10. alterations in lacrimation46: 20% (increased in 17% decreased in 3%)
11. herpes simplex eruption: prescribe antitherpetic drug if patient develops symptoms, e.g. Acyclovir® (p.366).
12. bradycardia and hypotension: 1% with RFR compared to up to 15% with glycerol injection)
13. rare47,48:
   a) temporal lobe abscess
   b) aseptic meningitis
   c) intracerebral abscess: 0.1%

d) trigeminal trophic syndrome (TTS)\textsuperscript{49}: triad of unilateral crescentic nasal alar ulceration with anesthesia and paresthesia of the trigeminal dermatome (may present with severe pruritus and self-induced skin lesions from scratching). A result of trigeminal nerve injury. Treatment has included: carbamazepine, diazepam, amitriptyline, chlorpromazine, clonazepam or pimozide\textsuperscript{50}

e) complications related to needle placement\textsuperscript{51}:
- carotid cavernous fistula (CCF): may occur with any percutaneous technique\textsuperscript{52} (including balloon microcompression\textsuperscript{53})
- blindness: from penetration of inferior orbital fissure\textsuperscript{54}
- injury to other cranial nerves: II, III, IV, VI\textsuperscript{55}

f) subarachnoid hemorrhage

g) seizures

Microvascular decompression (MVD)
See also more detailed information (p. 488).

Recommended for patients with inadequate medical control of pain with >5 years anticipated survival and able to tolerate a small craniotomy\textsuperscript{34} (surgical morbidity increases with age). Relief is often long lived, persevering 10 yrs in 70% Incidence of facial anesthesia is much less than with PTR, and anesthesia dolorosa does not occur. Mortality: <1% Incidence of aseptic meningitis (AKA hemogenc meningitis): 20% 1–10% major neurologic morbidity. Failure rate: 20–25%
1–2% of patients with MS will have a demyelinating plaque at the root entry zone, this usually does not respond to MVD, and one should attempt a PTR.

Stereotactic radiosurgery (SRS)
The first use of SRS by Leksell was for the treatment of TGN. Initially, this was reserved for refractory cases following multiple operations,\textsuperscript{57} now becoming more widely practiced. The least invasive procedure. Generally recommended for patients with co-morbidities, high-risk medical illness, pain refractory to prior surgical procedures, or those on anticoagulants (anticoagulation does not have to be reversed to have SRS).

Treatment plan: 4 - 5 mm isocenter in the trigeminal nerve root entry zone identified on MRI. Use 70–80 Gy at the center, keeping the 80% isodose curve outside of the brainstem.
Results: Significant pain reduction after initial SRS: 80–96\%\textsuperscript{38,59,60,61} but only ≈ 65% become pain free. Median latency to pain relief: 3 months (range: 1 d-13 months).\textsuperscript{62} Recurrent pain occurs within three years in 10–25% Patients with TN and multiple sclerosis are less likely to respond to SRS than those without MS. SRS can be repeated, but only after four months following the original procedure.

 Favorable prognosticators: higher radiation doses, previously unoperated patient, absence of atypical pain component, normal pre-treatment sensory function.\textsuperscript{63}

 Side effects: Hypesthesia occurred in 20% after initial SRS, and in 32% of those requiring repeat treatment\textsuperscript{62} (higher rates associated with higher radiation doses\textsuperscript{39}).

Management of surgical treatment failures
90% of recurrences are in distribution of previously involved divisions; 10% are in new division and may represent progression of the underlying process. Some treatment failures are not persistent TN, but rather represent trigeminal neuropathic pain (AKA trigeminal deafferentation pain).

PTR may be repeated in patients who have a recurrence with some preservation of facial sensation. Attempted repeat PTR is often productive, and failures can be managed as below.

MVD may be performed in patients failing PTR, but the success rate may be reduced\textsuperscript{64} (91% for patients undergoing MVD first, vs. 43% for those having MVD following PTR; note: 91% may be an unrealistically high success rate, and taking patients that fail PTR may select for a more difficult subgroup). Repeat MVD may also be performed, with attention given to possible slippage of the insulating sponge, or the fact that the true offending vessel may be “artificially” moved away from the nerve secondary to the surgical positioning.

SRS can be repeated, using the same dose, with reported significant reduction in pain in 89% and complete relief in 58%\textsuperscript{62}

Intradural retrogasserian trigeminal nerve section

May be used as a measure of last resort in patients who have recurrent TGN following one or more PTRs in the presence of total facial anesthesia, or in patients undergoing posterior-fossa cranietomy for the purpose of MVD when no impinging vessel can be identified. In the latter case, a partial rhizotomy is performed by sectioning 2/3 of nerve, with resulting partial anesthesia. In the case of patients with facial anesthesia pre-op, consideration should be given to sectioning the motor division (portio minor) as an alternate pain pathway.\textsuperscript{11}
Percutaneous trigeminal rhizotomy (PTR)

Due to concerns about hemorrhage, check coagulation profile (PT/PTT, consider bleeding time), and discontinue ASA and NSAIDs, preferably 10 days pre-op. Procedure may be performed in OR with fluoro, or in angiography suite in x-ray department.

Booking the case: Percutaneous trigeminal rhizotomy

(For any of the percutaneous methods: balloon, glycerol, RFR)
Also see defaults & disclaimers (p. 27) and pre-op orders (see below).

1. position: supine
2. anesthesia: MAC with sedation
3. equipment:
   a) lesion generator and needle kit for radiofrequency rhizotomy
   b) C-arm fluoroscopy (2 C-arms for balloon compression)
   c) calibrated inflatable balloons (as in kyphoplasty) for balloon rhizotomy

4. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: put a needle into the cheek to numb the nerve to the face
   b) alternatives: medical treatment, surgery through the back of the skull (microvascular decompression), radiation (stereotactic radiosurgery)
   c) complications: facial numbness is anticipated, rarely: stroke, bleeding, blindness

Pre-op orders (RFR)

1. NPO after MN except meds
2. continue Tegretol® & other meds PO with sips of water
3. AM of procedure: IV NS @ KVO in arm contralateral to neuralgia
4. atropine 0.4 mg IM PRN (contraindications include rapid a-fib)
5. non-disposable LP tray to accompany patient

Technique: Percutaneous trigeminal radiofrequency rhizotomy (RFR)

Adapted technique:

NR: needle insertion and/or lesioning may cause HTN, consider monitoring BP. Use either a straight electrode (bare 5 mm for 1 division, 7.5 mm for 2 divisions, or 10 mm for total lesions) or a curved electrode.

Electrode insertion

1. attach ground electrode to patient’s upper arm
2. prep the cheek on the involved side with Betadine
3. entry point: under short-acting anesthetic agent e.g. propofol (Diprivan®) (p.133) or methohexital (Brevitol®) (p.132) - , insert electrode-needle 2.5 – 3 cm lateral to oral commissure
4. trajectory:
   a) palpate the buccal mucosa with a gloved finger inside the mouth (lateral to the teeth) and with the other hand pass the electrode medial to the coronoid process of the mandible (keeping the needle deep to the oral mucosa, i.e. outside the oral cavity) initially aiming towards the plane intersecting a point 3 cm anterior to EAM and the medial aspect of the pupil when the eye is directed forward. Be careful not to contaminate the field with the hand that was in the patient’s mouth
   b) as insertion progresses, use fluoroscopy to direct the tip towards the intersection of the top of the petrous bone with the clivus (5–10 mm below floor of sella along clivus)
   c) upon entering foramen ovale the masseter often contracts, causing the jaw to briefly close. Remove the stylet, look for CSF to verify location (may not occur in re-do cases), and insert electrode through needle

In difficult cases, intraoperative fluoroscopy may assist in localizing the needle to Meckel’s cave and to R/O e.g. entry into superior orbital fissure (which can cause blindness after lesioning), or entry into foramen spinosum (middle meningeal artery). If necessary to visualize (e.g. when there is difficulty entering), the foramen ovale is optimally seen on a submental x-ray by hyperextending neck 20° and rotating head 15–20° away from side of pain.
Impedance measurements: from the tip of the electrode when available may help indicate location of needle tip. Impedance: CSF (or any fluid) low (≈ 40–120 Ω); connective tissue, muscle, or nerve is usually 200–300 Ω (may be up to 400 Ω); if >400 Ω this likely indicates electrode is contacting periosteum or bone. After starting the lesion, impedance often goes down by 30 Ω transiently, and then as the lesioning continues it gradually returns to baseline or ≈ 20 Ω above it. If char develops on the electrode tip, the impedance will read higher than where it started.

Stimulation and repositioning

Once the foramen ovale is entered, the needle is positioned with the following guidelines: for V3 division lesion the curved electrode should be just short of the clivus and pointing down, for V2 it is at the clivus and directed up, for V1 it is 5 mm beyond clivus and pointing up. At no time should the needle tip extend >8 mm beyond clival line (to avoid Cr. N. III or V1 complications).

The patient is allowed to wake up and is stimulated through the electrode with the following settings: frequency = 50–75 Hz, 1 mS duration, start at 0.1 V amplitude and slowly increase (usually 0.2–0.5 V is adequate, higher voltages may indicate that the needle is not near the target and that stimulation is due to far-field currents, however, in previously lesioned patients up to 4 V may sometimes be necessary). If stimulation does not reproduce pain in the distribution of the patient’s TGN, then the amplitude is returned to 0, the electrode is repositioned (straight electrode: advance needle <5 mm at a time, until the tip is in the vicinity of the clival line; curved tip electrode: advance and/or rotate) and then slowly elevate the voltage again from 0 and repeat the repositioning-stimulating process until stimulation reproduces the distribution of tic pain. If previous lesions have produced analgesia and the patient cannot feel the stimulating current, one may stimulate at 2 Hz. and watch for masseter twitch (requires preserved motor root).

Lesioning

When stimulation produces pain in the involved distribution of the TGN, perform the first lesion under short-acting anesthesia at 60–70° C×90 sec. A facial flush may be noted. After every lesion, perform a post-lesion assessment (see below). The goal is analgesia (but not anesthesia) in the areas of tic pain and hypalgesia in areas of trigger points. An average of three lesions are necessary at the first sitting, each ≈ 5° C higher than the previous for 90 seconds. Anesthetic may not be needed after the first lesion if moderate analgesia has been produced by previous lesions.

Post-lesion assessment

After each lesion and at completion of procedure, assess:
1. sensitivity to pinprick and light touch in all three divisions of trigeminal nerve (grading: normal, hypalgesic, analgesic, anesthetic)
2. corneal reflex bilaterally
3. EOM function
4. masseter muscle strength (patient clenches teeth, palpate cheeks for contraction)
5. pterygoid muscle strength (ask patient to open mouth, chin deviates towards side of pterygoid weakness)

Post-op care (PTR)

Include in post-op orders:
1. ice pack to face on side of procedure for 4 hrs
2. soft diet
3. routine activity when alert
4. avoid narcotics (usually not necessary)
5. if corneal reflex impaired: risk of neuroparalytic keratitis. Natural tears 2 gtt q 2 hrs while awake to eye on affected side. Lacrilube® to eye & tape eye shut q hs

Prior to discharge from hospital, repeat post-lesion assessment (see above). Patients are then weaned off of carbamazepine as tolerated.

Percutaneous microcompression rhizolysis balloon (PMC)

Via inflation of No. 4 Fogarty catheter balloon.

Technique
1. the needle is placed as with RFR (p. 486).
2. aim for balloon placement in the medial foramen ovale (to avoid entering the middle fossa). After placing the balloon, insert the stylet to visualize where the balloon will go. Use Omnipaque 240 to fill the balloon
3. inflate to 1.4 atmospheres of pressure

http://e-surg.com
Results of various PTR techniques compared to microvascular decompression (MVD) are shown in Table 28.4. Recurrence rate is higher in patients with multiple sclerosis (50% at 3 yrs mean F/U).67

**Microvascular decompression (MVD) for trigeminal neuralgia**

**Indications**
1. patients unable to achieve adequate medical control of trigeminal neuralgia with ≥5 yrs anticipated survival, without significant medical or surgical risk factors34 (although a small p-fossa exploration is usually well tolerated, surgical morbidity increases with age)
2. may be used in patients who do not fit the above criteria, but have intractable pain and fail PTR
3. patient with tic involving V1 for whom the risk of exposure keratitis due to corneal anesthesia would be unacceptable (e.g. already blind in contralateral eye) or patient wishing to avoid facial anesthesia for any reason
4. patients with MS are usually not considered candidates for MVD due to low response rate

**Booking the case: Microvascular decompression**

Also see defaults & disclaimers (p. 27) and pre-op preparation (see below).
1. position: park bench
2. equipment: microscope
3. implants: Ivalon sponge or shredded Teflon
4. intra-op monitoring: (optional) BAER, facial EMG (monitors VII and portio minor (motor) of VII), VIII (CNAP (compound nerve action potential) using Cueva electrode placed directly on VIII nerve referenced to ipsilateral earlobe)
5. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery behind the ear to move a blood vessel from the sensory nerve of the face, if no offending vessel can be identified then possible partial sectioning of the appropriate part of the trigeminal nerve with associated numbness
   b) alternatives: needle procedures through the cheek (percutaneous rhizotomy), radiation (stereotactic radiosurgery)
   c) complications: (in addition to usual craniotomy complications), CSF leak, hearing loss (≈10%), facial numbness, pain near incision (occipital neuralgia or lesser occipital neuralgia), rarely: diplopia, facial paralysis, failure of the procedure

**Technique**

Also see Paramedian suboccipital craniectomy (p.1447), for important pointers, including use of armored endotracheal tube.
Preoperative preparation
An MRI is recommended (with FIESTA sequence or equivalent, if available) to rule-out mass lesion or vascular abnormality. Baseline BAER are performed by some\textsuperscript{68} (see below for intra-op monitoring).

O.R. setup
Setup for lateral oblique suboccipital (posterior-fossa) craniotomy (p.1446). Microscope: observer’s eyepiece is placed on the side opposite to that of the tic.

Positioning
See reference.\textsuperscript{69}
1. lateral oblique position (p.1446), symptomatic side up, axillary roll
2. thorax elevated 10–15° to reduce venous pressure
3. 3-pin skull fixation. Head position:
   a) head rotation: head rotated 10–15° away from the affected side. Do not exceed 30° rotation
   b) lateral head tilt
      • for trigeminal neuralgia or VIII nerve approach: the head is parallel to the floor (if it is lower, nerves VII & VIII will obscure view of V)
      • for VII nerve or lower, the vertex is tilted 15° down from the horizontal
   c) flex neck: leave 2 fingerbreadths room between the chin and the sternum
4. upper shoulder retracted caudally with adhesive tape
5. option: lumbar spinal drain. Drain 20–30 cc during craniotomy, then drain off small amounts from time-to-time during the case to keep the field mostly dry, but occasionally letting CSF build up to bathe cranial nerves

Intra-operative monitoring
Option: intra-operative monitoring of facial EMG and BAER (assesses acoustic nerve).\textsuperscript{68}

Approach
1. skin incision\textsuperscript{69}: vertical incision 3–5 cm in length, 5 mm medial to mastoid notch, a small “5–6-4” incision (p.1448); in thick or short-necked patients, a slightly longer incision that angles inferomedially is used. 75% of the incision is inferior to the transverse sinus, 25%superior
2. burr hole:
   a) 1 cm inferior and 1 cm medial to the asterion\textsuperscript{70} (p.60)
   b) if the asterion is not easily identified or if there are concerns about the reliability of the asterion as a landmark for the junction of the transverse and sigmoid sinuses,\textsuperscript{71} place the burr hole directly over the mastoid emissary vein which drains superolaterally into the sigmoid sinus
3. craniotomy: top of bone opening as close as possible to transverse sinus. The position of the transverse sinus can be approximated by a line drawn from the posterior base of the zygomatic process to the inion, or roughly = 2 finger-breadths above the upper end of the mastoid notch. Lateral limit of bone opening is sigmoid sinus. A triangular bony opening with a leg along each sinus works well. Cranietomy diameter needs to be only = 3 cm. Apply bone wax liberally (blocks off any possible opening into the mastoid air cells)
4. dural opening: either a curvilinear with each end at a sinus and the convexity away from the junction (Jannetta) or an inverted “T” (with one incision towards each sinus and the third towards junction of sinuses)
5. minimal or no retraction of cerebellum is usually required
6. allow CSF to drain before proceeding: this may require gentle advancement of a cottonoid in the CPA. A lumbar drain should be placed if CSF cannot be drained
7. follow the junction of tentorium with temporal bone deep. Place a retractor that both medially displaces the cerebellum and slightly “lifts” the cerebellum towards the surgeon (medial displacement alone is not as effective)
8. petrosal vein: coagulate and divide the petrosal vein complex (usually 2–3 veins connecting to the tentorial dura). If the vein is torn, the dural side is tamponaded (sometimes up to 30 minutes is needed) while the free end is coagulated
9. V is deeper than the VII/VIII complex, which should not even be seen with this approach. If VII/VIII are seen, move the retractor superiorly as even gentle traction may cause hearing loss ( Fig. 1.9). There is often a hillock of bone just posterior to Meckel’s cave obscuring the site where the fifth nerve enters the cave
Decompression of nerve

1. arachnoid overlying the fifth nerve is sharply divided (caution re Cranial Nerve IV which follows the tentorial opening in the arachnoid rostral to the fifth nerve). Intra-op changes in BAER are often attributed to retraction of arachnoid that is tethered to the VII/VIII complex
2. the fifth nerve may be markedly atrophic if previous PTRs have been done
3. identify the smaller motor root (portio minor) of the fifth nerve
4. arteries and/or veins compressing V should be dissected off the nerve. NB: vessels located proximally are the most likely offenders, however, the dorsal root entry zone (which is the sensitive part of the nerve) may be variable in location and peripheral vessels may be culpable. The nerve should be inspected and freed of vessels from its origin at the brainstem all the way to its entrance into Meckel's cave. Veins may be coagulated and then should be divided (to prevent recanalization)
5. the most common cause of compression is the superior cerebellar artery (SCA)
6. check the nerve at the junction with brainstem for any residual compression prior to the next step
7. insulating material is interposed between nerve and vessel to prevent re-compression. Options include:
   a) e.g. Ivalon®, (polyvinyl formyl alcohol) sponge (Ivalon Surgical Products, 1040 OCL Parkway, Eudora, KS, 66025, U.S.A distributed by Fabco in the U.S.A. (860) 536–8499, toll free: (888) 813–8214, http://fabco.net/catalog/ivalon-ophthalmic/) cut in a saddle shape. Note: if an Ivalon block is used instead of pre-packaged sterile pads, it must be rinsed thoroughly to remove formalin, then autoclaved. Ivalon should be hydrated in NS for 10 minutes prior to cutting it
   b) shredded Teflon felt; see merits of Ivalon® vs. Teflon or muscle (p.1536)
8. Wilson recommends performing a partial sensory rhizotomy of the inferior one-half to two-thirds of the portio major for the following: cases where no vascular contact with the nerve or no deformity of the nerve is identified, in most cases of patients undergoing a repeat MVD, or for cases with duration of symptoms >8–9 yrs as this latter group tends to have a lower success rate with MVD alone
9. if the procedure is for a failed MVD and it is desired to partially divide the nerve, the nerve is organized somatotopically with V1 fibers superiorly, and V3 inferiorly. If the goal is total elimination of pain pathways and there is concern about pain conduction through ancillary pathways, consider also dividing the motor root (portio minor)

Closure

1. bone wax should be applied liberally to the exposed lateral bone edges (to paraphrase Dr. Jannetta and Mr. Miyagi, “Wax in, wax out.”)
2. irrigate gently with warm saline (avoid “jet” irrigation which can damage the VIII nerve)
3. intra-op BAER decline may occur on dural closure and should prompt re-opening of the dura and checking for tension on the VIII nerve from a vessel or Telfa
4. perform several Valsalva maneuvers to ensure watertight closure of dura
5. the bone defect should be covered e.g. with Burr hole cover to reduce chance of pain associated with uncovered craniectomy
6. after fascial closure, Valsalva maneuver is performed again to ensure watertight closure
7. use 4–0 running locked nylon to approximate skin in watertight fashion (avoid excessive tension)

Post-op care following MVD

Include in post-op orders
1. admit to ICU
2. arterial-line for continuous BP monitoring
3. analgesics (e.g. codeine 30–60 mg IM q 3 hrs)
4. anti-emetics (e.g. ondansetron 4 mg IV q 6 hrs)
5. medication to aggressively treat HTN (viz. SBP > 160 mm Hg)

Post-op H/A, nausea and pain

Patients routinely have H/A and nausea for 2–3 days (there tends to be less intracranial air and less “pneumoencephalogram sickness” if the park-bench position is used instead of the sitting position). However, severe H/A should prompt a STAT CT to R/O bleeding. If the CT is negative, severe H/A may be due to transient elevation of CSF pressure that occurs in some, and which usually responds to 1, or at most 2, LPs to halve the pressure. Aseptic meningitis usually responds to steroids. Some patients have continued but lessened tic douloureux pain for several days post-op, this usually subsides.
Complications
The short list:
1. cerebellar injury
2. hearing loss
3. CSF leak

The long list:
1. mortality: 0.22–2% in experienced hands (>900 procedures)^74,75
2. meningitis
   a) aseptic meningitis (AKA hemogenic meningitis): H/A, meningismus, mild fever, culture negative CSF, pleocytosis. Incidence: ≈ 2%(up to 20%has been reported). Usually occurs 3–7 days post-op. Responds to LP+steroids
   b) bacterial meningitis: 0.9%
3. major neurologic morbidity: 1–10%(higher rates with less experienced surgeons), including:
   a) deafness: 1%
   b) vestibular nerve dysfunction
   c) facial nerve dysfunction
4. mild facial sensory loss: 25%
5. cranial nerve palsies^76:
   a) fourth nerve (diplopia): 4.3%(only ≈ 0.1%are permanent)
   b) facial nerve: 1.6%(most are transient)
   c) eighth nerve (hearing loss): 3%
6. postoperative hemorrhage^77: subdural, intracerebral (1%^24), subarachnoid
7. seizures: including status epilepticus^77
8. infarction^77: including posterior cerebral artery distribution, brain stem
9. CSF leak: resolves with lumbar drainage in most cases
10. pneumonia: 0.6%

Outcome
1. success rate: 75–80%(rates may be lower in patients having prior destructive procedure); good but not total relief in an additional ≈ 10%
2. recurrence rate in large series is difficult to ascertain from literature; in a series of 40 patients followed 8.5 yrs mean^75:
   a) major recurrence (recurrent tic not controlled by medications) rate: 31%
   b) minor recurrence (mild or controlled by medications) rate: 17%
   c) using Kaplan-Meier curve, expect 70%to be either pain free or have minor recurrence by 8.5 years (or ≈ 80%at 5 years)
      the risk for a major recurrence after MVD is 3.5%annually
      the risk for a minor recurrence after MVD is 1.5%annually
   d) major recurrence rate is lower for patients having major arterial cross-compression of the nerve discovered at the time of surgery (patients with venous compression had much higher rate)
   e) this study found no correlation between previous destructive surgery and major recurrence rate (in 11 patients)

Some feel that the longer one waits before performing a MVD, the lower the success rate.

28.3.4 Supraorbital and supratrochlear neuralgia

Anatomy
The supraorbital and supratrochlear nerves arise from the frontal nerve and are 2 of the 5 branches of V1 (ophthalmic division of the trigeminal nerve). The supraorbital nerve is the largest branch. It exits the orbit through the supraorbital notch or foramen, usually within the medial third of the orbital roof (mean distance from exit to medial angle of orbit: 20 mm (range: 5–47)^78). The supratrochlear nerve exits the orbit without a foramen or notch 3–38 mm medial to the supraorbital nerve (mean: 15.3 mm)^78), the most medial branch varies from 8–30 mm lateral to the patient’s midline.^78

Supraorbital neuralgia characteristics
Trigeminal neuralgia (TGN) may present with pain in the distribution of the supraorbital nerve, however, the supraorbital nerve may be involved in supraorbital neuralgia (SON), a distinct syndrome
with different clinical characteristics. SON is a rare condition slightly more common in women, with onset typically 40–50 years of age.\textsuperscript{79} Characteristics\textsuperscript{80}: 1) unilateral pain in the distribution of the supraorbital nerve (Fig. 93.2), 2) tenderness in the region of the supraorbital notch or along the distribution of the nerve, and 3) temporary relief with nerve block.

The pain is usually chronic-continuous or remitting-intermittent.\textsuperscript{79} SON may be:

1. primary (no identifiable etiology): these cases lack any sensory loss
2. secondary (e.g. due to trauma to the area, or resulting from chronic pressure such as with wearing swim goggles): more common than primary SON. Most cases remit within one year\textsuperscript{79} with elimination of the offending pressure

**Supratrochlear neuralgia**

Cases of pain isolated to the supratrochlear nerve appear to exist. Supratrochlear neuralgia (STN) may be differentiated from SON by restriction of pain in the more medial forehead, and with relief on blockade of the supratrochlear nerve alone.

**Differential diagnosis**

1. migraine: suggested by nausea, vomiting and photophobia
2. associated autonomic activity is rare with SON, and should prompt consideration of cluster H/A (p.175) or SUNCT (p.478)
3. TGN: typical TGN features lacking in SON include characteristic triggers and pain consisting exclusively of paroxysmal/ultra-brief electric shock-like pain
4. hemicrania continua: continuous unilateral pain that tends to be located more posteriorly and is absolutely responsive to indomethacin\textsuperscript{80}
5. trochleitis: inflammation of the trochlea/superior-oblique muscle complex, may mimic supratrochlear neuralgia with pain of the medial upper orbit extending a short distance to the forehead.\textsuperscript{81} The pain is typically exacerbated by supraduction of the eye and to palpation of the trochlea, and is relieved with injection of local anesthetic or, by the usually definitive treatment of infiltration of corticosteroids close to the trochlea. Diplopia is rare and minimal
6. nummular (coin-like) H/A\textsuperscript{82}: round or oval 2–6 cm diameter area of pressure-like continuous head pain without underlying structural abnormality. In 13 patients, 9 (70%) the area was located at the parieto-occipital junction. 9 (70%) demonstrated hypoesthesia and touch provoked paresthesias in the affected area

**Treatment**

Gabapentin (800–2400 mg/d) or pregabalin (150 mg/d) is helpful for some.\textsuperscript{83} Topical capsaicin (p.482) applied to the symptomatic area may help.

Refractory cases may respond to rhizotomy with alcohol (providing an average of 8.5 months relief\textsuperscript{84}) or with radiofrequency ablation.

Persistent cases may require exploration and decompression of the nerve by lysing bands overlaying the supraorbital notch,\textsuperscript{85} or, ultimately, to neurectomy (p.483) which provides an average of 33.2 months relief.\textsuperscript{86}

**28.3.5 Glossopharyngeal neuralgia**

**Epidemiology**

Incidence: 1 case for every 70 of trigeminal neuralgia.\textsuperscript{87}(p 3604–5)

**Clinical**

Severe, lancinating pain in the distribution of the glossopharyngeal and vagus nerves (throat & base of tongue most commonly involved, radiates to ear (otalgia), occasionally to neck), occasionally with salivation and coughing. Rarely: hypotension,\textsuperscript{88} syncope,\textsuperscript{89} cardiac arrest and convulsions may accompany. May be triggered by swallowing, talking, chewing. Trigger zones are rare.

**Treatment**

Pain may be reduced by cocaineization of tonsillar pillars and fossa. Usually, the persistence and severity of pain requires surgical intervention. One may either perform microvascular decompression,
or nerve division via extra- or intra-cranial approach (latter may be required for permanent relief).

Intracranial approach: Section of preganglionic glossopharyngeal nerve (IX) and upper one–third or two fibers (whichever is larger) of vagus (X). IX is readily identified at its dural exit zone where it is separated from X by a dural septum. The upper third of X is usually composed of a single rootlet, or less commonly, multiple small rootlets. Initial post-op dysphagia usually resolves. Cardiovascular complications following vagal section have been reported, warrants close monitoring × 24 hrs.

28.3.6 Geniculate neuralgia

General information

Geniculate neuralgia (GeN) AKA Hunt’s neuralgia AKA nervus intermedius neuralgia: a very rare neuralgia affecting the nervus intermedius (the somatic sensory branch of the facial nerve primarily innervating mechanoreceptors of the hair follicles on the inner surface of the pinna and deep mechanoreceptors of nasal and buccal cavities and chemoreceptors in the taste buds on the anterior 2/3 of the tongue).

Symptoms: unilateral paroxysmal otalgia (lancinating pain experienced deep within the ear, often described as an “ice pick in the ear”) radiating to the auricle, with occasional burning sensations around the ipsilateral eye and check, and prosopalgia (pain referred to deep facial structures, including orbit, posterior nasal and palatal regions). During pain attacks, some patients have: salivation, bitter taste, tinnitus, or vertigo.

GeN occasionally has cutaneous trigger points in the anterior EAC and tragus, and pain may also be triggered by cold, noise, or swallowing.

Work-up includes neuro-otologic evaluation with audiometry and ENG. Some patients may require imaging (MRI or high-resolution CT) and angio (to R/O aneurysm).

Variants

Tic convulsif (AKA convulsive tic): GeN combined with hemifacial spasm, usually due to neurovascular compression of both the sensory and motor roots of the facial nerve, most often by AICA. First described by Cushing in 1920.

GeN may be associated with herpetic infections of the geniculate ganglion (AKA herpetic ganglionitis, AKA Ramsay Hunt syndrome (RHS)) in which case herpetic lesions appear on pinna, in EAC, and possibly on TM. May include facial palsy, decreased auditory acuity, tinnitus or vertigo. Unlike idiopathic GeN, RHS is more chronic and less paroxysmal, tends to remit with time, and is usually refractory to carbamazepine. Idiopathic GeN tends to be more painful than RHS, and does not remit spontaneously.

Treatment

1. medical therapy
   a) mild cases may respond to carbamazepine, sometimes in combination with phenytoin
   b) may respond to valproate (Depakote®) 250 mg PO BID
   c) topical antibiotics for secondary infections of herpetic lesions
   d) local anesthetic to EAC

2. surgery: for severe cases where medical treatment fails or is not tolerated
   a) microvascular decompression together with division of the nervus intermedius (nerve of Wrisberg)90. To find the nerve, a micro nerve hook is hooked around the VII nerve, the hook is rotated 90°, and the nerve is fished out from in front of VII. Operating under local anesthesia allows verification by stimulating nerve
   b) geniculate ganglion section91

28.4 Postherpetic neuralgia

28.4.1 General information

Herpes zoster (HZ) (Greek: zoster – girdle) (shingles in lay terms): painful vesicular cutaneous eruptions caused by the herpes varicella zoster virus (VZV) (the etiologic agent of chickenpox, a herpesvirus that is distinct from herpes simplex virus). It occurs in a dermatomal distribution over one side of the thorax in ≈ 65% of cases (rarely, infections occur without vesicles, called zoster sine herpete). In 20% of cases it involves the trigeminal nerve (with a predilection for the ophthalmic division, called herpes zoster ophthalmicus). Pain usually resolves after 2–4 weeks. When the pain persists >1
month after the vesicular eruption has healed, this pain syndrome is known as postherpetic neuralgia (PHN). PHN can follow a herpes varicella infection in any site and is difficult to treat by any means (medical or surgical). It can occasionally be seen in a limb, and follows a dermatomal distribution (not a peripheral nerve distribution). PHN may remit spontaneously, but if it hasn’t done so by 6 mos this is unlikely.

28.4.2 Epidemiology

Incidence of herpes zoster is \( \approx 125/100,000/\text{year} \) in the general population, or about 850,000 cases per year in the U.S.\(^{92}\) Both sexes are equally affected. There is no seasonal variance. HZ is also more common in those with reduced immunity and in those with a coexistent malignancy (especially lympho-proliferative).\(^{93,94}\) PHN occurs in \( \approx 10\% \) of cases of HZ.\(^{92}\) Both HZ and PHN are more common in older patients (PHN is rare in age <40 yrs, and usually occurs in age >60) and in those with diabetes mellitus. PHN is more likely after ophthalmic HZ than after spinal segmental involvement.

28.4.3 Etiology

It is postulated that the VZV lies dormant in the sensory ganglia (dorsal root ganglia of the spine, trigeminal (semilunar) ganglion for facial involvement) until such time that the patient’s immune system is weakened and then the virus erupts. Inflammatory changes within the nerve are present early and are later replaced by fibrosis.

28.4.4 Clinical

PHN is usually described as a constant burning and aching. There may be superimposed shocks or jabs. It rarely produces throbbing or cramping pain. Pain may be spontaneous, or may be triggered by light cutaneous stimulation (allodynia) (e.g. by clothing), and may be relieved by constant pressure. The pain is present to some degree at all times with no pain-free intervals. Scars and pigmentary changes from the acute vesicular eruption are usually visible. It is not known if PHN can follow zoster sine herpete. The involved area may demonstrate hypesthesia, hypalgesia, paresthesias and dysesthesias.

28.4.5 Medical treatment

For herpes zoster

Varicella vaccination of older individuals can increase immunity to herpes zoster, but it will be several years before it can be determined if this will reduce PHN.\(^{92}\) Treatment for the pain of the acute attack of herpes zoster may be accomplished with epidural or paravertebral somatic (intercostal) nerve block.\(^{95}(p\ 4018)\)

Oral antiviral drugs: Also effective (they shorten the duration of pain) and also reduce the incidence of PHN. They may cause thrombotic thrombocytopenic purpura/hemolytic uremic syndrome (TTP/HUS) when used in severely immunocompromised patients at high doses. These drugs include:

- Acyclovir (Zovirax®): poorly absorbed from the GI tract (15–30% bioavailability). 800 mg PO q 4 hrs 5 times/d \( \times \) 7 d.
- Valacyclovir (Valtrex®)\(^{96}\) is a prodrug of acyclovir and is more completely absorbed and should be equally as effective with fewer daily doses. 1,000 mg PO TID starting within 72 hrs of onset of the rash \( \times \) 7 days.
- Famciclovir (Famvir®): 500 mg PO TID \( \times \) 7 d.

For post-herpetic neuralgia

General information

Most drugs useful for trigeminal neuralgia (p.481) are less effective for PHN. Some treatment alternatives for PHN are summarized in Table 28.5. Details of some drugs follows. It is suggested to initiate therapy with lidocaine skin patches (p.496) since this modality has the lowest potential for serious side effects.\(^{92}\)
An antiepileptic drug

Drug info: Gabapentin (Neurontin®)

FDA approved only for partial seizures and postherpetic neuralgia (PHN).

Side effects: dizziness and somnolence (usually during titration, often diminish with time). Ataxia, fatigue, peripheral edema, confusion and depression may occur.

Rx For PHN, start with 300 mg on Day 1, 300 mg BID on Day 2, and 300 mg TID on Day 3. Dose may be titrated up to 1800 mg/d divided TID. To limit daytime drowsiness, patients may need to start with 100 mg at hs and increase slowly over 3–8. Although doses up to 3600 mg/day (the antiseizure dose) were studied there was no significant benefit for PHN over 1800 mg/d. Lower doses are required for renal insufficiency. Supplied: 100, 300 & 400 mg capsules; 600 & 800 mg scored tabs. 50 mg/ml suspension.

*modified with permission from Rubin M, Relief for postherpetic neuralgia, Neurology Alert, 6: 33–4, 2001

babbreviations: oxycodone CR=controlled release (Oxycontin®); HZ=herpes zoster; PHN=postherpetic neuralgia; SNRIs=serotonin-norepinephrine reuptake inhibitor; SSRIs=selective serotonin reuptake inhibitors (e. g. Prozac®),
Drug info: Oxcarbazepine (Trileptal®)

150 mg PO BID.

Drug info: Zonisamide (Zonegran®)

Initiate therapy with 100 mg PO q PM × 2 wks, then increase dose by 100 mg/d q 2 wks up to 400 mg/d. Bioavailability is not affected by food. Steady state is achieved within 14 days of dosage changes. Supplied: 100 mg capsules.

Tricyclic antidepressants (TCA)

Drug info: Amitriptyline (Elavil®)

Helpful in ≈ 66% of patients at a mean dose of 75 mg/d even without antidepressant effect. Side effects: see Amitriptyline, side effects (p. 545), minimized by starting low and slowly incrementing dose. Start with 12.5–25 mg PO q hs, and increase by the same amount q 2–5 days to a maximum of 150 mg/d.

Drug info: Nortriptyline (Pamelor®)

Fewer side effects than amitriptyline. Start with 10–20 mg PO q hs, and increase gradually.

Topical treatment

Drug info: Capsaicin (Zostrix®)

A vanillyl alkaloid derived from hot peppers, available without prescription for topical treatment of the pain of herpes zoster and diabetic neuropathy. Beneficial in some patients with either of these conditions (response rate at 8 weeks was 90% for PHN, 71% for diabetic neuropathy, vs. 50% with placebo in either group), although the high placebo response rate is disturbing and many authorities are skeptical. Expensive. Side effects: include burning and erythema at the application site (usually subsides by 2–4 weeks). Manufacturer recommends massaging the medication into the affected area of the skin TID-QID (apply a very thin coat). Some authorities recommend q 2 hr application. Avoid contact with eyes or damaged skin. Supplied as Zostrix® (0.25% capsaicin) or Zostrix-HP® (0.75%).

Drug info: Lidocaine patch 5% (Lidoderm®)

Often better tolerated by elderly patients than TCAs (due to pre-existing cognitive impairments, cardiac disease, or systemic illness). Apply up to 3 patches of 5% lidocaine (to cover a maximum of 420 cm²) to intact skin q 12 hrs to cover as much of the area of greatest pain as possible.
Intrathecal steroids
Over 90% of patients receiving intrathecal methylprednisolone (60 mg) + 3% lidocaine (3 ml) given once per week for up to 4 weeks, reported good to excellent pain relief for up to 2 years. This technique was not studied for use in PHN involving the trigeminal nerve. Further clinical trials are needed to verify the efficacy and safety (potential long-term side effects include adhesive arachnoiditis).

Surgical treatment
There is no operation that is uniformly successful in treating PHN. Numerous operations have been shown to work occasionally. Procedures that have been tried include:
1. nerve blocks: once PHN is established, nerve blocks provide only temporary relief
2. cordotomy: although percutaneous cordotomy (p. 1542) may work when the level of PHN is at least 3–4 segments below the cordotomy, this procedure is not recommended for pain of benign etiology because of possible complications and the high likelihood of pain recurrence
3. rhizotomy: including retrogasserian for facial involvement
4. neurectomies
5. sympathectomy
6. DREZ (p. 1550): often offers good early relief, but recurrence rate is high.
7. acupuncture
8. TENS
9. spinal cord stimulation (p. 1547)
10. undermining the skin
11. motor cortex stimulation: for facial PHN

28.5 Complex regional pain syndrome (CRPS)

28.5.1 General information
The terminology is confusing. Formerly also called causalgia (reflex sympathetic dystrophy). The term causalgia (Greek: kausis–burning, algos–pain) was introduced by Weir Mitchell in 1864. It was used to describe a rare syndrome that followed a minority of partial peripheral nerve injuries in the American civil war. Triad: burning pain, autonomic dysfunction and trophic changes.

CRPS Type II (AKA major causalgia) follows nerve injury (originally described after high velocity missile injuries). CRPS Type I (AKA reflex sympathetic dystrophy or causalgia minor) denoted less severe forms, and has been described after non-penetrating trauma. Shoulder-hand syndrome and Sudeck’s atrophy are other variant designations. In 1916, the autonomic nervous system was implicated by René Leriche, and the term reflex sympathetic dystrophy (RSD) later came into use (but RSD may be distinct from causalgia).

Post-op CRPS has been described following carpal tunnel surgery as well as surgery on the lumber and cervical spine.

At best, CRPS must be regarded as a symptom complex, and not as a discrete syndrome nor medical entity (for a cogent editorial on the subject, see the essay by Ochoa). Patients exhibiting CRPS phenomenology are not a homogeneous group, and include:
1. actual CRPS (for these, Mailis proposes the term “physiogenic RSD”): a complex set of neuropathic phenomena that may occur with or without nerve injury
2. medical conditions distinct from CRPS but with signs and symptoms that mimic CRPS: vascular, inflammatory, neurologic…
3. the product of mere immobilization: as in severe pain avoidance behavior, or at times psychiatric disorders
4. part of a factitious disorder with either a psychological basis (e.g. Munchausen’s syndrome) or for secondary gain (financial, drug seeking… ) i.e. malingering

28.5.2 Pathogenesis
Early theories invoked ephaptic transmission between sympathetics and afferent pain fibers. This theory is rarely cited currently. Another more recent postulate involves nor-epinephrine released at sympathtic terminals together with hypersensitivity secondary to denervation or sprouting. Many modern hypotheses do not even embrace involvement of the autonomic nervous system in all cases.

Thus, many of the alterations seen in CRPS may simply be epiphenomena rather than part of the etiopathogenetic mechanism.
28.5.3 Clinical
CRPS may be described as a phenomenology, i.e. a variable complex of signs and symptoms due to multiple etiologies included in this nonhomogeneous group.\textsuperscript{110} No diagnostic criteria for the condition have been established, and various investigators select different factors to include or exclude patients from their studies.

28.5.4 Symptoms
Pain: affecting a limb, usually burning, and prominent in the hand or foot. Onset in the majority is within 24 hrs of injury (unless injury causes anesthesia, then hrs or days may intervene); however, CRPS may take days to weeks to develop. Median, ulnar and sciatic nerves are the most commonly cited involved nerves. However, it is not always possible to identify a specific nerve that has been injured. Almost any sensory stimulus worsens the pain (allodynia is pain induced by a nonnoxious stimulus).

28.5.5 Signs
The physical exam is often difficult due to pain.
Vascular changes: either vasodilator (warm and pink) or vasoconstrictor (cold, mottled blue). Trophic changes (may be partly or wholly due to immobility): dry/scaly skin, stiff joints, tapering fingers, ridged uncut nails, either long/course hair or loss of hair, sweating alterations (varies from anhidrosis to hyperhidrosis).

28.5.6 Diagnostic aids
In the absence of an agreed upon etiology or pathophysiology, there can be no basis for specific tests, and the lack of a “gold-standard” diagnostic criteria makes it impossible to verify the authenticity of any diagnostic marker. Numerous tests have been presented as aids to the diagnosis of CRPS, and essentially all have eventually been refuted. Candidates have included:
1. thermography: discredited in clinical practice
2. three-phase bone scan: typical CRPS changes also occur after sympathectomy,\textsuperscript{111} which has traditionally been considered curative of CRPS
3. osteoporosis on x-ray,\textsuperscript{112} particularly periarticular demineralization: nonspecific
4. response to sympathetic block (once thought to be the sine qua non for causalgia major and minor, the response sought was relief (complete or significant) with sympathetic block of appropriate trunk (stellate for UE, lumbar for LE)): has failed to hold up once stringent placebo-controlled trials were executed
5. various autonomic tests\textsuperscript{113}: resting sweat output, resting skin temperature, quantitative sudomotor axon reflex test

28.5.7 Treatment
In the absence of a delineated pathophysiology, treatment is judged purely by subjective impression of improvement. CRPS treatment studies have had an unusually high placebo response rate.\textsuperscript{114} Medical therapy is usually ineffective. Proposed treatments include:
1. tricyclic antidepressants
2. 18–25% have satisfactory long-lasting relief after a series of sympathetic blocks, see Stellate ganglion block (p.1521) and Lumbar sympathetic block (p.1521), although one report found no long-lasting benefit in any of 30 patients\textsuperscript{115}
3. intravenous regional sympathetic block, particularly for UE CRPS: agents used include guanethidine\textsuperscript{116} 20 mg, reserpine, bretylium..., injected IV with arterial tourniquet (sphygmomanometer cuff) inflated for 10 min. If no relief, repeat in 3–4 wks. No better than placebo in several trials\textsuperscript{117},\textsuperscript{118}
4. surgical sympathectomy (p.1537): some purport that this relieves pain in >90% of patients (with a few retaining some tenderness or hyperesthesia). Others opine that there is no rational reason to consider sympathectomy since sympathetic blocks have been shown to be no more effective than placebo\textsuperscript{106}
5. spinal cord stimulation: some success has been reported

Peripheral Nerves

29 Peripheral Nerves 504

30 Entrapment Neuropathies 515

31 Non-Entrapment Peripheral Neuropathies 541
29 Peripheral Nerves

29.1 General information

29.1.1 Peripheral nervous system definition

The peripheral nervous system (PNS) consists of those structures (including cranial nerves III-XII, spinal nerves, nerves of the extremities, and the cervical, brachial and lumbosacral plexi) containing nerve fibers or axons that connect the central nervous system (CNS) with motor and sensory, somatic and visceral, end organs. Table 29.1 shows classification of motor and sensory nerves.

29.1.2 Grading strength and reflexes

Muscle strength grading most commonly employs the Royal Medical Research Council of Great Britain (MRC) scale, a common modification of which is shown in Table 29.2. Muscle stretch reflexes may be graded as shown in Table 29.3.

29.1.3 Upper motor neuron vs. lower motor neuron

Lower motor neurons (LMN) (first-order motor neuron): cell bodies (soma) reside in spinal cord (in anterior gray matter) or in brainstem (for cranial nerve motor nuclei). Axons connect directly to neuromuscular junction of muscles.

Upper motor neurons (UMN) (second-order motor neurons): some soma reside in the primary motor cortex (precentral gyrus) of the brain. Axons project to LMNs.

See Table 29.4 for comparison of weakness due to UMN vs. LMN.

*these fibers to the posterior columns are more medial in the root entry zone than the C-fibers (important in DRZ lesions where the goal is to lesion C-fibers and spare A-beta)
Fasciculations vs. fibrillations

Fasciculations are coarse muscle contractions that are visible to the naked eye, whereas fibrillations are not visible and require EMG to detect; AKA fibrillation potentials (p.242).
Fasciculations represent discharge of a group of muscle fibers (all or part of an entire motor unit), and occur most often in diseases involving anterior horn cells, including:

1. amyotrophic lateral sclerosis (ALS) (p.183)
2. spinal muscular atrophy (p.1413)
3. polio
4. syringomyelia

<sup>a</sup>Peripheral Nerves

<sup>b</sup>http://e-surg.com

<sup>c</sup>http://e-surg.com
29.3 Peripheral nerve injury/surgery

29.3.1 Nerve action potentials

Stimulating a healthy nerve fiber with an electrical stimulus of an amplitude and duration that exceeds its threshold will produce a conducted impulse, or nerve action potential (NA P). Medium-sized axons (fibers) have a lower threshold than large ones which have lower threshold than small or fine axons.

29.3.2 Use of NA P with lesion in continuity

There is some degree of continuity in ≥60% of nerve injuries. For a lesion in continuity (LIC), if surgical repair is needed, it may be too late if one waits until there is failure of anticipated clinical improvement. Presence of a NAP (regardless of amplitude or latency) distal to an LIC in the first few months after an injury usually indicates that operative intervention will not be needed. For recommended timing to obtain NAP recording, see Table 29.8.
29.3.3 Timing of surgical repair

The longer the distance from the injury site to the functional unit to be reinnervated, the earlier surgical intervention should be considered. 4(p.74)

24 month rule 4(p.74): after 24 months of denervation, most muscles cannot recover useful function even with reinnervation. Exceptions: facial muscles, large bulky muscles such as biceps, brachialis, gastrocs, and some lesions in continuity with some preserved innervation.

29.3.4 Brachial plexus

General information

Formed by ventral rami (the dorsal rami innervate the paraspinal muscles), most commonly of nerve roots C5-T1 (schematically depicted in Fig. 29.1.

Table 29.8 Recommended timing to obtain NAP recording

Table 29.5 shows action, etc. of specific muscles. Also see Fig. 29.1. indicates that the nerve supplies the muscles listed; denotes a branch of the preceding nerve.

Nerves arising from the brachial plexus

Radial nerve (C5-C8)

See Fig. 29.2.
Radial nerve (and its branches) innervate the extensors of arm and forearm:
- triceps (all 3 heads)
- anconeus
- brachioradialis
- extensor carpi radialis longus & brevis (latter originates at terminal branch)
- supinator (originates near the terminal branch)
- continues into forearm as posterior interosseous nerve (C7, C8)
  - extensor carpi ulnaris
  - extensor digitorum
  - extensor digiti minimi
  - extensor pollicis brevis & longus
  - abductor pollicis longus
  - extensor indicus

Axillary nerve (C5, C6)

See Fig. 29.2.
- teres minor
- deltoid

Median nerve (C5-T1)

See Fig. 29.3, also see Martin-Gruber anastomosis (p. 514).
- nothing in arm
- all forearm pronators and flexors except the two supplied by ulnar nerve
  - pronator teres
  - flexor carpi radialis
  - palmaris longus
  - flexor digitorum superficialis
- in the hand only the “LOAF muscles”
  - Lumbricals 1 & 2
  - Opponens pollicis
  - Abductor pollicis brevis
  - Flexor pollicis brevis (C8, T1)
- branch at or just distal to elbow anterior interosseous nerve (purely motor)
- flexor digitorum profundus I & II
- flexor pollicis longus
  - pronator quadratus

Ulnar nerve (C8, T1)

Fig. 29.3. (Note: This is classic winging of the scapula. A variant of winging can occur with loss of trapezius muscle, e.g., with accessory nerve injury, and typically manifests when the patient pushes forward with the elbow held at the side of the thorax.)
- nothing in arm
- only 2 muscles in forearm:
  - flexor carpi ulnaris
  - half of flexor digitorum profundus (parts III & IV)
- all hand muscles excluding “LOAF” muscles (see above), viz.:
  - adductor pollicis
  - all interossei (4 dorsal & 3 palmar)
  - lumbricals 3 & 4
  - 3 hypothenar muscles: abductor, opponens & flexor digiti minimi
  - deep part of flexor pollicis brevis (by deep branch of ulnar nerve)
  - palmaris brevis (by the superficial branch of the ulnar nerve)
Musculocutaneous nerve (C5, C6)
Supplies arm flexors
• Coracobrachialis
• Biceps
• Brachialis

Lateral cutaneous nerve of the forearm (terminal branch) supplies cutaneous sensation to radial aspect of forearm.

Dorsal scapular nerve (C4, C5)
• Rhomboids (major & minor)
• Levator scapulae
Suprascapular nerve (C5, C6)
- Supraspinatus
- Infraspinatus

Subscapular nerve (C5–7)
- teres major
- subscapularis

Thoracodorsal nerve (C6, C7, C8)
- latissimus dorsi

Fig. 29.3 Muscles of the median and ulnar nerves
Long thoracic nerve (C5–7)
Originates off of proximal nerve roots
serratus anterior (holds scapula to chest wall): lesion → winging of the scapula. To test: patient leans forward against wall with arms outstretched, scapula separates from posterior chest wall if the serratus anterior is not contracting. (Note: This is classic winging of the scapula. A variant of winging can occur with loss of trapezius muscle, e.g. with accessory nerve injury, and typically manifests when the patient pushes forward with the elbow held at the side of the thorax.)

Anatomic variants
Martin-Gruber anastomosis
See reference. See reference.
Anastomosis between median and ulnar nerves in the forearm found in 16 of 70 (23%) cadavers, bilateral in 3 (19%). Pattern I (90%): 1 anastamotic branch, Pattern II (10%) had 2.
Classification based on the origin from the median nerve: Type a (47.3%) from the branch to the superficial forearm flexor muscles, Type b (10.6%) from the common trunk, and Type c (31.6%) from the anterior intersseous nerve. Pattern II was a duplication of Type c (10.5%). The anastomotic branch was undivided in 15 cases, and divided into two branches in four cases. The anastomosis took an oblique angle or arched course to the ulnar nerve and passed superficial to the ulnar artery in four cases, deep to it in six, and in nine cases it was related to the anterior ulnar recurrent artery. See reference.

Richie-Cannieu anastomosis
Motor connections from median to ulnar nerve at the palm. Found in 70% of patients.

References
Entrapment Neuropathies

30.1 General information
Entrapment neuropathy is a peripheral nerve injury resulting from compression either by external forces or from nearby anatomic structures. Mechanism can vary from one or two significant compressive insults to many localized, repetitive mild compressions of a nerve. Certain nerves are particularly vulnerable at specific locations by virtue of being superficial, fixed in position, traversing a confined space, or in proximity to a joint. The most common symptom is pain (frequently at rest, more severe at night, often with retrograde radiation causing more proximal lesion to be suspected) with tenderness at the point of entrapment. Referred pain is so common that Frank Mayfield once said that patients with nerve entrapment don’t know where the problem is located. Always consider the possibility of a systemic cause. Entrapment neuropathies may be associated with:
1. diabetes mellitus
2. hypothyroidism: due to glycogen deposition in Schwann cells
3. acromegaly
4. amyloidosis: primary or secondary (as in multiple myeloma)
5. carcinomatosis
6. polymyalgia rheumatica (p.198)
7. rheumatoid arthritis: 45% incidence of 1 or more entrapment neuropathies
8. gout

30.2 Mechanism of injury
Brief compression primarily affects myelinated fibers, and classically spares unmyelinated fibers (except in cases of severe acute compression). Acute compression compromises axoplasmic flow which can reduce membrane excitability. Chronic compression affects both myelinated and unmyelinated fibers and can produce segmental demyelination in the former, and if the insult persists, axolysis and wallerian degeneration will occur in both types. The issue of ischemia is more controversial. Some contend that simultaneous venous stasis at the site of compression can produce ischemia which can lead to edema outside the axonal sheath which may further exacerbate the ischemia. Eventually, fibrosis, neuroma formation, and progressive neuropathy can occur.

30.3 Occipital nerve entrapment
30.3.1 General information
Greater occipital nerve (nerve of Arnold) is a sensory branch of C2 (Fig. 28.1 for dermatome). Entrapment presents as occipital neuralgia: pain in occiput usually with a trigger point near the superior nuchal line. Pressure here reproduces pain radiating up along back of head towards vertex. More common in women.

30.3.2 Differential diagnosis
1. headache
   a) may be mimicked by migraine headache
   b) may be part of muscle contraction (tension) headache
2. myofascial pain: the pain may be widely separated from the trigger point
3. vertebrobasilar disease including aneurysm and SAH
4. cervical spondylosis
5. pain from Chiari I malformation (p.277)

30.3.3 Possible causes of entrapment
1. trauma
   a) direct trauma (including iatrogenic placement of suture through the nerve during surgical procedures, e.g. in closing a posterior fossa craniectomy)
   b) following traumatic cervical extension which may crush the C2 root and ganglion between the C1 arch and C2 lamina
   c) fractures of the upper cervical spine
2. atlanto-axial subluxation (AAS) (e.g. in rheumatoid arthritis) or arthrosis
3. entrapment by hypertrophic C1–2 (epistrophic) ligament
4. neuromas
5. arthritis of the C2–3 zygapophyseal joint

30.3.4 Treatment

General information

Σ

For idiopathic occipital neuralgia: available evidence is from small, retrospective, case series studies and is insufficient to conclude that either local injection or surgery are effective. Nerve blocks with steroids and local anesthetics provide only temporary relief. Surgical procedures such as nerve root decompression or neurectomy may provide effective pain relief for some patients; however, patient-selection criteria for these procedures have not been defined, and recurrence is common.

In idiopathic cases with no neurologic deficit, the condition is usually self limited.

Non surgical treatment

1. greater occipital nerve block with local anesthetic and steroids (see below)
   a) may provide relief typically lasting ≈ 1 month
   b) is no longer considered diagnostic because it is not sufficiently specific
2. physical therapy: massage and daily stretching exercises
3. TENS unit: provided ≥ 50% relief in 13 patients for up to 5 yrs
4. oral antiinflammatory agents
5. centrally acting pain medications: Neurontin, Paxil, Elavil...
6. botulinum toxin injection: although this study had quite a few placebo responders

If these measures do not provide permanent relief in disabling cases, surgical treatment may be considered, although caution is advised by many due to poor results. Alcohol neurolysis may be tried. A collar is not indicated as it may irritate the condition.

Occipital nerve block

Inject trigger point(s) if one or more can be identified (there is usually a trigger point near the superior nuchal line). The nerve may also be blocked at the point where it emerges from the dorsal neck muscles.

If the pathology is more proximal (e.g. at C2 spinal ganglion), then block of the ganglion may be required. Technique (done under fluoroscopy): shave hair below the mastoid process; prep with iodine; infiltrate with local; insert a 20 gauge spinal needle midway between C1 and C2, halfway between the midline and the lateral margin of the dorsal neck muscles. Aim rostrally, the final target is the midpoint of the C1–2 joint on AP fluoro, and almost but not touching the inferior articular process of C1. Infiltrate 1–3 ml of anesthetic and check for analgesia in the C2 distribution.

Surgical treatment

1. decompression of C2 nerve root if compressed between C1 and C2
2. in cases of AAS, decompression and atlanto-axial fusion (p. 1479) may work

Surgical treatment options for idiopathic occipital neuralgia:

1. peripheral occipital nerve procedures: these may not be effective for proximal compression of the C2 root or ganglion:
   a) occipital neurectomy (see below)
      • peripheral avulsion of the nerve
      • avulsion of the greater occipital nerve as it exits between the transverse process of C2 and the inferior oblique muscle
   b) alcohol injection of greater occipital nerve
2. occipital nerve stimulators
3. release of the nerve within the trapezius muscle. Immediate results: relief in 46% improvement in 36% Only 56% reported improvement at 14.5 mos
4. intradural division of the C2 dorsal route via a posterior intradural approach
5. ganglionectomy

Occipital neurectomy: The occipital nerve usually pierces the cervical muscles ≈ 2.5 cm lateral to the midline, just below the inion. Palpation or doppler localization of the pulse of the accompanying greater occipital artery sometimes helps to locate the nerve. However, relief only occurs in ≈ 50% and recurrence, usually within a year, is common.

30.4 Median nerve entrapment

30.4.1 General information
The two most common sites of entrapment of the median nerve:
1. at the wrist by the transverse carpal ligament: carpal tunnel syndrome (see below)
2. in upper forearm by pronator teres muscle: pronator teres syndrome (p.521)

30.4.2 Anatomy
Contributing nerve roots: C5 through T1. The median nerve arises from the medial and lateral cords of the brachial plexus (Fig. 29.1), and descends the upper arm adjacent to the lateral side of the brachial artery. It crosses to the medial side of the artery at the level of the coracobrachialis. In the cubital fossa, the median nerve passes behind the lacertus fibrosus (bicipital aponeurosis) and enters the upper forearm between the two heads of the pronator teres and supplies this muscle.

Just beyond this point, it branches to form the purely motor anterior interosseous nerve which supplies all but 2 muscles of finger and wrist flexion. It descends adherent to deep surface of flexor digitorum superficialis (FDS), lying on the flexor digitorum profundus. Near the wrist, it emerges from the lateral edge of FDS becoming more superficial, lying medial to the tendon of flexor carpi radialis, just lateral to and partially under the cover of the palmaris longus tendon. It passes under the transverse carpal ligament (TCL) through the carpal tunnel which also contains the tendons of the flexor digitorum profundus and superficialis deep to the nerve (9 tendons total, 2 to each finger, 1 to the thumb). The motor branch arises deep to the TCL, but may anomalously pierce the TCL. It supplies the “LOAF muscles” (Lumbricals 1 & 2, Opponens pollicis, and Abductor and Flexor pollicis brevis).

The TCL attaches medially to pisiform and hook of hamate, laterally to trapezium and tubercles of scaphoid. TCL is continuous proximally with fascia over FDS and antebrachial fascia, distally with the flexor retinaculum of the hand. The TCL extends distally into the palm to ≈ 3 cm beyond the distal wrist crease. The palmaris longus tendon, which is absent in 10% of population, partially attaches to the TCL.

Palmar cutaneous branch (PCB) of median nerve: arises from the radial aspect of the median nerve approximately 5.5 cm proximal to styloid process of the radius, underneath the cover of FDS of the middle finger. It crosses the wrist above the TCL to provide sensory innervation to the base of the thenar eminence (and is thus spared in carpal tunnel syndrome).

The sensory distribution of the average median nerve is shown in Fig. 30.1.

30.4.3 Injuries to the main trunk of the median nerve

General information
Above the elbow, the median nerve may rarely be compressed by Struther’s ligament (see below). At the elbow and forearm, the median nerve may rarely be trapped at any of three sites: 1) lacertus fibrosus (bicipital aponeurosis), 2) pronator teres, 3) sublimis bridge. Neuropathy may also result from direct or indirect trauma or external pressure (“honeymoon paralysis”). Longstanding compression of the main trunk of the median nerve produces a “benediction hand” when trying to make a fist (index finger extended, middle finger partially flexed; due to weakness of flexor digitorum profundus I & II).
**Struther’s ligament**

Distinct from struthers arcade (p. 527) which is a normal finding. The supracondylar process (SCP) is an anatomical variant located 5–7 cm above medial epicondyle, present in 0.7–2.7% of population. Struther’s ligament bridges the SCP to the medial epicondyle. The median nerve and brachial artery pass underneath, the ulnar nerve may also. Usually asymptomatic, but occasionally may cause typical median nerve syndrome.

**Pronator (teres) syndrome**

From direct trauma or repeated pronation with tight hand-grip. Trapped where nerve dives between 2 heads of pronator teres. Causes vague aching and easy fatiguing of forearm muscles with weak grip and poorly localized paresthesias in index finger and thumb. Nocturnal exacerbation is absent. Pain in palm distinguishes this from carpal tunnel syndrome (CTS) since the median palmar cutaneous branch (PCB) exits before the TCL and is spared in CTS.

Treat with resting forearm. Surgical decompression indicated for cases that progress while on rest or when continued trauma is unavoidable.

**Anterior interosseous neuropathy**

General information

**Key concepts**

- weakness of 3 muscles: FDP I & II, FPL, & pronator quadratus. No sensory loss
- loss of flexion of the distal phalanges of the thumb and index finger (pinch sign)
The anterior interosseous nerve is a purely motor branch of the median nerve that arises in the upper forearm. Anterior interosseous neuropathy (AIN) produces no sensory loss and weakness of the 3 muscles supplied by the nerve:
1. flexor digitorum profundus (FDP) I & II: flexion of distal phalanx of digits 2 & 3
2. flexor pollicis longus (FPL): flexion of distal phalanx of thumb
3. pronator quadratus (in the distal forearm): difficult to isolate clinically

Etiologies of AIN
Include: idiopathic, amyotrophy, ulna/radius fractures, penetrating injuries, forearm lacerations.

Clinical
Symptoms: Patients complain of difficulty grasping small objects between the thumb and the index finger. Idiopathic cases may be preceded with forearm aching.
Physical exam: Sensory: no sensory loss. Strength: digits 1, 2 & 3 are examined individually. The proximal interphalangeal joints are stabilized by the examiner and the patient is asked to flex the DIP. With AIN, there is no significant flexion of the DIP.
Pinch sign: the patient attempts to forcefully pinch the tips of the index finger and thumb as in making an “OK” sign (Fig. 30.2, left), with AIN the terminal phalanges extend and the pulps touch instead of the tips (Fig. 30.2, right).

Diagnosis
In addition to the physical exam, EMG may be helpful.
EMG: primarily assesses pronator quadratus & flexor pollicis longus (FDP I & II is difficult on EMG because it has dual innervation with the ulnar nerve innervated portion being more superficial than the median nerve innervated portion). Important to evaluate pronator teres (abnormalities suggest involvement more proximal than forearm).

Management
In the absence of an identifiable cause of nerve injury, expectant management is recommended for 8–12 weeks, following which exploration is indicated which may reveal a constricting band near the origin.

30.4.4 Carpal tunnel syndrome
General information

Key concepts
- the most common compression neuropathy. Involves median nerve in the wrist
- symptoms: tingling in the hand, worse at night and with elevation of hands
- physical exam is not very sensitive:
  - sensory: decreased pinprick in digits 1–3 and the radial half of 4
  - sensitivity: Tinel’s (tapping on wrist) 60%, Phalen’s (flexion of wrist) 80%
- electrodiagnostics: sensory latency @ wrist > 3.7 ms is the most sensitive test
Carpal tunnel syndrome (CTS) is the most common entrapment neuropathy in the upper extremity.\textsuperscript{14,15,16} Carpal tunnel release (CTR) is one of the most frequently performed hand procedures.\textsuperscript{17,18} The majority of patients have a satisfactory outcome from surgical treatment; see Outcome of surgical treatment (carpal tunnel release) (p.526). The median nerve is compressed within its course through the carpal tunnel just distal to the wrist crease. Table 30.1 shows the effect of pressure within the carpal tunnel.

### Epidemiology

Usually occurs in middle aged patients. Ratio of female:male = 4:1. It is bilateral in over 50% of cases, but is usually worse in the dominant hand. The prevalence of CTS and UNE is increased in diabetics.

### Common etiologies

See reference.\textsuperscript{19}

In most cases, no specific etiology can be identified. CTS is very common in the geriatric population without any additional risk factors. The following etiologies tend to be more common in younger patients:

1. “classic” CTS: chronic time course, usually over a period of months to years
   a) trauma: often job-related (may also be associated with avocations)
      - repetitive movements of hand or wrist: e.g. carpenter’s
      - repeated forceful grasping or pinching of tools or other objects
      - awkward positions of hand and/or wrist, including wrist extension, ulnar deviation, or especially forced wrist flexion
      - direct pressure over carpal tunnel
      - use of vibrating hand tools

   b) systemic conditions: in addition to systemic causes listed for entrapment neuropathies (p.515) – especially rheumatoid arthritis, diabetes -, also consider:
      - obesity
      - local trauma
      - pregnancy: 54% remained symptomatic 1 year post-partum, and patients with onset early in pregnancy were less likely to improve\textsuperscript{20}
      - mucopolysaccharidosis V
      - tuberculous tenosynovitis
      - multiple myeloma (p.714) (amyloid deposition in flexor retinaculum)

   c) patients with A-V dialysis shunts in the forearm have an increased incidence of CTS, possibly on an ischemic basis (steal and/or venous stasis) or possibly from the underlying renal disorder

2. “acute” CTS: an uncommon condition where the symptoms of CTS appear suddenly and severely, usually following some type of exertion or trauma. Etiologies:
   a) median artery thrombosis: < 10% of individuals have a persistent median artery
   b) hemorrhage or hematoma in the transverse carpal ligament

Signs and symptoms

The physical exam for CTS is fairly insensitive. Signs and symptoms may include:

1. Dysesthesias:
   a) Characteristically patients are awakened at night by a painful numbness in the hand (often described as the “hand falling asleep”) that often subjectively feels like a loss of circulation of blood. They often seek relief by: shaking or dangling or swinging the hand, opening and closing or rubbing the fingers, running hot or cold water over the hand, or pacing the floor. It may radiate up the arm, occasionally as far as shoulder.
   b) Daytime activities that characteristically elicit symptoms usually involve prolonged hand elevation: holding a book or newspaper to read, driving a car, holding a telephone receiver, brushing the hair.
   c) Distribution of symptoms:
      - On palmar side in radial 3.5 fingers (palmar side of thumb, index finger, middle finger, and radial half of ring finger).
      - Dorsal side of these same fingers distal to the PIP joint.
      - Radial half of palm.
      - Subjective involvement of little finger occurs not infrequently for reasons that are not clear.

2. Weakness of hand, especially grip. Characteristically manifests as difficulty opening jars. May be associated with thenar atrophy (late change, severe atrophy is seldom seen with current awareness of CTS by most physicians). An occasional patient may present with severe atrophy and no history of pain.

3. Clumsiness of the hand and/or difficulty with fine motor skills: probably due mostly to numbness more than a motor deficit. Often presents as difficulties buttoning buttons or zipping zippers, putting on earrings, fastening bra straps...

4. Hypesthesia in median nerve sensory distribution: usually best appreciated in finger tips, loss of 2-point discrimination may be more sensitive test.

5. Phalen’s test: 30–60 secs wrist flexion to a 90° angle exaggerates or reproduces pain or tingling. Positive in 80% of cases (80% sensitive).

6. Tinel’s sign at the wrist: paresthesias or pain in median nerve distribution produced by gently percussing over the carpal tunnel. Positive in 60% of cases. May also be present in other conditions. Reverse Tinel’s sign: produces symptoms radiating up the forearm for variable distance.

7. Ischemic testing: place blood pressure cuff proximal to wrist, inflation x 30–60 seconds may reproduce CTS pain.

Differential diagnosis

Differential diagnosis includes (modified):

1. Cervical radiculopathy: coexists in 70% of patients with either median or ulnar neuropathy (C6 radiculopathy may mimic CTS). Usually relieved by rest, and exacerbated by neck movement. Sensory impairment has dermatomal distribution. It has been postulated that cervical nerve root compression may interrupt axoplasmic flow and predispose the nerve to compressive injury distally (the term double-crush syndrome was coined to describe this), and although this has been challenged it has not been disproven.

2. Thoracic outlet syndrome (p. 554): Loss of bulk in hand muscles other than thenar. Sensory impairment in ulnar side of hand and forearm.

3. Pronator teres syndrome (p. 518): More prominent palmar pain than with CTS (median palmar cutaneous branch does not pass through carpal tunnel).

4. De Quervain’s syndrome: Tenosynovitis of the abductor pollicis longus and extensor pollicis brevis tendons often caused by repetitive hand movements. Results in pain and tenderness in the wrist near the thumb. Onset in 25% of cases is during pregnancy, and many in 1st postpartum year. Usually responds to wrist splints and/or steroid injections. NCVs should be normal. Finkelstein’s test: the thumb is passively abducted while thumb abductors are palpated, positive if this aggravates the pain.

5. Reflex sympathetic dystrophy: may respond to sympathetic block (p. 1521).

6. Tenosynovitis of any of the flexor ligaments: may occasionally be due to TB or fungus. Usually a long, indolent course. Fluid accumulation may be present.

Diagnostic tests

Electrodiagnostics (EDX)

Electromyogram (EMG) and nerve conduction study (NCS) which includes measurement of nerve conduction velocities (NCV): may help confirm the diagnosis of CTS and distinguish it from cervical root abnormalities and from tendonitis.
CTS is predominantly a demyelinating injury although it can progress to axonal loss. Two sensory comparison techniques that clearly agree (either normal or abnormal) are adequate to confirm or refute the diagnosis. For borderline abnormalities additional sensory comparison testing or the combined sensory index (CSI) can clarify the diagnosis. If sensory responses are absent, the median motor latency in comparison to the ulnar latency can help localize a focal abnormality.

Practice guideline: Electrodiagnostic criteria for CTS

The practice guideline for CTS recommends diagnostic examination strategies:

1. Standard: perform a median sensory nerve conduction study (NCS) across the wrist with conduction distance of 13 to 14 cm. If abnormal, compare to an adjacent sensory nerve in the symptomatic limb.
2. Standard: if the initial median sensory NCS across the wrist is normal then additional comparison studies are recommended.
3. Guideline: motor NCS of the median nerve recording from the thenar muscle and of 1 other nerve in the symptomatic limb.
4. Option: supplementary NCS.
5. Option: needle electromyography (EMG) of cervical root screen muscles including a thenar muscle.

NCV: Electrophysiologic studies support a diagnosis of carpal tunnel syndrome (CTS) using median nerve conduction studies across the transverse carpal ligament. Characteristic abnormalities: prolongation of sensory and motor distal latencies, slowing of the conduction velocity and decreased amplitudes of sensory and motor responses. Guidelines regarding recommended studies are published by the American Association of Neuromuscular and Electrodiagnostic Medicine (AANEM), AAPM&R, and AAN. Adhering to the guidelines, sensitivity is greater than 85% and specificity is greater than 95%. Sensory latencies are more sensitive than motor. (Note: although up to 15% of cases may have normal electrodiagnostic studies, great reservation should be exercised in considering operating on CTS with normal sensory NCV and amplitude.)

Normal findings are shown in Table 30.2. Abnormal values also listed are a rough guide, but the correlation between severity of EDX findings and symptoms in CTS is not well established. Nevertheless, classification as follows can in part predict the outcome of carpal tunnel release (surgery) with normal and very severe NCS abnormalities having a worse prognosis than patients with moderate NCS abnormalities.

EDX interpretation (reports may also include the degree of slowing in the summary of findings or interpretation);
- mild: Prolonged (relative or absolute) median nerve sensory latencies with normal motor studies. No evidence of axonal loss
- moderate: Prolonged (relative or absolute) median nerve sensory latencies with prolongation of motor distal latency. No evidence of axonal loss.
- severe: Any of the aforementioned NCS abnormalities with evidence of axonal loss on EMG.

\(^c\)to index finger. Sensory latency is measured to the peak of the waveform
\(^d\)to abductor pollicis brevis

Table 30.2 Distal conduction latencies through carpal tunnel

http://e-surg.com
Additional comparison studies for uncertain cases compare median nerve sensory conduction velocity to that of the ulnar nerve (or radial nerve): normal median nerve should be at least 4 m/sec faster than the ulnar, reversal of this pattern suggests median nerve injury. Alternatively, the sensory latencies for the palmar median and ulnar nerves can be compared; the median nerve latency should not be ≥0.3 ms longer than the ulnar.

EMG: normal in up to 31% of cases of CTS. In relatively advanced CTS, it may show increased polyphasicity, positive waves, fibrillation potentials, and decreased motor unit numbers on maximal voluntary thenar muscle contraction. EMG may detect cervical radiculopathy if motor involvement is present.

With severe “end stage” CTS, sensory and motor potentials may not be recordable, and EMG is not helpful in localizing (i.e. differentiating CTS from other etiologies).

Laboratory tests
Recommended in cases where an underlying peripheral neuropathy is suspected (e.g. unclear etiology in a young individual with no risk factors such as repetitive hand use). This same protocol is a useful initial workup for any case of peripheral neuropathy:
1. thyroid hormone levels (T4 (total or free) & TSH): to R/O myxedema
2. CBC: anemia is common in multiple myeloma, also to R/O amyloidosis
3. electrolytes:
   a) to R/O chronic renal failure that could cause uremic neuropathy
   b) blood glucose: R/O diabetes
4. in cases suspicious for multiple myeloma: see full details (p. 714)
   a) 24 hour urine for kappa Bence-Jones protein
   b) bloodwork: serum protein electrophoresis (SPEP) and immune electrophoresis (IEP) (looking for lgG kappa band)
   c) skeletal radiologic survey
   d) anemia is common on the CBC

Imaging studies
Not routinely done unless a mass lesion is suspected.

  Wrist MRI: very sensitive. Findings with CTS include: flattening or swelling of the nerve, palmar bowing of the flexor retinaculum. May also demonstrate ganglion cysts, lipomas... Enhancement may occur with hypervascular edema.

  Diagnostic ultrasound: faster and less expensive than MRI, and can assess bloodflow and changes with different wrist positions. 18 MHz probes may improve images.

Management of CTS

Practice guideline: Management of CTS

American Association of Orthopedic Surgeons (AAOS) Clinical Practice Guideline endorsed by American Association of Neurological Surgeons, Congress of Neurological Surgeons, American Society of Plastic Surgeons, American Academy of PM&R and AANEM

1. A course of non-operative treatment is an option in patients diagnosed with CTS. Early surgery is an option when there is clinical evidence of median nerve denervation or the patient elects to proceed directly to surgical treatment (Grade C, Level V)
2. another non-operative treatment or surgery is suggested when the current treatment fails to resolve the symptoms within 2-7 weeks (Grade B, Level I and II)
3. There is not sufficient evidence to provide specific treatment recommendations for CTS when found in association with diabetes, coexisting cervical radiculopathy, hypothyroidism, polyneuropathy, pregnancy, rheumatoid arthritis and CTS in the workplace. (inconclusive)
4. Management specifics
   • local steroid injection or splinting is suggested when treating patients with CTS before considering surgery (Grade B, Level I and II)
   • oral steroids or ultrasound are options for treatment of CTS (Grade C, Level II)
   • carpal tunnel release is recommended for treatment of CTS (Grade A, level I)

Notwithstanding the AAOS recommendations, multiple studies report the results of carpal tunnel release in diabetics are good even when polyneuropathy is present,35,36
Non-surgical management

Options include:
1. rest
2. medications: non-steroidal anti-inflammatory drugs (NSAIDs), diuretics, and pyridoxine (vitamin B6) have been studied with no evidence of efficacy.
3. treatment of associated conditions (e.g. hypothyroidism or DM) is appropriate, but there is no data as to whether this relieves CTS.
4. neutral position splints: alleviates symptoms in >80% of patients (usually within a few days) and reduces prolonged sensory latencies. Relapse is common (works best when patient does not return to heavy manual labor). A trial of at least 2–4 weeks is recommended.
5. steroid injection: symptoms improve in >75% of patients. 33% relapse within 15 mos. Repeat injections are possible, but most clinicians limit to 3/year.
   a) use 10–25 mg hydrocortisone. Avoid local anesthetics (may mask symptoms of intra-neural injection).
   b) inject into carpal tunnel (deep to transverse carpal ligament) to ulnar side of palmaris longus to avoid median nerve (in patients without palmaris longus, inject in line with fourth digit).
   c) median nerve injuries have been reported with this technique, primarily due to intra-neural injection (all steroids are neurotoxic upon intrafascicular injection, and so are some of the carrier agents).
   d) risk factors for recurrence: severe electrodiagnostic abnormalities, constant numbness, impaired sensation, & weakness or atrophy of thenar muscles.

Surgical treatment

General information
The operation is commonly called a carpal tunnel release (CTR), AKA neurotomy or neuroplasty of the median nerve at the wrist.

Indications
Surgical intervention is recommended for: constant numbness, symptoms >1 year duration, sensory loss, or thenar weakness/atrophy. Surgical treatment of cases due to amyloidosis from multiple myeloma is also effective.

With bilateral CTS, in general one operates on the more painful hand first. However if the condition is severe in both hands (on EMG) and if it has progressed beyond the painful stage and is only causing weakness and/or numbness, it may be best to operate on the “better” hand first in order to try and maximize recovery of the median nerve at least on that side. Simultaneous bilateral procedures may also be done. In severe cases, nerve recovery may not occur, it may be necessary to wait up to a year to determine extent of recovery.

Success rate
>70% of patients report satisfaction with their surgical results, with 70–90% being free of nocturnal pain.

Surgical techniques
A number of techniques are popular, including: incision through palm of hand, transverse incision through wrist crease (with or without a retinaculotome), and endoscopic techniques (using single or dual incisions). The efficacies of the various approaches have not been compared in an adequately powered randomized study and there is no consensus on the superiority of any one technique, including endoscopic vs. open CTR.

Transpalmar approach (Fig. 30.3): For a right-handed surgeon, sit in patient’s “axilla” (facing head of patient) for left sided CTS. Sit above patient’s arm (facing feet) for right sided CTS. Usually performed under local or regional anesthesia on outpatient basis. Magnification (operating loupes) are helpful.

Incision along imaginary line extending proximally from space between digits 3 and 4 (usually stay just to the ulnar side of the interthenar crease to avoid the PCB). The location of the median nerve may also be estimated by the palmaris longus tendon (stay slightly to ulnar side of tendon). Incision starts at distal wrist flexion crease, and the length depends on thickness of hand (it may extend as far distally as a line even with the crotch of the thumb). Optionally: curve ulnarward at proximal wrist flexion crease (to facilitate retraction).
The median nerve is carefully approached through the TCL with progressively deepening incisions made with a 15 blade. All approaches to CTS surgery require complete division of TCL at and distal to the wrist. If tendons of the flexor digitorum superficialis are encountered, you need to look radially (towards the thumb) to find the nerve. In selected cases, the epineurium may be opened; however, internal neurolysis probably does more harm than good and in general should be avoided.

Close with absorbable 4–0 inverted sutures. Approximate skin edges with 4–0 nylon running or interrupted vertical mattress. Pad palm with several fluffs (opened dressing sponge). Cover with Kerlix®.

Post-op: wrap hand with thumb exposed. Wrist elevation and rest is recommended for several days. Analgesics for mild-to-moderate pain (e.g. acetaminophen with codeine) for 3–4 days. Sutures are removed at 7–10 days. No heavy work with hand for 2–3 weeks.

Complications of carpal tunnel surgery

See reference.47

1. pain due to neuroma formation following transection of palmar cutaneous branch (PCB) of the median nerve
   a) branches of PCB may cross interthenar crease
   b) avoid by: using magnification and making incision slightly to ulnar side of interthenar crease
   c) treated by ligating this branch where it originates from median nerve in forearm (results in small area of numbness at base of thenar eminence)

2. neuroma of dorsal sensory branch of radial nerve
   a) caused by extending incision proximally and radially
   b) may be treated by neurolysis of neuroma

3. injury to recurrent thenar (motor) branch of median nerve
   a) anomaly may cause nerve to lie above or to pierce TCL
   b) avoided by: staying to ulnar side of midline

4. direct injury to median nerve

5. volar displacement and entrapment of median nerve in healing edges of TCL

6. hypertrophic scar causing compression of median nerve
   a) usually caused by incision crossing wrist perpendicular to flexion crease
   b) avoid by not crossing flexion crease, or in cases where necessary (e.g. in releasing Guyon’s canal entrapment of ulnar nerve, in tenosynovectomy for rheumatoid arthritis, or in dealing with an anomalous superficialis or palmaris muscle) by crossing wrist obliquely at 45° angle directed toward ulnar side47 (see optional extension line in Fig. 30.3)

7. failure to improve symptoms
   a) incorrect diagnosis: if EMG or NCV not done pre-op, they should be done after surgical failure (to R/O e.g. cervical root involvement (look for posterior myotome involvement), or generalized peripheral neuropathy)
b) incomplete transection of TCL: the most common cause for failure if diagnosis is correct (also possibility of accessory ligament or fascial band proximal to TCL in cases where division was complete). When this is identified on re-exploration, 75% of patients will be cured or improved after division is completed.

8. joint stiffness
   a) caused by excessively long immobilization of wrist and fingers
9. injury to superficial palmar arch (arterial): usually results from “blind” distal division of TCL
10. bowstringing of flexor tendons
11. complex regional pain syndrome AKA reflex sympathetic dystrophy: exact incidence is unknown, reported in 4 of 132 patients in one series (probably too high, most surgeons will see only one or two cases in their career). Treatment with IV phentolamine has been suggested, but most cases are self limited after ≈ 2 weeks
12. infection: usually causes exquisite tenderness
13. hematoma: also usually quite painful and tender

Outcome of surgical treatment (carpal tunnel release)
75-90% of patients have symptom resolution or are improved to a satisfactory state following carpal tunnel release. Clinical improvement peaks at 6 months post-op although paresthesias may take ≥ 9 months to resolve. The results of decompression are good in diabetics with CTS even when a generalized peripheral neuropathy is present. In comparison, ulnar neuropathy at the elbow is often severe in diabetics and predominantly motor with axonal injury. These patients usually do not respond well to surgery.

Managing surgical treatment failures
Less than satisfactory outcomes following CTR should be categorized as:
1. new symptoms: may include neuropathic pain out of proportion to the surgery, new areas of numbness/paresthesias or marked weakness of the thenar muscles. When present immediately post-op, this suggests iatrogenic injury to branches of the median nerve
2. persistent symptoms (primary failure or failure to improve) defined as symptoms which remain unchanged compared to preop. Etiologies include: incorrect initial diagnosis, incomplete release of the transverse carpal ligament and severe (i.e. irreversible) CTS at initial diagnosis.
3. or recurrent symptoms: requires symptom free interval before return of symptoms (there is no standardization of either the level of recurrent symptoms or length of interval, although 6 months has been used in some studies). Etiologies include: circumferential fibrosis around the median nerve, soft tissue adhesions, synovial proliferation, tenosynovitis, ganglions, amyloid deposits and subtle palmar subluxation.

Electrodiagnostic (EDX) studies. Following CTR, distal motor latency improves after 3 months and 6 months and may continue to improve for up to 2 years. Electrophysiologic abnormalities may improve but may not return to normal range after CTR even with clinical improvement. Electrophysiologic studies are most helpful when it is possible to compare to pre-op studies. There are no guidelines or standard recommendations for when to obtain postoperative studies for surgical failures. It is reasonable to obtain repeat studies at 3 to 6 months following carpal tunnel release for persistent symptoms and at onset for new or recurrent symptoms. If the repeat nerve conduction studies are worse or if the EMG needle exam has findings of denervation (fibrillation potentials and positive sharp waves) not previously present, then repeat surgery is indicated. If the preoperative study is not available, repeating the EDX study with comparison at 2 points in time to evaluate for improvement or worsening is advised. Prolonged latencies alone are not an indication for reoperation.

30.5 Ulnar nerve entrapment
30.5.1 General information
Ulnar nerve has components of C7, C8 and T1 nerve roots. Even though this is the second most prevalent entrapment neuropathy after CTS, it is still relatively uncommon. Potential sites of compression:
1. above elbow: possibly by the arcade of Struthers
2. at the elbow: retroepicondylar groove (“ulnar groove”): between the medial epicondyle and the olecranon process. Compression by fascia or by dynamic compression or repetitive trauma
3. cubital: just distal to the ulnar groove, under the aponeurosis between the heads of the flexor carpi ulnaris (FCU)
4. at the point of exit from the FCU
5. wrist: Guyon’s canal

Etiologies: structural, mechanical or idiopathic.

Motor findings include:
1. wasting of the interossei may occur, and is most evident in the first dorsal interosseous (in the thumb web space)
2. Wartenberg’s sign: one of the earliest findings of ulnar nerve entrapment (abducted little finger due to weakness of the third palmar interosseous muscle – patient may complain that the little finger doesn’t make it in when they reach into their pocket)
3. Froment’s prehensile thumb sign: grasping a sheet of paper between thumb and the extended index finger results in extension of the proximal phalanx of the thumb and flexion of the distal phalanx as a result of substituting flexor pollicis longus (which is spared since it is innervated by anterior interosseous nerve) for the weak adductor pollicis
4. claw deformity of the hand (main en griffe): in severe ulnar nerve injuries on attempted finger extension (some have called this “benediction hand”, which differs from that with the same name in median nerve injury where the named sign occurs on trying to make a fist. Fingers 4 and 5 and to a lesser extent 3 are hyperextended at the MCP joints (extensor digitorum is unopposed by interossei and “ulnar” lumbricals III & IV) and flexed at the interphalangeal joints (due to pull of long flexor muscles). NB: C8 radiculopathy can also cause benediction sign

Sensory findings: Disturbance of sensation involving:
1. The little finger and ulnar half of the ring finger
2. Sensory loss over the ulnar side of the dorsum of the hand. This will be spared in ulnar nerve entrapment at the wrist (dorsal ulnar cutaneous nerve branches proximal to the wrist)

30.5.2 Injury above elbow
May occur with injury to the medial cord of the brachial plexus.

In the upper arm, the ulnar nerve descends anterior to the medial head of triceps; in 70% of people it passes under arcade of Struthers – distinct from Struther’s ligament (p. 518) – a flat, thin, aponeurotic band. This is not normally a point of entrapment, but may cause kinking after ulnar nerve transposition if not adequately divided.

30.5.3 Ulnar nerve entrapment at elbow (UNE)

General information
Entrapment at or just distal to the elbow produces the cubital tunnel syndrome. (Technically, the cubital tunnel is formed by the fibrous arch between the two heads of the FCU, the proximal entrance to which is just distal to the retrocondylar groove. However, common vernacular usually includes entrapment within the groove itself as being “cubital tunnel syndrome.”

Can also present as so-called tardy ulnar palsy because of delayed onset following bony injury at the elbow, initial case reports occurred ≥ 12 years later, with the majority commencing ≥ 10 years following the original injury. The elbow is the most vulnerable point of ulnar nerve: here the nerve is superficial, fixed, and crosses a joint. Most cases are idiopathic, although there may be a history of elbow fracture (especially lateral condyle of the humerus, with associated cubitus valgus deformity), dislocation, arthritis, or repeated minor trauma. The aponeurotic arch extending over the ulnar groove and attaching on the medial epicondylic may become thickened and can compress the nerve, especially with elbow flexion. The ulnar nerve may also be injured during anesthesia.

Presentation
Typically presents with discomfort (pain, numbness and/or tingling) in little finger and ulnar half of ring finger, elbow pain, and hand weakness. Early symptoms may be purely motor (see Froment’s sign and claw deformity above) – unlike the median nerve where sensory involvement is almost always present. Symptoms may be exacerbated by the cold, and are often somewhat vague and may be described as a loss of finger coordination or clumsiness. Cramping and easy fatiguing of the ulnar
innervated muscles of the hand may occur. Pain may not be a significant feature, but if present tends to be aching in nature along the ulnar aspect of the elbow or forearm. Atrophy of interossei is common by the time of presentation.

The ulnar nerve is usually tender and may be palpably enlarged in the ulnar groove. Tinel’s sign may be positive over the elbow, but this is not very specific.

Grading: the classification system proposed by Stewart is shown in Table 30.3.

Evaluation

Electrodiagnostic studies

The literature review from AANEM Practice Parameters for EDX studies in ulnar neuropathy at the elbow (UNE) report sensitivities to range from 37% to 86% with specificities of 95%. EDX interpretation: Reports should include localization and may comment on whether the lesion is predominantly demyelinating or axonal. Reports may use grading classification.

The following suggest a focal lesion involving the ulnar nerve at the elbow. Multiple internally consistent abnormalities are more convincing than isolated abnormalities. These are listed in order of strength of evidence.

Sensory abnormalities of the distal sensory or mixed nerve action potential (NAP), especially loss of amplitude, are not localizing for ulnar neuropathy (in contradistinction to median nerve/carpal tunnel), the motor component of the exam for the ulnar nerve is more useful for localization of the site of entrapment.

Practice guideline: Electrodiagnostic criteria for ulnar neuropathy at the elbow

Not all criteria need to be present and an EMG needle exam is not required:

1. absolute motor nerve conduction velocity (NCV) < 50 m/sec from below elbow (BE) to above elbow (AE)
2. drop of NCV > 10 m/sec comparing BE to wrist segment to the AE to BE segment
3. amplitude of compound motor action potential (CMAP) normally decreases with distance, but a drop > 20% from BE to AE is abnormal (in the absence of anomalous innervation, e.g. Martin-Gru-ber anastomosis (p. 514))
4. if ulnar motor studies with stimulation at the wrist, above and below the elbow recording from ADQ are inconclusive, the following may be of benefit:
   • NCS recorded from the FDI (first dorsal interosseus muscle, innervated by ulnar nerve)
   • inching study recording latencies and amplitudes at cm increments.
   • with severe UNE and wallerian degeneration-comparison of AE to BE with axilla to AE
   • needle EMG should always include FDI and ulnar innervated forearm muscles (flexor digitorum profundus (FDP) to ring or little finger and/or abductor digiti quinti/minimi (ADQ)). If abnormal then extend to include non-ulnar innervated C8, medial cord, lower trunk muscles and cervical paraspinals to exclude brachial plexopathy/cervical radiculopathy.

The 2 most important parameters that predict a good outcome are preserved compound muscle action potential (CMAP) amplitudes in ulnar hand muscles and conduction block (CB) with slowed conduction velocity across the elbow which is consistent with demyelination and has a better prognosis. Poor prognosis correlates with small or absent CMAP and no CB consistent with axonal loss.
Diagnostic ultrasound
Localizing ulnar nerve lesions with electrodagnostic studies can be difficult. There has been a recent renewed interest in diagnostic ultrasound using high frequency (18 MHz) probes to help with localization, and also for identification of pathology, including nerve swelling, transection, and neuroma, that exceeds MRI in some aspects and at a lower cost and with faster acquisition time.

Management of ulnar neuropathy at the elbow
There are no Clinical Practice Guidelines for treatment of UNE endorsed by AANEM, AAOS, CNS, AANS, AAPM&R, or Am Society of Plastic Surgeons. A fundamental difficulty in treating UNE are the multiple etiologies and locations so that the natural history and responses to treatment vary widely. The primary management decision is conservative versus surgical treatment.

A Cochrane Database Review concluded the available evidence is not sufficient to identify the best treatment for UNE on the basis of clinical, neurophysiologic and imaging characteristics. Nonsurgical treatment (see below) may be considered for the patient with intermittent symptoms, no atrophy and mild EDX findings. Surgical intervention has been advised for patients who fail conservative management, although the best nonsurgical management and duration of treatment are not welldefined. Suggested protocol:

- mild or moderate UNE (grade 1 and 2, table 30.3): treat conservatively as studies report improvement or complete recovery in 30-90%. Follow these patients every 2 months to detect deterioration. If worsening occurs image with CT or MRI. Surgical exploration is indicated regardless of imaging results.
- severe (grade 3) UNE: initiate conservative treatment, obtain imaging and f/u in 1 month. If there is worsening or if structural abnormality found or both then surgical intervention. If stable or improving and imaging normal then follow at monthly intervals. Surgical intervention for worsening.

There is a probable increased prevalence of UNE in diabetics. The UNE is often more severe with predominant axonal injury and these patients do not respond well to surgery.

Non-surgical treatment
Patient education on positions to avoid (prolonged elbow bending to ≥90° flexion). Avoid trauma to the elbow, including resting it on firm surfaces (tables, rigid armrests in motor vehicles…), an elbow pad may help. Results are often better when definite traumatic etiology can be identified and eliminated.

Surgical treatment
General approach
Most operations utilize a “lazy omega” skin incision centered over the medial epicondyle, extending at least ≈ 6 cm proximal and distal to elbow with the central “hump” directed anteriorly. The ulnar nerve is most constant and therefore most easily found immediately at the entrance to the ulnar groove. It may then be followed proximally and distally. Nerve branches that should be preserved include: posterior branches of the medial antebrachial cutaneous nerve (or else numbness or dyesthesias along medial forearm may occur) and branches to the flexor carpi ulnaris (which may branch early). Small articular branches at or proximal to the elbow joint can be preserved with simple decompression but may need to be sacrificed in transposition if they cannot be dissected far enough along the ulnar nerve. Internal neurolysis should be avoided as it may promote intraneural fibrosis.

The choice of one of the options below will determine subsequent steps.

Surgical options primarily consist of:
1. simple nerve decompression without transposition (see below). Includes all of the following:
   a) at the elbow: division of the cubital tunnel retinaculum
   b) distal to the elbow: dividing the aponeurosis connecting the two heads of the flexor carpi ulnaris, some advocate resuturing the aponeurosis underneath the nerve
   c) proximal to the elbow: dividing the medial intermuscular septum (between distal biceps and triceps muscles) and the arcade of Struthers (if present)
   d) preservation of the branch to the flexor carpi ulnaris and the dorsal cutaneous branch to the hand (arises 5 cm proximal to wrist)
2. nerve decompression and transposition (extent of surgery differs because degree of entrapment varies; all forms of transposition require fashioning a sling to retain the nerve in its new location). Transposition may be to:
   a) subcutaneous tissue: this leaves the nerve fairly superficial and vulnerable to further trauma
   b) within the flexor carpi ulnaris muscle (intramuscular transposition): some contend this actually worsens the condition due to intramuscular fibrosis
   c) a submuscular position: below
3. medial epicondylectomy. Usually combined with decompression. Normally reserved for patients with a bony deformity
4. sometimes excision of neuroma and possibly jump graft may be required

Submuscular transposition
Placement under pronator teres, within a groove fashioned in the flexor carpi ulnaris (FCU). Usually requires general anesthesia (endotracheal or laryngeal mask airway).

Some key concepts:
1. the skin incision must extend at least ≈ 8 cm distal and proximal to the medial epicondyle to mobilize the nerve (spare the medial antebrachial cutaneous nerve in the subcutaneous fatty tissue just distal to the elbow)
2. the nerve is mobilized, sparing branches to flexor carpi ulnaris (FCU) and the ulnar flexor profundus branch(es) (usually arise 2–4 cm distal to olecranon)
3. the medial intermuscular septum (between distal biceps and triceps muscles) must be cut in the distal arm to prevent the nerve from being kinked over it
4. the pronator teres muscle must be sectioned completely through just distal to the medial epicondyle
   a) start by undermining the muscle just distal to the medial epicondyle
   b) a mosquito hemostat may be passed under the muscle to assist
   c) the muscle is cut sharply, cautery is used to treat bleeding areas
5. a trough is cut in the volar aspect of the FCU to accommodate the nerve
6. after the pronator teres is reattached over the nerve, make sure that the nerve can slide back-and-forth easily under the muscle
7. test the elbow through a range of motion after the transposition to look for snapping of the medial portion of the triceps over the medial epicondyle

Transposition vs. decompression

Σ

For most cases, simple decompression is recommended over transposition. Possible exceptions include: bony deformity, nerve subluxation

Randomized studies have shown similar success but lower complication rate with simple decompression vs. transposition. Advantages of simple decompression include shorter operation that can be done more easily under local anesthesia, avoidance of nerve kinking and muscular fibrosis around the transposed nerve, reduced risk of wound infection and scar formation, and preservation of cutaneous branches, ulnar branches, and nourishing blood vessels (vasa nervorum) that are sometimes sacrificed with transposition, rendering portions of the nerve ischemic.

Arguments against simple decompression: Continued dynamic compression with elbow flexion, possible nerve subluxation (if present pre-op, simple decompression may make this worse; to avoid nerve subluxation and loss of vascular supply with simple decompression, avoid a 360° freeing of the nerve) and incomplete release of pressure points.

Results with surgery
Not as good as with CTS, possibly due in part to the fact that patients tend to present much later. Overall, a good to excellent result is obtained in 60\% fair result in 25\% and a poor result (no improvement or worsening) in 15\% [p 2530]. These results may be worse in patients with symptoms
present >1 year, with only 30% of these symptomatically improved in one series. Lower success rate is also seen in older patients and those with certain medical conditions (diabetes, alcoholism …). Pain and sensory changes respond better than muscle weakness and atrophy.

30.5.4 Entrapment in the forearm

Very rare. Just distal to the elbow, the ulnar nerve passes from the retroepicondylar groove to pass under the fascial band connecting the two heads of the flexor carpi ulnaris (FCU), superficial to the flexor superficialis and pronator teres. Findings with entrapment in the forearm are similar to tardy ulnar nerve palsy (see above).

Surgical treatment consists of steps outlined for nerve distal to the elbow in ulnar nerve decompression (see above). A technique for locating the course of the ulnar nerve distal to the elbow: the surgeon takes the little finger of his/her own hand (using the hand contralateral to the patient’s side that is being decompressed) and places the proximal phalanx in the ulnar groove aiming it toward the ulnar side of the wrist.76 (p 262)

30.5.5 Entrapment in the wrist or hand

At the wrist, the terminal ulnar nerve enters Guyon’s canal, the roof of which is the palmar fascia and palmaris brevis, the floor is the flexor retinaculum of the palm and the pisohamate ligament.

Guyon’s canal. Is superficial to the transverse carpal ligament (which overlies the carpal tunnel and compresses the median nerve in carpal tunnel syndrome).

The canal contains no tendons, only the ulnar nerve and artery. At the middle of the canal the nerve divides into a deep and superficial branch. The superficial branch is mostly sensory (except for the branch to palmaris brevis), and supplies hypothenar eminence and ulnar half of ring finger. The deep (muscular) branch innervates hypothenar muscles, lumbricals 3 & 4, and all interossei. Occasionally the abductor digitii minimi branch arises from the main trunk or superficial branch.

Shea and McClain83 divided lesions of the ulnar nerve in Guyon’s canal into 3 types shown in Table 30.4. Injury to the distal motor branch can also occur in the palm and produces findings similar to a Type II injury.

Injury is most often due to a ganglion of the wrist,84 but also may be due to trauma (use of pneumatic drill, pliers, repetitively slamming a stapler, leaning on palm while riding bicycle). Symptoms are similar to those of ulnar nerve involvement at the elbow, except there will never be sensory loss in the dorsum of the hand in the ulnar nerve territory because the dorsal cutaneous branch leaves the nerve in the forearm 5–8 cm proximal to the wrist (sparing of flexor carpi ulnaris and flexor digitorum profundus III & IV is not helpful in localizing because these are so rarely involved even in proximal lesions). Electrodiagnostics are usually helpful in localizing the site of the lesion. Pain, when present, may be exacerbated by tapping over pisiform (Tinel’s sign). It may also radiate up the forearm.

Surgical decompression may be indicated in refractory cases. To locate: find the ulnar artery, and the nerve is on the ulnar side of the artery. Controversial whether simple decompression vs. subcutaneous transposition is best, the outcome is similar but there may be more complications in the transposition group79,80 but studies are small.

*palmar ulnar distribution: the hypothenar eminence and ulnar half of ring finger, both on the palmar surface only (the dorsum is innervated by the dorsal cutaneous nerve)

bdepending on the location, may spare hypothenar muscles
30.6 Radial nerve injuries
See reference.85 (p 1443–45)

30.6.1 Applied anatomy
The radial nerve arises from the posterior divisions of the 3 trunks of the brachial plexus. Receives contributions from C5 to C8. The nerve winds laterally along the spiral groove of the humerus where it is vulnerable to compression or injury from fracture.

Distinguish radial nerve injury from injury of posterior cord of brachial plexus by sparing of deltoid (axillary nerve) and latissimus dorsi (thoracodorsal nerve).

30.6.2 Axillary compression
Etiologies: crutch misuse; poor arm position during (drunken) sleep.

30.6.3 Mid-upper arm compression
Etiologies
1. “Saturday night palsy”: improper positioning of arm in sleep (especially when drunk and therefore less likely to self-reposition in response to the accompanying discomfort, e.g. due to a bedmate’s head resting on the arm)
2. from positioning under general anesthesia
3. from callus due to old humeral fracture

Clinical: weakness of wrist extensors (wrist drop) and finger extensors. Key: triceps is normal because takeoff of nerve to triceps is proximal to spiral groove. Involvement of distal nerve is variable, may include thumb extensor palsy and paresthesias in radial nerve distribution. Differential diagnosis: isolated wrist and finger extensor weakness can also occur in lead poisoning (usually bilateral, more common in adults).

Forearm compression
General information
The radial nerve enters the anterior compartment of the arm just above the elbow. It gives off branches to brachialis, brachioradialis, and extensor carpi radialis (ECR) longus before dividing into the posterior interosseous nerve and the superficial radial nerve. The posterior interosseous nerve dives into the supinator muscle through a fibrous band known as the arcade of Frohse.

Posterior interosseous neuropathy
Posterior interosseous neuropathy (often referred to by its acronym “PIN”) may result from: lipomas, ganglia, fibromas, rheumatoid arthritis changes at elbow, entrapment at the arcade of Frohse (rare), and occasionally from strenuous use of the arm.

Treatment: cases that do not respond to 4–8 weeks of expectant management should be explored, and any constrictions lysed (including arcade of Frohse).

Radial tunnel syndrome
AKA supinator syndrome. Controversial. The “radial tunnel” extends from just above the elbow to just distal to it, and is composed of different structures (muscles, fibrous bands...) depending on the level.86 It contains the radial nerve and its two main branches (posterior interosseous and superficial radial nerves). Repeated forceful supination or pronation or inflammation of supinator muscle attachments (as in tennis elbow) may traumatize the nerve (sometimes by ECR brevis). Characteristic finding: pain in the region of the common extensor origin at the lateral epicondyle on resisted extension of the middle finger which tightens the ECR brevis. May be mistakenly diagnosed as resistant “tennis elbow” (lateral epicondylitis must be excluded). There may also be paresthesias in the distribution of the superficial radial nerve and local tenderness along the radial nerve anterior to the radial head. Even though the site of entrapment is similar to PIN, unlike PIN, there is usually no muscle weakness. Surgery: rarely required, consists of nerve decompression.86
Injury in the hand

The distal cutaneous branches of the superficial radial nerve cross the extensor pollicis longus tendon, and can often be palpated at this point with the thumb in extension. Injury to the medial branch of this nerve occurs commonly e.g. with handcuff injuries, and causes a small area of sensory loss in the dorsal web-space of the thumb.

30.7 Axillary nerve injuries

Isolated neuropathy of the axillary nerve may occur in the following situations:

1. shoulder dislocation: the nerve is tethered to the joint capsule
2. sleeping in the prone position with the arms abducted above the head
3. compression from a thoracic harness
4. injection injury in the high posterior aspect of the shoulder
5. entrapment of the nerve in the quadrilateral space (bounded by the teres major and minor muscles, long head of triceps, and neck of humerus) which contains the axillary nerve and the posterior humeral circumflex artery. Arteriogram may show loss of filling of the artery with the arm abducted and externally rotated

30.8 Suprascapular nerve

General information. The suprascapular nerve is a mixed peripheral nerve arising from the superior trunk of the brachial plexus, with contributions from C5 & C6. There is often a history of shoulder trauma or frozen shoulder. Entrapment results in weakness & atrophy of infra- and supraspinatus (IS & SS) and deep, poorly localized (referred) shoulder pain (the sensory part of the nerve innervates the posterior joint capsule but has no cutaneous representation).

Etiologies

1. nerve entrapment within the suprascapular notch beneath the transverse scapular (suprascapular) ligament (TSL)
2. repetitive shoulder trauma: may be bilateral when the injury is from activities such as weight-lifting
3. ganglion or tumor (MRI is the test of choice for imaging these)
4. paralabral cyst from labral tear (the tendon of the long head of the biceps attaches to the superior glenoid labrum; test of choice for labral tears is MR arthrography)

Differential diagnosis

1. pathology in or around shoulder joint
   a) rotator cuff injuries (distinction may be very difficult)
   b) adhesive capsulitis
   c) bicipital tenosynovitis
   d) arthritis
2. cases of Parsonage-Turner syndrome limited to the suprascapular nerve; see Neuralgic amyotrophy (p.543)
3. cervical radiculopathy (= C5)
4. upper brachial plexus lesion

NB: cervical radiculopathy and upper brachial plexus lesion will also produce rhomboid and deltoid weakness and, usually, cutaneous sensory loss.

Diagnosis requires temporary relief with nerve block, and EMG abnormalities of SS & IS (in rotator cuff tears, fibrillation potentials will be absent). Transient pain relief with a suprascapular nerve block helps verify the diagnosis.

Treatment. In cases where a mass is not the underlying cause, initial treatment consists of resting the affected UE, PT (including gentle conditioning), NSAIDs, topical capsaicin cream, and sometimes corticosteroid injection.

Surgical treatment is indicated for documented cases that fail to improve with conservative treatment (PT, NSAIDs, steroid/local anesthetic injection…). Position: lateral decubitus. Incision: 2 cm above and parallel to the scapular spine (atrophy of SS facilitates this). Only the trapezius needs to be split along its fibers (caution re spinal accessory nerve). To locate suprascapular notch, follow omohyoid to where it attaches to scapula and palpate just lateral to this. The suprascapular artery
and vein pass over the TSL and should be preserved. Elevate the TSL with a dull nerve hook and divide it (exposure of the nerve and/or resection of the bony notch are not necessary).

30.9 Meralgia paresthetica

30.9.1 General information
AKA Originally known as the Bernhardt-Roth syndrome, and sometimes called “swashbuckler’s disease”, meralgia paresthetica (MP) (Greek: meros – thigh, algos – pain) is a condition often caused by entrapment of the lateral femoral cutaneous nerve (LFCN) of the thigh, (a purely sensory branch with contributions from L2 and L3 nerve roots, see Fig. 1.14 for distribution) where it enters the thigh though the opening between the inguinal ligament and its attachment to the anterior superior iliac spine (ASIS). Anatomic variation is common, and the nerve may actually pass through the ligament, and as many as four branches may be found. May also be an initial manifestation of diabetes (diabetic neuropathy).

30.9.2 Signs and symptoms
Burning dysesthesias in the lateral aspect of the upper thigh, occasionally just above the knee, usually with increased sensitivity to clothing (hyperpathia). There may be decreased sensation in this distribution. Spontaneous rubbing or massaging the area in order to obtain relief is very characteristic.59 MP may be bilateral in up to 20% of cases. Sitting or lying prone usually ameliorates the symptoms.
There may be point tenderness at the site of entrapment (where pressure may reproduce the pain), which is often located where the nerve exits the pelvis medial to the ASIS. Hip extension may also cause pain.

30.9.3 Occurrence
Usually seen in obese patients, may be exacerbated by wearing tight belts or girdles, and by prolonged standing or walking. Recently found in long distance runners. Higher incidence in diabetics. May also occur post-op in slender patients positioned prone, tends to be bilateral (p.549).
Possible etiologies are too numerous to list, more common ones include: tight clothing or belts, surgical scars post-abdominal surgery, cardiac catheterization (p.549), pregnancy, iliac crest bone graft harvesting, ascites, obesity, metabolic neuropathies, and abdominal or pelvic mass.

30.9.4 Differential diagnosis
1. femoral neuropathy: sensory changes tend to be more anteromedial than MP
2. L2 or L3 radiculopathy: look for motor weakness (thigh flexion or knee extension)
3. nerve compression by abdominal or pelvic tumor (suspected if concomitant GI or GU symptoms)

The condition can usually be diagnosed on clinical grounds. When it is felt to be necessary, confirmatory tests may help (but frequently are disappointing), including:
1. EMG: may be difficult, the electromyographer cannot always find the nerve)
2. MRI or CT/myelography: when disc disease is suspected
3. pelvic imaging (MRI or CT)
4. somatosensory evoked potentials
5. response to local anesthetic injections
6. recent promise of diagnostic ultrasound using high frequency (18 MHz) probes

30.9.5 Treatment
Nonsurgical management
Tends to regress spontaneously, but recurrence is common. Nonsurgical measures achieve relief in ≈ 91% of cases and should be tried prior to considering surgery93:
1. remove offending articles (constricting belts, braces, casts, tight garments…)
2. in obese patients: weight loss and exercises to strengthen the abdominal muscles is usually effective, but is rarely achieved by the patient
3. elimination of activities involving hip extension

http://e-surg.com
4. application of ice to the area of presumed constriction × 30 minutes TID
5. NSAID of choice × 7–10 days
6. capsaicin ointment applied TID (p.496)
7. lidoderm patches (p.477) in areas of hyperesthesia may help
8. centrally acting pain medications (e.g. gabapentin, carbamazepine…) are rarely effective
9. if the above measures fail, injection of 5–10 ml of local anesthetic (with or without steroids) at the point of tenderness, or medial to the ASIS may provide temporary or sometimes long lasting relief, and confirms the diagnosis

Surgical treatment
Options include:
1. surgical decompression (neurolysis) of the nerve: higher failure and recurrence rate than neurectomy
2. decompression and transposition
3. selective L2 nerve stimulation
4. division of the nerve (neurectomy) may be more effective, but risks denervation pain, and leaves an anesthetic area (usually a minor nuisance). May be best reserved for treatment failures

Technique
See references.93,95
The operation is best performed under general anesthesia. A 4–6 cm oblique incision is centered 2 cm distal to the point of tenderness. Since the course of the nerve is variable, the operation is exploratory in nature, and generous exposure is required. If the nerve can’t be located, it is usually because the exposure is too superficial. If the nerve still cannot be found, a small abdominal muscle incision can be made and the nerve may be located in the retroperitoneal area. CAUTION: cases have occurred where the femoral nerve has erroneously been divided.

If neurectomy instead of neurolysis is elected, electrical stimulation should be performed prior to sectioning to rule out a motor component (which would disqualify the nerve as the LFCN). If the nerve is to be divided, it should be placed on stretch and then cut to allow the proximal end to retract back into the pelvis. Any segment of apparent pathology should be resected for microscopic analysis. Neurectomy results in anesthesia in the distribution of the LFCN that is rarely distressing and gradually reduces in size.

A supra-inguinal ligament approach has also been described.95

30.10 Obturator nerve entrapment
Controversial if this exists. The obturator nerve is composed of L2–4 roots. It courses along the pelvic wall to provide sensation to the inner thigh, and motor to the thigh adductors (gracilis and adductors longus, brevis, and magnus). It may be compressed by pelvic tumors, also from the pressure of the fetal head or forceps during parturition.

The result is numbness of the medial thigh and weak thigh adduction.

30.11 Femoral nerve entrapment
Composed of roots L2–4. Entrapment is a rare cause of femoral neuropathy. More commonly due to fracture or surgery. See Femoral neuropathy (p.546).

30.12 Common peroneal nerve palsy
30.12.1 General information and applied anatomy
The peroneal nerve is the most common nerve to develop acute compression palsy.

Functional anatomy: the sciatic nerve (L4-S3) consists of 2 separate nerves within a common sheath that separate at a variable location in the thigh (the peroneal division of the sciatic nerve is more vulnerable to injury than the tibial division); see Fig. 92.1 for diagram:
1. posterior tibial nerve, or, just tibial nerve (AKA medial popliteal nerve) which provides for foot inversion among other motor functions
2. common peroneal nerve (CPN), or, just peroneal nerve (AKA lateral popliteal nerve): high injuries may involve the lateral hamstring (short head of the biceps femoris) in addition to the following.
The CPN passes behind the fibular head where it is superficial and fixed, making it vulnerable to pressure or trauma (e.g. from crossing the legs at the knee). Just distal to this, the CPN divides into:

a) deep peroneal nerve (AKA anterior tibial nerve): primarily motor
   - motor: foot and toe extension (extensor hallucis longus (EHL), anterior tibialis (AT), extensor digitorum longus (EDL))
   - sensory: very small area between great toe and second toe
b) superficial peroneal nerve (AKA musculocutaneous nerve)
   - motor: foot eversion (peroneus longus and brevis)
   - sensory: lateral distal leg and dorsum of foot

30.12.2 Causes of common peroneal nerve injury

The most frequent cause of serious peroneal nerve injury is knee injury ± fracture; see also causes of foot drop other than peroneal nerve palsy (p.1417).

1. entrapment as it crosses the fibular neck or as it penetrates the peroneus longus
2. diabetes mellitus and other metabolic peripheral neuropathies
3. inflammatory neuropathy: including Hansen's disease (leprosy)
4. traumatic: e.g. clipping injury in football players, stretch injury due to dislocating force applied to the knee, fibular fracture, injury during hip or knee replacement surgery
5. penetrating injury
6. masses in the area of the fibular head/proximal lower leg: popliteal fossa cysts (Baker cyst), anterior tibial artery aneurysm (rare)
7. pressure at fibular head: e.g. from crossing the legs at the knee, casts, obstetrical stirrups...
8. traction injuries: severe inversion sprains of the ankle
9. intraneural tumors: neurofibroma, schwannoma, neurogenic sarcoma, ganglion cysts
10. vascular: venous thrombosis
11. weight loss

30.12.3 Findings in peroneal nerve palsy

General information

1. sensory changes (uncommon): involves lateral aspect of lower half of leg
2. muscle involvement: See Table 30.5

Common peroneal nerve palsy (most common) produces weak ankle dorsiflexion (foot drop) due to anterior tibialis palsy, weak foot eversion, and sensory impairment in areas innervated by deep and superficial peroneal nerve (lateral calf and dorsum of foot). There may be a Tinel's sign with percussion over the nerve near the fibular neck. Occasionally, only the deep peroneal nerve is involved, resulting in foot drop with minimal sensory loss. Must differentiate from other causes of foot drop (p.1416).

Examination/clinical correlation

See reference.76 (p 293)

- buttock level injury: unless the injury is one that permits spontaneous regeneration, prognosis is poor for return of peroneal nerve function even with surgery

| Table 30.5 Muscle involvement in peroneal nerve palsy |
|----------------|---------------------------------|----------------|
| Muscle         | Nerve              | Action         | Involvement                  |
| EHL            | deep peroneal      | great toe dorsiflexion | Most commonly involved |
| anterior tibialis | ankle dorsiflexion |                |                               |
| EDL            |                    | toe extension   | Least commonly involved (often spared) |
| peroneus longus & brevis | superficial peroneal | foot eversion |                               |
• thigh level injury: also difficult to get improvement with surgical repair. Some peroneus function may occur at ≥ 6 mos, early contraction of AT may take ≥ 1 yr
• knee level injury: with successful regeneration, peroneus contraction may begin by 3–5 months.
  First signs: quivering of muscle lateral to the proximal fibula on attempted foot eversion, or tightening of tendon posterior and behind the lateral malleolus on attempted ankle dorsiflexion

30.12.4 Evaluation

EMG

EMG takes 2–4 weeks from the onset of symptoms to become positive. Stimulate above and below fibular head for prognostic information: if absent in both sites, the prognosis is poor (indicates retrograde degeneration has occurred). Wallerian degeneration takes ≈ 5 days to cause deterioration.

In addition to the expected findings of denervation – PSWs & fibs (p. 242) – in the anterior tibialis, evaluate:
1. L5 innervated muscles outside the distribution of the common peroneal nerve:
   a) posterior tibialis
   b) flexor digitorum longus
2. L5 muscles whose nerve originates above the knee (these muscles are spared in cases of compression of the peroneal nerve at the fibular head due to the fact that the nerve takeoff is proximal to the popliteal fossa):
   a) biceps femoris (short or long head)
   b) tensor fascia lata
3. paraspinal muscles: signs of denervation solidifies the location of the lesion as nerve root; not helpful if negative

MRI

May demonstrate causes such as tumor or a ganglion cyst arising from the superior tibiofibular articulation.

30.12.5 Treatment

General information

When treatment can eliminate a reversible cause, the outcome is usually good. Surgical exploration and decompression may be considered when there is no reversible cause or when improvement does not occur.

Nonsurgical management

Bracing: ankle-foot-orthosis (AFO) compensates for loss of ankle dorsiflexion which inserts unobtrusively into a shoe. If this is inadequate, or to stabilize the ankle, a spring-loaded kick-up foot brace built into a shoe may be used. The patient should be instructed in techniques to avoid contracture of the Achilles tendon (heel cord) which would impair ankle dorsiflexion if nerve function returns.

Surgical management

At the level of the popliteal fossa the skin incision is made just medial to the tendon of the short head of the biceps femoris (lateral hamstring) as the peroneal nerve is best located deep to or slightly medial to this tendon. The incision is carried distally slightly laterally along the surgical neck of the fibula. The biceps femoris is retracted laterally and the nerve is isolated and tagged with a Penrose drain. The sensory sural nerve branches off the peroneal nerve at variable sites ranging from the sciatic portion of the nerve (proximal to the flexor crease) or distal to this.

In cases of compression, the fascia from the lateral gastrocnemius and soleus overlying the nerve distal to the fibular head is lysed and the nerve is exposed in 360°. As the nerve crosses the fibular neck it divides into superficial and deep branches. The superficial branch travels directly distally to supply the peroneus longus and brevis (foot plantarflexors). The deep branches curve anteriorly to the anterior tibialis, EHL, and toe extensors.

If a graft is needed, the contralateral sural nerve is usually used, which may be supplemented with the ipsilateral sural nerve if needed.

http://e-surg.com
30.13 Tarsal tunnel

30.13.1 General information

Entrapment of (posterior) tibial nerve may occur in the tarsal tunnel, posterior and inferior to medial malleolus. The tunnel is covered by the flexor retinaculum (laciniate ligament) which extends downward from the medial malleolus to the tubercle of the calcaneus. There is often (but not necessarily) a history of old ankle dislocation or fracture. The nerve may be trapped at the retinacular ligament. This results in pain and paresthesias in the toes and sole of foot (often sparing the heel because the sensory branches often originate proximal to the tunnel), typically worse at night. May cause clawing of toes secondary to weakness of intrinsic foot muscles. Often caused by fracture or dislocation, also rheumatoid arthritis, rarely tumors.

30.13.2 Exam

Percussion of nerve at medial malleolus produces paresthesias that radiate distally (Tinel’s sign). Maximal inversion and eversion of the foot tend to exacerbate. Dorsiflexion-eversion test: examiner maximally everts and dorsiflexes the ankle while dorsiflexing the toes at the MTP joints for 5–10 seconds. Positive test reproduces the pain.

30.13.3 Diagnosis

EMG and NCV studies may help.

30.13.4 Nonsurgical management

External ankle support to improve foot mechanics.

30.13.5 Surgical management

Surgical decompression is indicated for confirmed cases that fail to improve. A curvilinear incision is used, ≈ 1.5 cm posterior and inferior to the medial malleolus. The flexor retinaculum is divided, as are any septa underneath, and the distal branches should be followed until they dive into the muscle.

References

31 Non-Entrapment Peripheral Neuropathies

31.1 Definitions

Peripheral neuropathy. (The term polyneuropathy is also sometimes used.) Diffuse lesions of peripheral nerves producing weakness, sensory disturbance, and/or reflex changes

Mononeuropathy. A disorder of a single nerve, often due to trauma or entrapment

Mononeuropathy multiplex. Involvement of 2 or more nerves, usually due to a systemic abnormality (e.g. vasculitis, rheumatoid arthritis, DM...). Treatment is directed at the underlying disorder

31.2 Etiologies of peripheral neuropathy

A mnemonic for etiologies of peripheral neuropathies is “GRAND THERAPIST” See Table 31.1). Diabetes, alcoholism, and Guillain-Barré (italicized in table) account for 90% of cases. Other etiologies include: arteritis/vasculitis, monoclonal gammopathy (p. 547), hepatitis C virus-associated cryoglobulinemia, acute idiopathic polyneuritis, Sjögren’s syndrome (disease).

31.3 Classification

1. inherited neuropathies
   a) Charcot-Marie-Tooth (CMT) (AKA peroneal muscular atrophy, AKA Hereditary Motor and Sensory Neuropathy (HMSN)): Up to 7 types, (the most common form is autosomal dominant, but X-linked recessive forms also exist). CMT Types 1 & 2 together make up the most common inherited disorder of peripheral nerves (up to 40/100,000). The most common forms involve demyelination. Progressive loss of motor (primarily distal LE) and, to a lesser degree, sensory function (predominantly proprioception and vibration), with atrophy in UEs & LEs. Earliest findings: pes cavus with hammer toes, foot drop and frequent ankle sprains. Patients are more susceptible to entrapment neuropathies due to underlying compromise of peripheral nerves. Patients with Type 1 usually maintain ability to ambulate, whereas Type 2 usually lose ambulation by their teenage years
   b) hereditary neuropathy with liability to pressure palsies (HNPP): similar to CMT but due to focal areas of irregular thickening of myelin sheaths (“tomaculous” changes), mild trauma or pressure can produce nerve palsies that may last for months

2. acquired neuropathies: see sections below for details
   a) acquired pure sensory neuropathies (in the absence of autonomic dysfunction) are rare. May be seen with pyridoxine therapy or paraneoplastic syndromes (see below)
   b) entrapment neuropathies (p. 515)

3. pseudoneuropathy
   a) definition: psychogenic somatoform disorders or malingering, reproducing the pains, paresthesias, hyperalgesia, weakness, and even objective findings such as changes in color and temperature which may mimic neuropathic symptoms

Table 31.1 Mnemonic for etiologies of peripheral neuropathy

31.4 Clinical

31.4.1 Presentation
Peripheral neuropathies can present as loss of sensation, pain, weakness, incoordination and difficulty ambulating.

31.4.2 Evaluation
Initial (screening) work-up for peripheral neuropathies of unknown etiology:
1. bloodwork: Hgb-A1C, TSH, ESR and vitamin B12
2. EMG

31.5 Syndromes of peripheral neuropathy

31.5.1 Critical illness polyneuropathy (CIP)
AKA neuropathy of critical illness, ICU neuropathy... See DDx under Guillain-Barré syndrome (p.186).
May occur in up to 70% of septic patients (not all are significantly symptomatic). Affects primarily distal muscles.
Diagnostic criteria:
1. presence of sepsis, multi-organ failure, respiratory failure, or septic inflammatory response syndrome (SIRS)
2. difficulty weaning from ventilator or extremity weakness
3. EMG: ↓ amplitudes of compound muscle action potentials (CMAP) & SNAP
4. widespread muscle denervation potentials
5. normal or only mild increase in serum CPK levels
Recovery occurs in weeks to months (faster than Guillain-Barré).
Treatment is supportive. Complete recovery occurs in 50%

31.5.2 Paraneoplastic syndromes affecting the nervous system
Occurs in <1% of cancer patients. Peripheral sensory neuropathy of unknown etiology has been associated with cancer since its earliest description. Therefore, However, in patients with sensory neuropathy of unknown etiology, occult neoplasms should be ruled out. If the work-up is negative, the patient should be followed since up to 35% of patients will be found to have cancer after a mean interval of 28 months after the onset of neuropathy (range: 3–72 months) (no one particular cancer type predominated, in spite of the fact that historically lung cancer is the most frequent neoplasm associated with sensory neuropathy).

31.5.3 Alcohol neuropathy
Characteristically produces a diffuse sensory neuropathy, with absent achilles reflexes.

31.5.4 Brachial plexus neuropathy
See reference (p 918)

Evaluation
When the etiology is unclear, check CXR (with apical lordotic view), glucose, ESR and ANA.
If no improvement by ≈ 4 weeks, obtain MRI of the plexus (idiopathic brachial plexitis will usually start to show some improvement by this time, therefore tumor should be ruled out if no improvement).

Differential diagnosis of etiologies of brachial plexopathy
1. Pancoast syndrome or Pancoast tumor AKA superior sulcus tumor. Clinical: various combinations of pain in the shoulder radiating into the upper extremity in the ulnar nerve distribution from
Involvement of the lower brachial plexus, atrophy of hand muscles, Horner’s syndrome (p. 564), UE edema. Etiologies:

a) neoplasms:
   - most common: bronchogenic cancer, usually non-small cell (NSCLC) (squamous cell or adenocarcinoma) arising in the pulmonary apex
   - metastases
b) infections

c) inflammatory: granulomas, amyloid

2. (idiopathic) brachial plexitis AKA neuralgic amyotrophy: most commonly upper plexus or diffuse (see below)

3. cervical rib
4. viral
5. following radiation treatment: often diffuse (see below)
6. diabetes
7. vasculitis
8. inherited: dominant genetics
9. trauma (p. 550)

Neuralgic amyotrophy of the upper extremity

General information
AKA idiopathic brachial plexus neuropathy AKA (paralytic) brachial neuritis, AKA brachial plexitis, AKA Parsonage-Turner syndrome, AKA immune-mediated brachial plexus neuropathy, among others. Idiopathic. Not clearly infectious or inflammatory; allergic mechanism possible. Prognosis is generally good. Common patterns: single or multiple mononeuropathy, plexopathy, or some combination. Demographics are shown in Table 31.2.

In a review of 99 cases: predominant symptom is acute onset of intense pain, with weakness developing simultaneously or after a variable period (70% occur within 2 weeks of pain) usually as the pain lessened. Weakness never preceded pain, onset of weakness was sudden in 80% . Pain was usually constant, and described as “sharp”, “stabbing”, “throbbing” or “aching.” Arm movement exacerbated pain, and muscle soreness was noted in 15% . Pain lasted hours to several weeks. Paresthesias occurred in 35% . Pain usually lacked radicular features. When bilateral, weakness is usually asymmetric.

Exam
Weakness or paralysis in 96% confined to shoulder girdle in 50% In descending order of involvement: deltoid, spinati, serratus anterior, biceps brachii, and triceps. Winging of the scapula occurred in 20% Sensory loss occurred in 60% of plexus lesions, of mixed variety (superficial cutaneous and proprioceptive). Sensory loss most common in outer surface of upper arm (circumflex nerve distribution) and radial aspect of forearm. Reflexes were variable.

</table>
Overall distribution judged to predominantly involve upper plexus in 56% diffuse plexus in 38% and lower in 6%

EMG/NCV
May help localize the portion of the plexus involved, and may detect subclinical involvement of the contralateral extremity. Must wait ≥3 weeks from onset for findings. Differentiating from cervical radiculopathy: SNAP should be normal in radiculopathy whereas some involvement usually occurs in plexitis. Cervical paraspinals will usually be normal in plexitis (except for very severe cases where there can be some retrograde involvement), and will be abnormal (fibrillations) in radiculopathy (except in cases where there has been enough time that significant recovery has occurred).

Outcome
Functional recovery is better in patients with primarily upper plexus involvement. After 1 year, 60% of upper plexus lesions were functioning normally, whereas none with lower involvement were (latter took 1.5–3 years). Rate of recovery estimated to be 36% within 1 year, 75% within 2, and 89% by 3 years. Recurrence was seen in only 5% No evidence that steroids altered the course of the disease although it is still often prescribed in the acute phase.

Radiation induced brachial plexus neuropathy
Often follows external beam irradiation in the region of the axilla for breast carcinoma. Produces sensory loss with or without weakness. CT or MRI or biopsy may be needed to rule-out tumor invasion of the brachial plexus.

31.5.5 Lumbosacral plexus neuropathy
See reference.10

General information
Analogous to idiopathic brachial plexitis (see above). It is controversial whether this actually exists in isolation without diabetes. Often starts with LE pain of abrupt onset, followed in days or a few weeks by weakness with or without muscle atrophy. Sensory symptoms are less prominent, and usually involve paresthesias. Objective sensory loss is only occasionally seen. There may be tenderness over the femoral nerve.

Differential diagnosis
May be confused with femoral neuropathy or L4 radiculopathy when quadriceps weakness and wasting occurs. Similarly, L5 radiculopathy or peroneal neuropathy may be erroneously suspected when foot drop is seen. Straight leg raising may occasionally be positive. Conspicuously absent are: back pain, exacerbation of pain by Valsalva maneuver or back motion, and significant sensory involvement. See differential diagnosis of foot drop (p.1417) and other causes of sciatica (p.1410).

Etiologies
Other etiologies are similar to that for brachial plexus neuropathy (see above) except that under tumor, a pelvic mass should also be included (check prostate on rectal exam).

Evaluation
Evaluation is as for brachial plexus neuropathy (see above), except that instead of a brachial plexus MRI, a lumbar MRI and pelvic CT should be done to rule out masses.

EMG is key to diagnosis: evidence of patchy denervation (fibrillation potentials, and motor unit potentials that are either decreased in number or increased in amplitude or duration and polyphasic) involving at least 2 segmental levels with sparing of the paraspinal muscles is highly diagnostic (once diabetes, etc. have been ruled-out).

Outcome
Recovery from pain precedes return of strength. Improvement is generally monophasic, slow (years), and incomplete.
31.5.6 Diabetic neuropathy

General information

≈ 50% of patients with DM develop neuropathic symptoms or show slowing of nerve conduction velocities on electrodiagnostic testing. Neuropathy may sometimes be the initial manifestation of diabetes. Diabetic neuropathy is reduced by tight control of blood glucose.11

Syndromes

Disagreement exists over the number of distinct clinical syndromes; there is probably a continuum12 and they likely occur in various combinations. Some of the more readily identified syndromes include:

1. primary sensory polyneuropathy: symmetric, affecting feet and legs more than hands. Chronic, slowly-progressive. Often with accelerated loss of distal vibratory sense (normal loss with aging is ≈ 1%/per year after age 40). Presents as pain, paresthesias, and dysesthesias. Soles of feet may be tender to pressure. Meralgia paresthetica (p.534) may be first manifestation

2. autonomic neuropathy: involving bladder, bowel, and circulatory reflexes (resulting in orthostatic hypotension). May produce impotence, impaired micturition, diarrhea, constipation, impaired pupillary light response

3. diabetic plexus neuropathy or proximal neuropathy: possibly secondary to vascular injury to nerves (similar to a diabetic mononeuritis):
   a) one that occurs in patients >50 years old with mild diabetes type II that is often confused with femoral neuropathy. Causes severe pain in the hip, anterior thigh, knee, and sometimes medial calf. Weakness of the quadriceps, iliopsoas, and occasionally thigh adductors. Loss of knee jerk. Possible sensory loss over medial thigh and lower leg. Pain usually improves in weeks, the weakness in months
   b) diabetic amyotrophy: occurs in similar patient population often with recently diagnosed DM. Alternative names include14: Bruns-Garland syndrome, ischemic mononeuropathy multiplex.....15 Abrupt onset of asymmetric pain (usually deep aching/burning with superimposed lancinating paroxysms, most severe at night) in back, hip, buttocks, thigh, or leg. Progressive weakness in proximal or proximal and distal muscles, often preceded by weight loss. Patellar reflexes are absent or reduced. Sensory loss is minimal. Proximal muscles (especially thigh) may atrophy. EMG findings consistent with demyelination invariably accompanied by axonal degeneration, with involvement of paraspinals and no evidence of myopathy. Symptoms may progress steadily or stepwise for weeks or even up to 18 months, and then gradually resolve. Opposite extremity may become involved during the course or may occur months or years later. Sural nerve biopsy may suggest demyelination
   c) diabetic proximal neuropathy (DPN): fairly similar findings to diabetic amyotrophy except for subacute onset of symmetric LE involvement that usually start with weakness may be a variant.16 Table 31.3 (adapted16) compares DPN to diabetic amyotrophy and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP)

Treatment

Treatment of Bruns-Garland syndrome is primarily expectant, although immunotherapy (steroids, immune globulin, or plasma exchange) may be considered in severe or progressive cases (efficacy is unproven).16

For sensory polyneuropathy, good control of blood sugar contributes to reduction of symptoms. Adjunctive agents that have been used include:

1. mexiletine (Mexitil®): start at 150 mg q 8 hrs, and titrate to symptoms to a maximum of 10 mg/kg/d

2. amitriptyline (Elavil®) and fluphenazine (Prolixin®): : start with 25 mg amitriptyline PO q hs and 1 mg fluphenazine PO TID; and work up to 75 mg amitriptyline PO q hs17 (≈ 100 mg qd amitriptyline alone may also be effective18). Usefulness has been challenged,18 but many studies do show benefit.18,20 Side effects: that may limit use include sedation, confusion, fatigue, malaise, hypomania, rash, urinary retention, and orthostatic hypotension

3. desipramine (Norpramin®): more selective blocker of norepinephrine reuptake (which seems more effective for this condition than serotonin reuptake blockers). Effectiveness at mean doses of 110 mg/day ≈ same as amitriptyline and therefore may be useful for patients unable to tolerate amitriptyline.18 Side effects: include insomnia (may be minimized by AM dosing), orthostatic hypotension, rash, bundle branch block, tremor, pyrexia. Supplied: 10, 25, 50, 75, 100 & 150 mg tablets

4. capsaicin (Zostrix®) (p.496): effective in some
5. paroxetine (Paxil®): a selective serotonin reuptake inhibitor (SSRI) antidepressant. Start with 20 mg PO q AM. If necessary, increase by 10 mg/d q week up to a maximum of 50 mg/day (except in elderly, debilitated, or renal or hepatic failure where maximum is 40 mg/day). Supplied: 20 mg (scored) & 30 mg tablets.

6. gabapentin (Neurontin®) doses of 1800–3600 mg/d produces at least moderate pain relief from painful diabetic neuropathy in 60% of patients and was as efficacious as amitriptyline. Dosage must be reduced with renal insufficiency. See details (p.455).

7. pregabalin (Lyrica®) : start with 50 mg T ID and increase up to a maximum of 100 mg PO T ID within 1 week in patients with creatinine clearance ≥ 60 ml/min, see Eq (7.1) to estimate. Dosage must be reduced with renal insufficiency. Supplied: 25, 50, 75, 100, 150, 200, 225, 300 mg capsules.

31.5.7 Drug-induced neuropathy

Many drugs have been implicated as possible causes of peripheral neuropathy. Those that are better established or more notorious include:

1. thalidomide: neuropathy may occur with chronic use, and may be irreversible.
2. metronidazole (Flagyl®)
3. phenytoin (Dilantin®)
4. amitriptyline (Elavil®)
5. dapsone: a rare complication reported with use in nonleprosy patients is a reversible peripheral neuropathy that may be due to axonal degeneration, producing a Guillain-Barré-like syndrome.
6. nitrofurantoin (Macrodantin®): may additionally cause optic neuritis
7. cholesterol lowering drugs: e.g. lovastatin (Mevacor®), indapamide (Lozol®), gemfibrozil (Lopid®)
8. thallium: may produce tremors, leg pains, paresthesias in the hands and feet, polyneuritis in the LE, psychosis, delirium, seizures, encephalopathy
9. arsenic: may produce numbness, burning and tingling of the extremities
10. chemotherapy: cisplatin, vincristine...

31.5.8 Femoral neuropathy

Clinical findings

1. motor deficits:
   a) wasting and weakness of the quadriceps femoris (knee extension)
   b) weakness of iliopsoas (hip flexion): if present, indicates very proximal pathology (lumbar root or plexus lesion) as the branches to the iliopsoas arise just distal to the neural foramina.

http://e-surg.com
2. diminution of the patellar (knee jerk) reflex
3. sensory findings:
   a) sensory loss over the anterior thigh and medial calf
   b) pain in same distribution may occur
4. mechanical signs: positive femoral stretch test (p.1048)

Etiologies
1. diabetes: the most frequent cause
2. femoral nerve entrapment: rare
   a) may occur secondary to inguinal hernia or may be injured by deep sutures placed during herniorrhaphy
   b) secondary to prolonged pelvic surgery from retractor compression (usually bilateral)
3. intraabdominal tumor
4. femoral arterial catheterization: see below
5. retroperitoneal hematoma (e.g. in hemophiliacs or on anticoagulants)
6. during surgery (p.549)

Differential diagnosis
1. L4 radiculopathy: L4 radiculopathy should not cause iliopsoas weakness; see L4 involvement (p.1412).
2. diabetic plexus neuropathy (see above)
3. (idiopathic) lumbosacral plexus neuropathy (see above)

31.5.9 AIDS neuropathy

General information
3.3% of patients with AIDS will develop peripheral nerve disorders^24 (whereas none who were just HIV positive developed neuropathy). The most common disorder is distal symmetric polyneuropathy (DSP), usually consisting of vague numbness and tingling, and sometimes painful feet (although it may also be painless). There may be subtle reduction of light touch and vibratory sense. Other neuropathies include mononeuropathies—usually meralgia paresthetica (p.534)—mononeuropathy multiplex, or lumbar polyradiculopathy. Drugs used to treat HIV can also cause neuropathies (see below).

The DSP in AIDS patients is often associated with CMV infection, Mycobacterium avium intracellulare infection, or may be due to lymphomatous invasion of the nerve or lymphomatous meningitis. May demonstrate a mixed axonal demyelinating type of neuropathy on electrodiagnostic testing.

Neuropathies associated with drugs used to treat HIV
1. nucleoside reverse transcriptase inhibitors
   a) zidovudine (Retrovir®) (formerly AZT)
   b) didanosine (ddI; Videx®): (formerly dideoxyinosine) can cause a painful dose-related neuropathy^25
   c) stavudine (d4T; Zerit®): can cause sensory neuropathy which usually improves when d4 T is discontinued, and may not recur if restarted at lower dose^25
   d) zalcitabine (ddC; Hivid®): the least potent of the nucleoside analogs, therefore rarely used; dose-related neuropathy can be severe and persistent. More common in patients with DM or didanosine treatment^25
2. protease inhibitors
   a) ritonavir (Norvir®): can cause peripheral paresthesias
   b) amprenavir (Agenerase®): can cause perioral paresthesias

31.5.10 Neuropathy associated with monoclonal gammopathy

General information
Monoclonal gammopathies include myeloma (p.714), Waldenstrom’s macroglobulinemia, and non-malignant entities such as monoclonal gamopathy of undetermined significance (MGUS). Much effort has gone into determining which benign gammopathies are or are not likely to progress, and will not be addressed here.
≈ 10% of patients with neuropathy with no apparent etiology will be determined to have a monoclonal gammopathy (malignant or otherwise).

**Etiologies**
1. antibodies directed primarily against oligosaccharides of peripheral nerves, e.g. myelin associated glycoprotein (MAG), producing demyelinating neuropathy
2. cryoglobulins may damage vaso-nervorum (small blood vessels nourishing peripheral nerves)
3. in malignant gammopathies, tumor cells can invade the peripheral nerves (lymphomatosis)
4. amyloidosis (p.549): deposition of amyloid in peripheral nerves
5. thalidomide (p.546) used to treat some myelomas may cause neuropathy

**Treatment**
1. IgM monoclonal gammopathies: reduce the IgM antibody concentration
2. IgG or IgA monoclonal gammopathies:
   a) treatment for myeloma related neuropathy is directed at treating the myeloma
   b) solitary plasmacytoma: excision or XRT can improve the neuropathy

**31.5.11 Perioperative neuropathies**

**General information**
Also, below. Represent ≈ 1/3 of all anesthesia-associated malpractice claims in the U.S. Most often involves ulnar nerve or brachial plexus. In many cases, a nerve that is abnormal but asymptomatic may become symptomatic as a result of any of the following factors: stretch or compression of the nerve, generalized ischemia or metabolic derangement. The injury may be permanent or temporary. Occurs almost exclusively in adults.

**Types of perioperative neuropathies**
Examples include:
1. ulnar neuropathy: controversial. Often blamed on external nerve compression or stretch as a result of malpositioning. Although this may be true in some cases, in one series this was felt to be a factor in only ≈ 17% of cases. Patient-related characteristics associated with these neuropathies are shown in Table 31.4. Many of these patients have abnormal contralateral nerve conduction, suggesting a possible predisposing condition. Many patients do not complain of symptoms until >48 hours post-op (if it were due to compression, deficit would be maximal immediately post-op). Risk may be reduced by padding the arm at, and especially distal to, the elbow, and avoiding flexion of the elbow (especially avoiding >110° flexion which tightens the cubital tunnel retinaculum) and by reducing the amount of time spent convalescing in the recumbent position with leaning on the elbows.
2. brachial plexus neuropathy: may be mistaken for ulnar neuropathy. May be associated with:
   a) median sternotomy (most common with internal mammary dissection). Posterior sternal retraction displaces the upper ribs and may stretch or compress the C6 through T1 roots (which are major contributors to the ulnar nerve)
   b) head-down (Trendelenburg) positions where the patient is stabilized with a shoulder brace. The brace should be placed over the acromioclavicular joint(s), and non-slip mattresses and flexion of the knees may be used as adjuncts
   c) prone position (rare): especially with shoulder abduction and elbow flexion with contralateral head rotation
3. median neuropathy: perioperative median nerve injury may result from stretch of the nerve. Rare. Seems to occur primarily in middle-aged muscular males with reduced extension of the elbows due to muscle mass. This may result in stretching of the nerve after muscle relaxants are administered.
given. Padding should be placed under the forearms and hands of these patients to maintain mild elbow flexion. 

4. lower extremity neuropathies: most occur in patients undergoing procedures in the lithotomy position. Frequency of involvement in a large series of patients undergoing procedures in the lithotomy position: common peroneal 81% sciatic 15% and femoral 4% Risk factors other than position: prolonged duration of procedure, extremely thin body habitus, and cigarette smoking in the preoperative period

a) common peroneal neuropathy: susceptible to injury in the posterior popliteal fossa where it wraps around the fibular head. May be compressed by leg holders, which should be padded in this area

b) femoral neuropathy: compression of the nerve by self-retaining abdominal wall retractor or rendering the nerve ischemic by occlusion of the external iliac artery. Hemorrhage into the iliopsoas muscle may also compress the nerve. Cutaneous branches of the femoral nerve may be injured during labor and/or delivery (most are transient)

c) sciatic neuropathy: stretch injuries may occur with hyperflexion of the hip and extension of the knee as may occur in some variants of the lithotomy position

d) meralgia paresthetica: tends to occur bilaterally in young, slender males positioned prone, with operations lasting 6–10 + hours. Onset: 1–8 days post-op. Spontaneous recovery typically occurs over an average of 5.8 months

Management

Once a neuropathy is detected, determine if it is sensory, motor, or both. Pure sensory neuropathies are more often temporary than motor, and expectant management for ≈ 5 days is suggested (have the patient avoid postures or activities that may further injure the nerve). Neurologic consultation should be requested for all motor neuropathies and for sensory neuropathies persisting >5 days (EMG evaluation will not usually be helpful earlier than ≈ 3 weeks after onset).

31.5.12 Other neuropathies

Amyloid neuropathy

Amyloid is an insoluble extracellular protein aggregate that can be deposited in peripheral nerves. Amyloidosis occurs in a number of conditions, e.g. in ≈ 15% of patients with multiple myeloma (p. 714). The neuropathy predominantly produces a progressive autonomic neuropathy and symmetric dissociated sensory loss (reduced pain and temperature, preserved vibratory sense). There is usually less prominent motor involvement. May predispose to pressure injury of nerves (especially carpal tunnel syndrome, see laboratory tests (p. 523).

Uremic neuropathy

Occurs in chronic renal failure. Early symptoms include calf cramps (“Charlie horses”), dyesthetic pain in feet (similar to painful diabetic neuropathy) and “restless legs.” Achilles reflexes are lost. A stocking sensory loss is followed later by LE weakness that starts distally and ascends. The offending toxin is not known. Dialysis or renal transplantation relieves the symptoms.

Neuropathy after cardiac catheterization

In a series of ≈ 10,000 patients followed after femoral artery catheterization (e.g. for coronary angiography or angioplasty), neuropathy occurred in 0.2% (with an estimated range in the literature up to ≈ 3%). Risk factors identified include: patients developing retroperitoneal hematomas or pseudoaneurysms after the procedure, procedures requiring larger introducer sheaths (e.g. angioplasty & stent placement > diagnostic catheterization), excessive anticoagulation (PTT > 90 for at least 12 hours).

Two groups of patients were identified and are shown in Table 31.5. Excruciating pain after the catheterization procedure often preceded the development or recognition of neuropathy.

Treatment

After considering available information, the recommendation is to repair pseudoaneurysms surgically, but to treat the neuropathy conservatively. A case could not be made that surgical drainage of hematoma reduced the risk of neuropathy. Weakness from femoral or obturator neuropathy was treated with inpatient rehabilitation.
Outcome

Group I patients all had resolution in < 5 mos. In group II, 50% had complete resolution in 2 mos. 6 patients had persistent symptoms, 5 had mild femoral sensory neuropathy (1 of whom felt it was at least somewhat disabling), 1 had mild persistent quadriceps weakness and occasionally walks with a cane.

31.6 Peripheral nerve injuries

31.6.1 General information

Anatomy of peripheral nerves

See Fig. 31.1. Endoneurium surrounds myelinated and unmyelinated axons. These bundles are gathered into fascicles surrounded by perineurium. The epineurium encases the nerve trunk, containing fascicles separated by interfascicular epineurium or mesoneurium.

Nerve regeneration

Peripheral nerves regenerate ≈1 mm/day (about 1 inch/month). Divide this figure into distance that the nerve has to traverse (from knowledge of anatomy) for guide as to how long to wait before considering failure of therapy (either operative or non-operative). However, this rule may not be applicable to long distances (> ≈ 12 inches), and it may take longer to traverse regions of entrapment, scar or nerve injury. There may also be fibrosis of the muscle beyond salvage.

Peripheral nerve injury classification

Table 31.6

There are numerous classification systems. The Seddon classification is an older 3-tiered system. The Sunderland system has 5 tiers, essentially dividing axonotmesis into 3 subgroups. Others have added a 6th category as shown in Table 31.6.

31.6.2 Brachial plexus injuries

Etiologies

Etiologies include:

1. penetrating trauma
2. traction (stretch injuries): more likely to affect the posterior and lateral cords than the medial cord and median nerve
3. first rib fractures
4. compression by hematoma
**Table 31.6 Classification of peripheral nerve injury**

<tr>
<td>Mixed lesion. Combination of elements of first through fourth degree. There may be some preserved sensory fascicles (may produce a positive Tinel’s sign).</td>
<td></td>
</tr>
</tbody>
</table>

<sup>a</sup>Comparing and showing approximate equivalence of Seddon and Sunderland systems.

<sup>b</sup>Wallerian degeneration after British physiologist Augustus Volney Waller (1816–1870), AKA orthograde degeneration, AKA secondary degeneration: degeneration of the axon distal to a focal lesion.

<sup>c</sup>Not part of original Sunderland system.
Differentiating preganglionic from postganglionic injuries

Initial exam seeks to differentiate preganglionic injuries (proximal to dorsal root ganglion) which cannot be repaired surgically, from postganglionic injuries. Clues to a preganglionic injury include:

1. Horner’s syndrome: preganglionic injury interrupts white rami communicantes
2. paralysis of serratus anterior (long thoracic nerve): produces winging of scapula
3. paralysis of rhomboids (dorsal scapular nerve)
4. early neuropathic pain suggests nerve root avulsion. MRI or myelogram will show pseudomeningealceles at the avulsed levels
5. EMG: requires ≥3 weeks from injury for some findings. Look for:
   a) denervation potentials in paraspinal muscles due to loss of neural input. The posterior ramus of the spinal nerve originates just distal to the dorsal root ganglion. Due to overlap, cannot localize to a specific segment
   b) normal sensory nerve action potential (SNAP): preganglionic injuries leave the dorsal ganglion sensory cell body and the distal axon intact, so that normal SNAP can be recorded proximally even in an anesthetic region
6. pseudomeningocele on myelography or MRI: suggests nerve root avulsion (very proximal), however, 15% of pseudomeningoceles are not associated with avulsions, and 20% of avulsions do not have pseudomeningoceles

Types of brachial plexus injuries

(Duchene)-Erb’s palsy

Upper brachial plexus injury (C5 & 6, some authors include C7) e.g. from forceful separation of humeral head from shoulder, commonly due to difficult parturition (see below) or motorcycle accident (downward force on shoulder can cause traumatic nerve root avulsion from the spinal cord). Paralysis of deltoid, biceps, rhomboids, brachioradialis, supra- & infra-spinatus, and occasionally supinator. C7 involvement produces weak wrist extension.

Motor: arm hangs at side internally rotated & extended at elbow and flexed at the wrist (“Bell-hop’s tip position”). Hand motion is unaffected.

Klumpke’s palsy

Injury to lower brachial plexus (C8 & T1, some authors include C7), from traction of abducted arm e.g. in catching oneself during a fall from a height, or by Pancoast tumor (lung apex tumor – check CXR with apical lordotic view). Characteristic claw deformity (also seen with ulnar nerve injury) with weakness and wasting of small hand muscles. Possible Horner’s syndrome if T1 involved.

Birth brachial plexus injury (BBPI)

Incidence is 0.3–2.0 per 1000 live births (0.1% in infants with birthweight <4000 gm). Rarely, a congenital case may be mistaken for BBPI. Some contend that the plexus injury may occur when uterine contractions push the shoulder against the mother’s pubic bone or with lowering of the shoulder with opposite inclination of the cervical spine.

Classification of BBPI injuries: Upper plexus injuries are most common, with about half having C5 & C6 injuries, and 25% involving C7 also. Combined upper and lower lesions occur in ≥20% Pure lower lesions (C7-T1) are rare, constituting only ≥2% and seen most commonly in breech deliveries. Lesions are bilateral in ≥4% A 4-level scale of intensity is shown in Table 31.7

Risk factors:
1. shoulder dystocia
2. high birth weight
3. primiparous mother
4. forceps or vacuum assisted delivery
5. breech presentation
6. prolonged labor
7. previous birth complicated by BBPI

Management of BBPI: Most surgeons observe all patients until age 3 months. Conservative surgeons may wait up to 9 months. More aggressive surgeons will explore the plexus at age 3 months if not antigravity in deltoid, biceps or triceps. In cases of proven avulsion (pseudomeningocele and EMG indicative of a preganglionic injury), nerve transfers are a valid option at 3 months. EMG may show signs of reinnervation, but the recovery may not be robust enough.
Management of brachial plexus injuries

1. most injuries show maximal deficit at onset. Progressive deficit is usually due to vascular injuries (pseudoaneurysm, A-V fistula, or expansile clot), these should be explored immediately

2. clean, sharp, relatively fresh lacerating injuries (usually iatrogenic, scalpel induced) should be explored acutely and repaired with tension-free end-to-end anastomoses within 24–48 hours (after that then ends will more edematous and therefore more difficult to suture)

3. penetrating non-missile injuries with severe or complete deficit should be explored as soon as the primary wound heals

4. gunshot wounds (GSW) to the brachial plexus: deficit is usually due to axonotmesis or neurotmesis (see below). Sometimes nerves may be divided. Nerves showing partial function usually recover spontaneously; those with complete dysfunction rarely do so. Surgery is of little benefit for discrete injuries to the lower trunk, medial cord, or C8/T1 roots. Most are managed conservatively for 2–5 months. Indications for surgery are shown in Table 31.8

5. traction injuries: incomplete postganglionic injuries tend to improve spontaneously. If recovery is not satisfactory, perform EMG at 4–5 months and explore at 6 months

6. neuromas in continuity: those that do not conduct a SNAP have complete internal disruption and require resection and grafting. Methods of repair:

   a) neurolysis:
      • external neurolysis: most commonly performed in exploration. Value is questionable
      • internal neurolysis: splitting the nerve into fascicles. Not recommended unless a clear neuroma in continuity is found eccentric in the nerve that conducts SNAP

   b) nerve grafting. Sural nerve is the most commonly used interposition graft following resection of neuroma in continuity

   c) nerve transfers. Donor nerve options:
      • spinal accessory nerve
      • intercostal nerves to musculocutaneous nerve
      • fascicles of the ulnar nerve for the median nerve (Oberlin procedure)
      • anterior interosseus nerve to median nerve

31.7 Missile injuries of peripheral nerves

This section deals primarily with gunshot wounds (GSW). Most injuries from a single bullet are due to shock and cavitation from the missile causing axonotmesis or neurotmesis, and are not from direct nerve transection. Approximately 70% will recover with expectant management.
However, if there is a lack of improvement on serial examinations including electrodiagnostic studies, intervention should be undertaken by about 5–6 months to avoid further difficulties due to nerve fibrosis and muscle atrophy.

See Table 31.8 for indications for surgery for missile injuries of the brachial plexus.

### 31.8 Thoracic outlet syndrome

#### 31.8.1 General information

The thoracic outlet is a confined area at the apex of the lung bordered by the 1st rib below and the clavicle above through which passes the subclavian artery, vein, and brachial plexus.

Thoracic outlet syndrome (TOS) is a term implying compression of one or more of the enclosed structures producing a heterogeneous group of disorders. TOS tends to be diagnosed more often by general and vascular surgeons than by neurologists and neurosurgeons. Four unrelated conditions with different structures involved:

1. **noncontroversial**, with characteristic symptom complex, reproducible clinical findings, confirmatory laboratory tests. Low incidence
   - arterial vascular: producing arm, hand and finger pallor and ischemia
   - venous vascular: producing arm swelling and edema
   - true neurologic: compressing the lower trunk or median cord of the brachial plexus (see below)
2. disputed neurologic: includes scalenus anticus syndrome (see below)

#### 31.8.2 Differential diagnosis

1. herniated cervical disc
2. cervical arthrosis
3. lung cancer (pancoast tumor)
4. tardy ulnar nerve palsy
5. carpal tunnel syndrome
6. orthopedic shoulder problems
7. complex regional pain syndrome (reflex sympathetic dystrophy)

#### 31.8.3 True neurologic TOS

**General information**

A rare condition primarily affecting adult women, usually unilateral.

**Neurologic structures involved**

1. most common: compression of the C8/T1 roots
2. or proximal lower trunk of the brachial plexus (BP)
3. less common: compression of the median cord of the BP

**Etiologies**

1. constricting band extending from the first rib to a rudimentary "cervical rib" or to an elongated C7 transverse process
2. scalenus (anticus) syndrome: controversial (below)
3. compression beneath the pectoralis minor tendon under the coracoid process: may result from repetitive movements of the arms above the head (shoulder elevation and hyperabduction)

**Signs and symptoms**

1. sensory changes in distribution of median cord (mainly along medial forearm), sparing median nerve sensory fibers (pass through upper and middle trunks)
2. hand clumsiness or weakness and wasting, especially abductor pollicis brevis and ulnar hand intrinsics (C8/T1 denervation/atrophy)
3. there may be tenderness over Erb’s point (2 to 3 cm above the clavicle in front of the C6 transverse process)
4. may be painless
5. usually unilateral
Confirmatory tests

1. EMG: unreliable (may be negative). Most common abnormality in neurogenic TOS is loss of medi- al antebrahial cutaneous SNAP
2. MRI does not show bony abnormalities well, but may occasionally demonstrate a kink in the lower BP. Can also rule out conditions that may mimic TOS such as herniated cervical disc
3. cervical spine x-rays with obliques and apical lordotic CXR may demonstrate bony abnormalities. However, not every cervical rib produces symptoms (some patients with bilateral cervical ribs may have unilateral TOS).

Treatment

Controversial. Conservative treatment (usually including stretching and physical therapy) is about equally as effective as surgery and avoids attendant risks.

Decompression can be achieved by removing the muscles that surround the nerves (scaleneatomy), by transaxillary first rib resection, or both.

31.8.4 Scalenus (anticus) syndrome (disputed neurologic TOS)

Controversial. More commonly diagnosed in the 1940s and 1950s. There is a lack of consensus regarding the pathophysiology (including structures involved), clinical presentation, helpful tests, and optimal treatment. Removal of first thoracic rib is often advocated for treatment, frequently via a transaxillary approach. Unfortunately, injuries, especially to the lower trunk of the brachial plexus, may result from the surgery.

Other variations include an “upper plexus” type for which total anterior scalenectomy is advocated. Again, very controversial.

32 Neuroophthalmology

32.1 Nystagmus

32.1.1 Definition

Involuntary rhythmic oscillation of the eyes, usually conjugate. Most common form is jerk nystagmus, in which the direction of the nystagmus is defined for the direction of the fast (cortical) component (which is not the abnormal component). Horizontal or upward gaze-provoked nystagmus may be due to sedatives or AEDs; otherwise vertical nystagmus is indicative of posterior fossa pathology.

32.1.2 Localizing lesion for various forms of nystagmus

1. seesaw nystagmus: intorting eye moves up, extorting eye moves down, pattern then reverses. Lesion in diencephalon. Also reported with chiasmal compression (occasionally accompanied with bitemporal hemianopia in parasellar masses)

2. convergence nystagmus: slow abduction of eyes followed by adducting (converging) jerks, usually associated with features of Parinaud’s syndrome. May be associated with nystagmus retractorius (see below) with similar location of lesion

3. nystagmus retractorius: resulting from co-contraction of all EOM’s. May accompany convergence nystagmus. Lesion in upper midbrain tegmentum (usually vascular disease or tumor, especially pinealoma)

4. downbeat nystagmus: nystagmus with the fast phase downward while in primary position. Most patients have a structural lesion in the posterior fossa, especially at the cervicomedullary junction (foramen magnum (FM)), including Chiari I malformation, basilar impression, p-fossa tumors, syringobulbia. Uncommonly occurs in multiple sclerosis (MS), spinocerebellar degeneration, and in some metabolic conditions (hypomagnesemia, thiamine deficiency, alcohol intoxication or withdrawal, or treatment with phenytoin, carbamazepine or lithium)

5. upbeat nystagmus: lesion in medulla

6. abducting nystagmus occurs in INO. Lesion in pons (MLF)

7. Brun’s nystagmus: lesion in pontomedullary junction (PMJ)

8. vestibular nystagmus: lesion in PMJ

9. ocular myoclonus: lesion in myoclonic triangle

10. periodic alternating nystagmus (PAN): lesion in FM and cerebellum

11. square wave jerks, macro square wave jerks, macro saccadic oscillations. Lesion in cerebellar pathways

12. “nystagmoid” eye movements (not true nystagmus)
   a) oculor bobbing (p. 570): lesion in pontine tegmentum
   b) oculor dysmetria: overshoot of eye on attempted fixation followed by diminishing oscillations until eye “hones in” on target. Lesion in cerebellum or pathways (may be seen in Friedreich’s ataxia)
   c) ping-pong gaze (p. 301)
   d) “windshield wiper eyes” (p. 301)

32.2 Papilledema

32.2.1 General information

AKA choked (optic) disk. Thought to be caused by axoplasmic stasis. One theory: elevated ICP is transmitted through the subarachnoid space of the optic nerve sheath to the region of the optic disc. Elevated ICP will usually obliterate retinal venous pulsation if the pressure is transmitted to the point where the central retinal vein passes through the subarachnoid space (≈ 1 cm posterior to the globe). Papilledema (PPD) may also be dependent on the ratio of retinal arterial to retinal venous pressure, with ratios <1.5:1 more commonly associated with papilledema than higher ratios.

Elevated ICP generally causes bilateral papilledema PPD (see below for unilateral papilledema). Papilledema may appear similar to optic neuritis on funduscopy, but the latter is usually associated with more severe visual loss and tenderness to eye pressure over the eye.

Pseudopapilledema may mimic papilledema in that the optic disc may appear swollen, but, unlike true papilledema, the peripapillary vessels are not obscured. It may be unilateral or bilateral. There
are a number of benign conditions that can cause pseudopapilledema (including a small optic cup, buried disc drusen ...), and extensive workup is generally not indicated.

Papilledema typically takes 24–48 hours to develop following a sustained rise in ICP. It is rarely seen as early as \( \approx 6 \) hours after onset, but not earlier. Papilledema does not cause visual blurring or reduction of visual fields unless very severe and prolonged.

### 32.2.2 Differential diagnosis of unilateral papilledema

1. compressive lesions
   a) orbital tumors
   b) tumors of optic nerve sheath (meningiomas)
   c) optic nerve tumors (optic gliomas)
2. local inflammatory disorder
3. Foster Kennedy syndrome (p.99)
4. demyelinating disease (e.g. multiple sclerosis)
5. elevated ICP in the setting of something that prevents manifestation in one eye, including:
   a) blockage which prevents transmission of elevated CSF pressure to that optic disc
   b) prosthetic eye (artificial eye)

### 32.3 Visual fields

#### 32.3.1 General information

Normal human visual field: extends approximately from 35° nasally in each eye, to 90°temporally, and 50° above and below the horizontal meridian. The normal physiological blind spot (due to absence of light receptors in the optic disc due to penetration of the retina by the optic nerve and vessels) is located to the temporal side of the macular visual area in each eye.

#### 32.3.2 Macular sparing/splitting

Macular splitting can occur both in lesions anterior or posterior to the lateral geniculate body (LGB). However, macular sparing tends to occur with lesions posterior to the LGB. Homonymous hemianopsia with macular sparing tends to occur with lesions in the optic radiation or infarcts of primary visual cortex. There is more than 1 way for this to occur: input from the macula is spread over a large portion of the optic radiation and primary visual cortex, and the occipital pole (primary visual cortex) receives dual blood supply.

### 32.4 Visual field deficits

Can be tested by:
1. bedside confrontational testing: detects only gross peripheral field deficits. Stimulus is brought in from non-seeing to seeing field (towards macular vision area) along 8 meridians
2. formal perimetry
   a) using a tangent screen
   b) Goldmann perimetry
   c) automated perimetry exam: Humphrey visual field (HVF)

**Knee of Wilbrand.** (Named for Hermann Wilbrand (1851–1935) German neuropathologist – the name of this physician is variously listed as: Hermann or Herman, and erroneously as von Willebrand, Willebrand, or Wildbrand...). A 1-2 mm anterior “bend” of the decussating fibers of the optic chiasm into the contralateral optic nerve before continuing to the optic tract.\(^5\) Initially identified histologically postmortem in subjects who had monocular enucleation. Optic nerve injury close to the chiasm produces a junctional scotoma involving an ipsilateral nerve fiber bundle defect and contralateral superior temporal quadrant anopia or contralateral temporal hemianopia stemming from injury to the proximal optic nerve and decussating “knee” fibers.\(^5,6\) Controversy as to the existence or significance of Wilbrand’s knee initially arose after further cadaveric studies suggested that Wilbrand’s knee is an anatomic artifact resulting from buckling of the decussating fibers into the contralateral optic nerve as the optic nerve and chiasm atrophy following enucleation.\(^5\) However, advanced optical imaging techniques have demonstrated a forward bend of the anterior inferior decussating fibers in chiasms with no pre-mortem pathology.\(^7\) However, case series with
intraoperative sectioning of the optic nerve at the level of the chiasm have not been shown to develop contralateral visual field deficits.\textsuperscript{8,9}

Visual field deficit patterns. Fig. 32.1.
1. bitemporal hemianopsia
2. posterior cerebral artery occlusion → infarction in the anterior visual cortex → contralateral homonymous hemianopsia with macular sparing

32.5 Pupillary diameter

32.5.1 Pupilodilator (sympathetic)

Pupilodilator muscle fibers are sympathetic and are arranged radially in the iris.

First-order sympathetic nerve fibers arise in the posterolateral hypothalamus, and descend uncrossed in the lateral tegmentum of the midbrain, pons, medulla and cervical spinal cord to the intermediolateral cell column of the spinal cord from C8-T2 (ciliospinal center of Budge). Here they synapse with lateral horn cells (neurotransmitter: ACh) and give off 2nd order neurons (preganglionics).

Second-order neurons enter the sympathetic chain and ascend but do not synapse until they reach the superior cervical ganglion, where they give rise to 3rd order neurons.
Third-order neurons (postganglionic) course upward with the common carotid artery, those that mediate sweat in the face split off with the ECA. The rest travel with the ICA passing over the carotid sinus. Some fibers accompany V1 (ophthalmic division of trigeminal nerve), passing through (without synapsing) the ciliary ganglion, reaching the pupillodilator muscle of the eye as 2 long ciliary nerves (neurotransmitter: NE). Other fibers from the ICA travel with the ophthalmic artery to innervate the lacrimal gland and Müller’s muscle (AKA the orbital muscle).

### 32.5.2 Pupilloconstrictor (parasympathetic)

Pupilloconstrictor muscle fibers are arranged as a sphincter in the iris.

Parasympathetic preganglionic fibers arise in the Edinger-Westphal nucleus (in high midbrain, superior colliculus level) and are situated peripherally on the intracranial portion of the oculomotor nerve (p.565).

### 32.5.3 Pupillary light reflex

Mediated by rods and cones of the retina which are stimulated by light, and transmit via their axons in the optic nerve. As with the visual path, temporal retinal fibers remain ipsilateral, whereas nasal retinal fibers decussate in the optic chiasm. Fibers subserving the light reflex bypass the lateral geniculate body (LGB) (unlike fibers for vision which enter the LGB) to synapse in the pretectal nuclear complex at the level of the superior colliculus. Intercalating neurons connect to both Edinger-Westphal parasympathetic motor nuclei. The preganglionic fibers travel within the third nerve to the ciliary ganglion as described above under Pupilloconstrictor (parasympathetic).

Monocular light normally stimulates bilaterally symmetric (i.e. equal) pupillary constriction (ipsilateral response is called direct, contralateral response is consensual).

### 32.5.4 Pupillary exam

To perform a complete bedside pupillary exam (see following sections for rationale for various aspects of the pupillary exam):

1. measure pupil size in a darkened room: anisocoria augmented in the dark indicates the smaller pupil is abnormal and suggests a sympathetic lesion
2. measure pupil size in a lighted room: anisocoria intensified in the light suggests the larger pupil is abnormal and that the defect is in the parasympathetics
3. note the reaction to bright light (direct and consensual)
4. near response (it is necessary to check this only if the light reaction is not good): the pupil normally constricts on convergence, and this response should be greater than the light reflex (accommodation is not necessary, and a visually handicapped patient can be instructed to follow their own finger as it is brought in)
   a) light-near dissociation: pupillary constriction on convergence but absent light response (Argyll Robertson pupil). Etiologies:
      • classically described in syphilis
      • Parinaud’s syndrome (p.99): dorsal midbrain lesion
      • oculomotor neuropathy (usually causes a tonic pupil as in oculomotor compression, see below): DM, EtOH
      • Adie’s pupil: see below
5. swinging flashlight test: alternate the flashlight from one eye to the other with as little delay as possible; watch ≥5 seconds for the pupil to redilate (dilation after initial constriction is called pupillary escape and is normal – due to retinal adaptation). Normal: direct and consensual light reflexes are equal. Afferent pupillary defect (see below): consensual reflex is stronger than the direct (i.e. pupil is larger on direct illumination than contralateral illumination)

### 32.5.5 Alterations in pupillary diameter

#### Anisocoria

**General information**

Definition. Unequal pupil sizes (usually ≥1 mm difference).

Note. An afferent pupillary defect (APD) (even with total blindness in one eye) alone does not produce anisocoria (i.e. an APD together with anisocoria indicates two separate lesions).
Evaluation
1. history is critically important. Check for exposure to drugs that affect pupillary size, trauma. Look at old photos (e.g. driver’s license) for physiologic anisocoria
2. exam: see Pupillary exam above
3. a non-contrast CT is usually not helpful and can provide a false sense of security

Differential diagnosis
1. physiologic anisocoria: occurs in \(\approx 20\%\) of population (more common in people with a light iris). Familial and nonfamilial varieties exist. The difference in pupils is usually \(<0.4\) mm. The inequality is the same in a light and dark room (or slightly worse in the dark)
2. pharmacologic pupil (see below): the most common cause of sudden onset of anisocoria
   a) mydriatics (pupillary dilators):
      - sympathomimetics (stimulate the dilator pupillae): usually cause only 1–2 mm of dilation, may react slightly to light. Includes: phenylephrine, clonidine, naphazoline (an ingredient in OTC eye drops for allergies), eye contact with cocaine, certain plants (e.g. jimsonweed)
      - parasympatholytics (inhibit the sphincter pupillae): cause maximal dilation (up to 8 mm) that does not react to light. Includes: tropicamide, atropine, scopolamine (including patches for motion sickness), certain plants (e.g. deadly nightshade)
   b) miotics (pupillary constrictors): pilocarpine, organophosphates (pesticides), flea powders containing anticholinesterase
3. Horner’s syndrome: interruption of sympathetics to pupilodilator. The abnormal pupil is the smaller (miotic) pupil. If there is ptosis it will be on the side of the small pupil. See etiologies, etc. (p.564)
4. third nerve palsy (p.565). If there is ptosis, it will be on the side of the large pupil
   a) oculomotor neuropathy (“peripheral” neuropathy of the third nerve): usually spares the pupil. Etiologies: DM (usually resolves in \(\approx 8\) weeks), EtOH ...
   b) third nerve compression: tends not to spare pupil (i.e. pupil is dilated). Produces loss of parasympathetic tone. Etiologies include:
      - aneurysm:
         - p-comm (the most common aneurysm to cause this)
         - basilar bifurcation (occasionally compresses the posterior III nerve)
      - uncal herniation: below
      - tumor
      - cavernous sinus lesions: including cavernous internal carotid aneurysm, carotid-cavernous fistula, cavernous sinus tumors
5. Adie’s pupil (AKA tonic pupil): see below
6. local trauma to the eye: traumatic iridoplegia. Injury to the pupillary sphincter muscle may produce mydriasis or less often miosis, shape may be irregular
7. pontine lesions
8. eye prosthesis (artificial eye) AKA pseudoanisocoria
9. occasionally some patients have anisocoria that occurs only during migraine
10. iritis
11. keratitis or corneal abrasion

Marcus Gunn pupil
AKA (relative) afferent pupillary defect (APD or RAPD), AKA amaurotic pupil. Finding: consensual pupillary reflex to light is stronger than the direct (normal responses are equal). Contrary to some textbooks, the amaurotic pupil is not larger than the other.\(^{11}\) The presence of the consensual reflex is evidence of a preserved third nerve (with parasympathetics) on the side of the impaired direct reflex. Best detected with the swinging flashlight test (see above).

Etiologies
Lesion anterior to the chiasm ipsilateral to the side of the impaired direct reflex:
1. either in the retina (e.g. retinal detachment, retinal infarct e.g. from embolus)
2. or optic nerve, as may occur in:
   a) optic or retrobulbar neuritis: commonly seen in MS, but may also occur after vaccinations or viral infections, and usually improves gradually
   b) trauma to the optic nerve: indirect (p.836) or direct
   c) compression by tumor anterior to the chiasm
Adie’s pupil (tonic pupil)

An iris palsy resulting in a dilated pupil, due to impaired postganglionic parasympathetics. Thought to be due to a viral infection of the ciliary ganglion. When associated with loss of all muscle tendon reflexes it is called Holmes-Adie’s (is not limited to knee jerks, as some texts indicate). Typically seen in a woman in her twenties.

Slit-lamp exam shows some parts of iris contract and others don’t.

These patients exhibit light-near dissociation (see above): in checking near response it is necessary to wait a few seconds.

Denervation supersensitivity: usually occurs after several weeks (not in acute phase). Administer two drops of dilute pilocarpine (0.1–0.125%), a parasympathomimetic in each eye. Miosis (constriction) will occur in Adie’s pupil within 30 minutes (normal pupils will react only to ~1% pilocarpine).

Pharmacologic pupil

General information

Follows administration of a mydriatic agent. The mydriatic agent may be “occult” when other care providers have not been alerted that this has been used on a patient (this should always be noted in the chart), or when health care personnel unwittingly inoculate agents, e.g. scopolamine, atropine into a patient’s eye or into their own eye. May present with accompanying H/A, and if it is unknown that a mydriatic is involved, this may be misinterpreted e.g. as a warning of an expanding p-comm aneurysm.

A pharmacologically dilated pupil is very large (7–8 mm), and is larger than typical mydriasis due to third nerve compression (5–6 mm).

To differentiate pharmacologic pupil from a third nerve lesion: instill 1% pilocarpine (a parasympathomimetic) in both eyes (for comparison). A pharmacologic pupil does not constrict, whereas the normal side and a dilated pupil from a third nerve palsy will.

Agents

Drugs intentionally used by physicians to dilate the pupils (e.g. Mydriacyl, see below). For other mydriatics, see above.

Management

Option: admit and observe overnight, pupil should normalize.

Using mydriatic agents to produce pupillary dilatation

Indications: to improve the ability to examine the retina. NB: ability to follow bedside examination of pupils will be lost for duration of drug effect. This could mask pupillary dilatation from third nerve compression due to herniation. Always alert other caregivers and place a note in the chart to document that the pupil has been pharmacologically dilated (see above), including the agent(s) used and the time administered.

- 2 gtt of 0.5% or 1% tropicamide (Mydriacyl®) blocks the parasympathetic supply to pupil, and produces a mydriasis that lasts a couple hrs to half a day. This can be augmented with 1 gtt 2.5% phenylephrine ophthalmic (Mydfrin®, Neofrin®, Phenoptic® and others) which stimulates the sympathetics.

Oculomotor nerve compression

Third nerve compression may manifest initially with a mildly dilated pupil (5–6 mm). Possible etiologies include uncal herniation or expansion of a p-comm or basilar bifurcation aneurysm. However, within 24 hours, most of these cases will also develop an oculomotor palsy (with down and out deviation of the eye and ptosis). These pupils respond to mydriatics and to miotic agents (the latter helps differentiate this from a pharmacologic pupil, see above).

Although it is possible for a unilaterally dilated pupil alone to be the initial presentation in uncal herniation, in actuality almost all of these patients will have some other finding, e.g. alteration in mental status (confusion, agitation, etc.) before midbrain compression occurs (i.e. it would be rare for a person undergoing early uncal herniation with a dilating pupil to be awake, talking, appropriate and neurologically intact).
Neuromuscular blocking agents (NMBAs)

Due to the absence of nicotinic receptors on the iris, non-depolarizing muscle blocking agents, such as pancuronium (Pavulon®) normally do not alter pupillary reaction to light except in large doses where some of the first and second order neurons may be blocked.

Paradoxical pupillary reaction

Pupils constrict when light is removed.
1. congenital stationary night blindness
2. Best disease: autosomal dominant hereditary progressive macular dystrophy
3. optic nerve hypoplasia
4. retinitis pigmentosa

32.5.6 Horner’s syndrome

General information

Horner’s syndrome (HS) is caused by interruption of sympathetics to the eye and face anywhere along their path; see Pupilodilator (sympathetic) (p. 560). Unilateral findings on the involved side in a fully developed Horner’s syndrome are shown in Table 32.1.

Miosis in HS

The miosis (pupillary constriction) in Horner’s syndrome is only $\approx 2–3$ mm. This will be accentuated by darkening the room, which causes the normal pupil to dilate.

Ptosis and enophthalmos

Ptosis is due primarily to paralysis of the superior and inferior tarsal muscles (weakness of the inferior tarsal muscle is technically called “inverse ptosis”). Enophthalmos is due to Müller’s muscle paralysis, which also contributes a maximum of $\approx 2$ mm to the ptosis. Ptosis in HS is partial, c.f. complete ptosis which is due to weakness of levator palpebra superioris which is not involved in Horner’s syndrome.

Possible sites of disruption of sympathetics

General information

See also anatomy of 1st, 2nd, and 3rd order sympathetic neurons (p. 560).

1st order neuron (central neuron)

 Interruption is often accompanied by other brainstem abnormalities. Etiologies of dysfunction: infarction from vascular occlusion (usually PICA), syringobulbia, intraparenchymal neoplasm.

2nd order neuron (preganglionic)

Etiologies of dysfunction: lateral sympathectomies, significant chest trauma, apical pulmonary neoplasms (Pancoast tumor), high thoracic or cervical neuroblastoma.

3rd order neuron (postganglionic)

The most common type. Etiologies of dysfunction: neck trauma, carotid vascular disease/studies – e.g. carotid dissections (p. 1324) -, cervical bony abnormalities, migraine, skull base neoplasms, cavernous sinus lesions (e.g. meningioma). With involvement only of fibers on ICA, anhidrosis does not occur (i.e. sweating is preserved) on ipsilateral face since fibers to facial sweat glands travel with ECA.

Pharmacologic testing in Horner’s syndrome

Establishing the diagnosis

If the diagnosis of Horner’s syndrome is in doubt, the following may be used (not necessary when a pupil lag upon darkening the room can be demonstrated in the affected eye) (does not localize lesion as 1st order, etc.).

Cocaine.: 1 gtt 4% cocaine OU (not the 10% solution that is commonly used in ENT procedures which will also anesthetize the sphincter pupillae, thus preventing miosis), repeat in 10 min. Observe pupils over 30 min. Cocaine blocks the NE re-uptake of postganglionic at the neuroeffector junction. In HS, no NE is released and cocaine will not dilate eye. If pupil dilates normally, no HS. Delayed dilatation occurs in partial HS.

Apraclonidine ophthalmic (lupidine®) has essentially replaced cocaine for establishing diagnosis. It works like low-dose pilocarpine works with Adie’s pupil. Lopidine causes the miotic pupil to dilate in Horner’s syndrome due to denervation hypersensitivity in the pupilodilator muscle fibers.

Localizing the site of the lesion

First order HS usually is accompanied by other hypothalamic, brainstem, or medullary findings.

To differentiate a second from third-order: 1% hydroxyamphetamine (Paradrine®) releases NE from nerve endings at neuroeffector junction causing dilation of pupil except in 3rd order neuron lesions (injured postganglionics do not release NE).

32.6 Extraocular muscle (EOM) system

32.6.1 General information

Cr. N. III (oculomotor) innervates the ipsilateral medial rectus (MR), inferior rectus (IR), inferior oblique (IO), and superior rectus (SR). Cr. N IV (trocchlear) innervates the ipsilateral superior oblique (SO), contralateral to the trochlear nucleus (p.567). Cr. N. VI (abducens) innervates the ipsilateral lateral rectus (LR).

The frontal eye field is the cortical area that initiates voluntary (supranuclear) lateral saccadic eye movements ("pre-programmed", rapid, ballistic) to the opposite side, involved in suppressing reflexive saccades and generating voluntary, non-visual saccades. It is located in Brodmann’s area 8 (in the frontal lobe, anterior to the primary motor cortex, Fig. 1.1). These corticobulbar fibers pass through the genu of the internal capsule to the paramedian pontine reticular formation (PPRF), which controls horizontal gaze, which sends fibers to the ipsilateral abducens/para-abducens (VI) nuclear complex, and via the medial longitudinal fasciculus (MLF) to the contralateral III nucleus to innervate the contralateral MR. Inhibitory fibers go to the ipsilateral third nerve to inhibit the antagonist MR muscle. Thus, the right PPRF controls lateral eye movements to right.

32.6.2 Internuclear ophthalmoplegia

Internuclear ophthalmoplegia (INO) is due to a lesion of the MLF (see above) rostral to the abducens nucleus. Findings in unilateral INO12 (see Fig. 32.2 for illustration):

1. on attempting to look to the side contralateral to the INO:
   a) the eye ipsilateral to the lesion fails to ADDuct completely
   b) abduction nystagmus in the contralateral eye (monocular nystagmus) often with some weakness of ADDuction

2. convergence is not impaired in isolated MLF lesions (INO is not an EOM palsy)

The most common causes of INO:

1. MS: the most common cause of bilateral INO in young adults
2. brainstem stroke: the most common cause of unilateral INO in the elderly

32.6.3 Oculomotor (Cr. N. III) nerve palsy (OMP)

General information

The oculomotor nerve exits the brainstem ventrally and has two components: motor neurons which originate in the oculomotor nucleus, and more peripherally situated parasympathetic fibers which arise from the Edinger-Westphal nucleus. The nerve passes through the cavernous sinus and enters the superior orbital fissure where it divides into a superior division (innervating the superior rectus and the levator palpebrae superioris) and an inferior division (supplying the medial rectus, inferior rectus and inferior oblique). The parasympathetic fibers travel with the inferior division and branch
off to the ciliary ganglion where they synapse. Postganglionic fibers enter the posterior globe to innervate the ciliary muscle (relaxes the lens which “thickens” and accommodates for near vision) and the constrictor pupillae muscle.

Oculomotor nerve motor palsy causes ptosis with eye deviated “down & out.” Nuclear involvement of 3rd nerve is rare. NB: 3rd nerve palsy alone can cause up to 3 mm exophthalmos (proptosis) from relaxation of the rectus muscles.

Also see Painful ophthalmoplegia (p.568) and Painless ophthalmoplegia (p.569). For brainstem syndromes, see Benedikt’s syndrome (p.99), and Weber’s syndrome (p.99). Also, see Anisocoria (p.561).

**Non pupil-sparing oculomotor palsy**

**The rule of the pupil in third nerve palsy**

Elucidated in 1958 by Rucker. In effect, states “Third nerve palsy due to extrinsic compression of the nerve will be associated with impaired pupillary constriction.” However, it is often overlooked that in 3%the pupil is spared.16

**Etiologies**

Most cases are due to extrinsic compression of 3rd nerve. Etiologies include:

1. tumor: the most common tumors affecting 3rd nerve:
   a) chordomas
   b) clival meningiomas
2. vascular: the most common vascular lesions:
   a) aneurysms of p-comm artery (pupil sparing with aneurysmal oculomotor palsy occurs in <1%). Development of a new 3rd nerve palsy ipsilateral to a p-comm aneurysm may be a sign of expansion with the possibility of imminent rupture, and is traditionally considered an indication for urgent treatment
   b) aneurysms of the distal basilar artery or bifurcation (basilar tip)
   c) carotid-cavernous fistula (p.1256): look for pulsatile proptosis
3. uncal herniation
4. cavernous sinus lesions: usually cause additional cranial nerve findings (V1, V2, IV, VI); see Cavernous sinus syndrome (p.1401). Classically the third nerve palsy e.g. from enlarging cavernous aneurysm will not produce a dilated pupil because the sympathetics which dilate the pupil are also paralyzed1 (p.1492)
Pupil sparing oculomotor palsy (pupil reacts to light)

General information
Usually from intrinsic vascular lesions occluding vaso-nervorum causing central ischemic infarction. Spares parasympathetic fibers located peripherally in 3rd nerve in 62–83% of cases.\(^{16}\)

Etiologies
Etiologies include:
1. diabetic neuropathy
2. atherosclerosis (as seen in chronic HTN)
3. vasculopathies: including giant cell arteritis (p.195) (temporal arteritis)
4. chronic progressive ophthalmoplegia: usually bilateral
5. myasthenia gravis

Rarely, pupil-sparing OMP has been described following an intra-axial lesion, as in a midbrain infarction.\(^{17}\)

Other causes of oculomotor palsy
Trauma, uncal herniation, laterally expanding pituitary adenomas, Lyme disease, cavernous sinus lesions: usually cause additional cranial nerve findings; see Multiple cranial nerve palsies (cranial neuropathies) (p.1399).

Lesions within the orbit tend to affect 3rd nerve branches unequally. Superior division lesion → ptosis and impaired elevation; inferior division lesion → impairment of depression, adduction and pupillary reaction.

32.6.4 Trochlear nerve (IV) palsy
Anatomy: the trochlear nucleus lies ventral to the cerebral aqueduct at the level of the inferior colliculi. Trochlear nerve axons pass dorsally around the aqueduct and decussate internally just caudal to the inferior colliculi. The nerve innervates the superior oblique muscle which primarily depresses the adducted eye, but in primary gaze it intorts and secondarily abducts and depresses the globe (i.e. it moves the eye down & out).

Some unique features of the trochlear nerve:
1. the only cranial nerve to decussate internally (i.e. the trochlear nucleus is on the contralateral side to the nerve that exits and to the superior oblique it goes to)
2. the only cranial nerve to exit posteriorly on the brain stem
3. the only cranial nerve passing through the superior orbital fissure that does not pass through the annulus of Zinn (AKA annulus tendineus or annular tendon)

Trochlear palsy results in eye deviation “up and in.” Patients tend to spontaneously tilt the head to the side opposite the IV palsy to “intort” the paretic eye and eliminate the diplopia. Diplopia is exacerbated when looking down (e.g. on descending stairs) especially when also looking inward, or when the examiner tilts the head towards the paretic side.

Isolated fourth nerve palsy is uncommon. It may occasionally occur with lesions of the cerebral peduncle or injury to the floor of the fourth ventricle near the aqueduct.

32.6.5 Abducens (VI) palsy
Produces a lateral rectus palsy. Clinically produces diplopia that is exaggerated with lateral gaze to the side of the palsy. Etiologies of isolated 6th nerve palsy include\(^{18}\):
1. vasculopathy: including diabetes and giant cell arteritis. Most cases resolve within 3 months (alternative cause should be sought in cases lasting longer)
2. increased intracranial pressure: palsy may occur with increased ICP even in the absence of direct compression of the nerve (a “false localizing” sign in this setting). Postulated to occur due to the fact that the VI nerve has a long intracranial course which may render it more sensitive to increased pressure. May be bilateral. Etiologies include:
   a) traumatically increased ICP
   b) increased ICP due to hydrocephalus (p.592), e.g. from p-fossa tumor
   c) idiopathic intracranial hypertension (pseudotumor cerebri) (p.766)
3. cavernous sinus lesions: cavernous carotid aneurysm (p.1225), neoplasm (meningioma...), carotid cavernous fistula (p.1256)
4. inflammatory:
   a) Gradenigo’s syndrome (p.570), involvement at Dorello’s canal
   b) sphenoid sinusitis: (involvement at Dorello’s canal)
5. intracranial neoplasm: e.g. clivus chordoma, chondrosarcoma
6. pseudoabducens palsy: may be due to
   a) thyroid eye disease: the most common cause of chronic VI palsy. Will have positive forced duction test (eye cannot be moved by examiner)
   b) myasthenia gravis: responds to edrophonium (Tensilon®) test
   c) long-standing strabismus
   d) Duane’s syndrome (p.570)
   e) fracture of the medial wall of the orbit with medial rectus entrapment
7. following lumbar puncture (p.1507): almost invariably unilateral
8. fracture through clivus (p.884)
9. idiopathic

32.6.6 Multiple extraocular motor nerve involvement
Lesions in cavernous sinus (see below) involve cranial nerves III, IV, VI and V1 & V2 (ophthalmic and maxillary divisions of trigeminal nerve), and spare II and V3.
Superior orbital fissure syndrome: dysfunction of nerves III, IV, VI and V1.
Orbital apex syndrome: involves II, III, IV, VI and partial V1.
4th nerve palsy may result from a contrecoup injury in frontal head trauma.

32.6.7 Painful ophthalmoplegia
Definition
Pain and dysfunction of ocular motility (may be due to involvement of one or more of cranial nerves III, IV, V & VI).

Etiologies
1. intraorbital
   a) inflammatory pseudotumor (idiopathic orbital inflammation): see below
   b) contiguous sinusitis
   c) invasive fungal sinus infection producing orbital apex syndrome. Rhinocerebral mucormycosis (AKA zygomycosis): sinusitis with painless black palatal or nasal septal ulcer or eschar with hyphal invasion of blood vessels by fungi of the order Mucorales, especially rhizopus. Usually seen in diabetic or immunocompromised patients, occasionally in otherwise healthy patients. Occasionally involves dural sinuses and may cause cavernous sinus thrombosis
   d) mets
   e) lymphoma
2. superior orbital fissure/anterior cavernous sinus
   a) Tolosa-Hunt syndrome: see below
   b) mets
   c) nasopharyngeal Ca
   d) lymphoma
   e) herpes zoster
   f) carotid-cavernous fistula
   g) cavernous sinus thrombosis
   h) intracavernous aneurysm
3. parasellar region
   a) pituitary adenoma
   b) mets
   c) nasopharyngeal Ca
   d) sphenoid sinus mucocele
   e) meningioma/chordoma
   f) apical petrositis (Gradenigo’s syndrome): see below
4. posterior fossa
   a) p-comm aneurysm
   b) basilar artery aneurysm (rare)
5. miscellaneous
   a) diabetic ophthalmoplegia
   b) migrainous ophthalmoplegia
   c) cranial arteritis
   d) tuberculous meningitis: may cause ophthalmoplegia, usually incomplete, most often primarily oculomotor nerve

32.6.8 Painless ophthalmoplegia
Differential diagnosis:
1. chronic progressive ophthalmoplegia: pupil sparing, usually bilateral, slowly progressive
2. myasthenia gravis: pupil sparing, responds to edrophonium (Tensilon®) test
3. myositis: usually also produces symptoms in other organ systems (heart, gonads…)

32.7 Neurophthalmologic syndromes
32.7.1 Pseudotumor (of the orbit)
General information
AKA “chronic granuloma” (a misnomer, since true epithelioid granulomas are rarely found). An idiopathic inflammatory disease confined to the orbit that may mimic a true neoplasm. Lymphocytic infiltration of extraocular muscles. Usually unilateral.
Typically presents with rapid onset of proptosis, pain, and EOM dysfunction (painful ophthalmoplegia with diplopia). Often follows URI, may be associated with scleral inflammation. Most commonly involves the superior orbital tissues.

Differential diagnosis
See Orbital lesions (p. 1375) for list.
Key points for Graves' disease (GD): the histologic appearance of GD (hyperthyroidism) may be indistinguishable from pseudotumor. Involvement with GD is usually bilateral.

Treatment
Surgery tends to cause a flare up, and is thus usually best avoided.
Steroids are the treatment of choice. 50–80 mg prednisone q d. Severe cases may necessitate treatment with 30–40 mg/d for several months.
Radiation treatment with 1000–2000 rads may be needed for cases of reactive lymphocytic hyperplasia.

32.7.2 Tolosa-Hunt syndrome
Non-specific inflammation in the region of the superior orbital fissure, often with extension into the cavernous sinus, sometimes with granulomatous features. A diagnosis of exclusion. May be a topographical variant of orbital pseudotumor (see above). Clinical diagnostic criteria:
1. painful ophthalmoplegia
2. involvement of any nerve traversing the cavernous sinus. The pupil is usually spared (frequently not the case with aneurysms, specific inflammation, etc.)
3. symptoms last days to weeks
4. spontaneous remission, sometimes with residual deficit
5. recurrent attacks with remissions of months or years
6. no systemic involvement (occasional N/V, due to pain?)
7. dramatic improvement with systemic steroids: 60–80 mg prednisone PO q day (slow taper), relief within about 1 day
8. occasional inflammation of rectus muscle from contiguous inflammation

32.7.3 Raeder’s paratrigeminal neuralgia
Two essential components:
1. unilateral oculosympathetic paresis (AKA partial Horner’s syndrome (HS), this usually lacks anhidrosis, and in this syndrome, possibly ptosis also)
2. Homolateral trigeminal nerve involvement (usually tic-like pain, but may be analgesia or masseter weakness; pain, if present, must be tic-like and does not include e.g. unilateral head, face or vascular pain)

Localizing value of syndrome: region adjacent to trigeminal nerve in middle fossa. The cause is often not determined, but may rarely be due to aneurysm compressing V1 with sympathetics.

32.7.4 Gradenigo’s syndrome

AKA apical petrotisitis. Mastoiditis with involvement of petrous apex (if pneumatized). Usually seen by ENT physicians. Classic triad:
1. Abducens palsy: from inflammation of 6th nerve at Dorello’s canal, which is where it enters the cavernous sinus just medial to the petrous apex
2. Retro-orbital pain: due to inflammation of V1
3. Draining ear

32.8 Miscellaneous neuroophthalmologic signs

Corneal mandibular reflex. Eliciting the corneal reflex produces a jaw jerk or contralateral jaw movement (ipsilateral pterygoid contraction). A primitive pontine reflex, may be seen in a variety of insults to the brain (trauma, intracerebral hemorrhage...).

Duane syndrome. AKA retraction syndrome: paradoxical innervation causing co-contraction of the lateral and medial rectus muscles on attempted adduction with relaxation on abduction, produces mild enophthalmos with ptosis. May be congenital (e.g. part of one of the following syndromes: acrorenal-ocular syndrome, Okihiro syndrome...).

Hippus. Rhythmic, irregular pupillary oscillations, changing by ≥2 mm. May confuse examination when checking pupillary responses; record the initial response. May be normal. No localizing value.

Marcus Gunn phenomenon. Not to be confused with Marcus Gunn pupil (p.562). Opening the mouth causes opening of a ptotic eye (abnormal reflex between proprioception of pterygoid muscles and third nerve). Reverse Marcus Gunn phenomenon: normal eye that closes with opening the mouth. Seen only in patients with peripheral facial nerve injuries, and probably results from aberrant regeneration.

Ocular bobbing. Abrupt, spontaneous, conjugate downward eye deviation with slow return to midposition, 2 to 12 times per min. It is associated with bilateral paralysis of horizontal gaze, including to doll’s-eyes and caloric tests. Most commonly seen with destructive lesions of the pontine tegmentum (usually hemorrhage, but also infarction, glioma, trauma), but has also been described with compressive lesions. Atypical bobbing is similar except that horizontal gaze is preserved, and can be seen with cerebellar hemorrhage, hydrocephalus, trauma, metabolicencephalopathy...

Opsoclonus. (Rare.) Rapid, conjugate, irregular, non-rhythmic (differentiates this from nystagmus) eye movements vertically or horizontally, persist (attenuated) during sleep (opsoclonus if dysconjugate). Usually associated with diffuse myoclonus (fingers, chin, lips, eyelid, forehead, trunk and LEs); also, malaise, fatigability, vomiting and some cerebellar findings. Often resolves spontaneously within 4 mos.

Oscillopsia. Visual sensation that stationary objects are swaying side-to-side or vibrating. Rarely the sole manifestation of Chiari I malformation (often associated with downbeat nystagmus). Other causes include MS, or injury to both vestibular nerves; e.g. aminoglycoside ototoxicity, bilateral vestibular neuritis; see Dandy’s syndrome (p.572).

Pseudo von Grafe sign. Lid retraction on downward gaze (true von Grafe sign is lid lag in hyperthyroidism) seen in aberrant nerve regeneration (inferior rectus innervation → activation of levator palpebrae).

Optic atrophy. Chronic, progressive optic atrophy is due to a compressive lesion (aneurysm, meningioma, osteopetrosis...) until proven otherwise.

33 Neurotology

33.1 Dizziness and vertigo

33.1.1 Differential diagnosis of dizziness

Near syncope. Some overlap with syncope; see Syncope and apoplexy (p. 1396)
1. orthostatic hypotension
2. cardiogenic hypotension
   a) arrhythmia
   b) valvular disease
3. vasovagal episode
4. hypersensitive carotid sinus; see Syncope and apoplexy (p. 1396)

Dysequilibrium
1. multiple sensory deficits: e.g. peripheral neuropathy, visual impairment
2. cerebellar degeneration

Vertigo. Sensation of movement (usually spinning)
1. inner ear dysfunction
   a) labyrinthitis
   b) Meniere’s disease (see below)
   c) trauma: endolymphatic leak
   d) drugs: especially aminoglycosides
   e) benign (paroxysmal) positional vertigo: AKA cupulolithiasis. Attacks of severe vertigo when
   the head is turned to certain positions (usually in bed). Due to calcium concretions in the
   semicircular canals. Self limited (most cases do not last >1 year). No hearing loss
   f) syphilis
   g) vertebrobasilar insufficiency (p. 1305)
2. vestibular nerve dysfunction
   a) vestibular neuronitis: sudden onset of vertigo, gradual improvement
   b) compression:
      • meningioma
      • vestibular schwannoma: usually slowly progressive ataxia instead of severe vertigo. BAER
        latencies usually abnormal. CT or MRI usually abnormal
3. disabling positional vertigo: as described by Ann etta et al.,2 constant disabling positional vertigo
   or dysequilibrium, causing ≈ constant nausea, no vestibular dysfunction nor hearing loss (tinnitus
   may be present). One possible cause is vascular compression of the vestibular nerve which
   may respond to microvascular decompression
4. brainstem dysfunction
   a) vascular disease; see Vertebrobasilar insufficiency (p. 1305): less distinct vestibular symp-
      toms, prominent nonvestibular symptoms
   b) migraine: especially basilar artery migraine
   c) demyelinating disease: e.g. multiple sclerosis
   d) drugs: anticonvulsants, alcohol, sedatives/hypnotics, salicylates
5. dysfunction of cervical proprioceptors: as in cervical osteoarthritis

Poorly defined lightheadedness. Mostly psychiatric. May also include:
1. hyperventilation
2. hypoglycemia
3. anxiety neurosis
4. hysterical

33.1.2 Vestibular neurectomy

General information

Complete loss of vestibular function from one side is thought to produce transient vertigo due to the
mismatch of vestibular input from the two ears. Theoretically, a central compensatory mechanism
(the “cerebellar clamp”) results in the amelioration of symptoms. In cases of unilateral fluctuating
vestibular dysfunction, this compensatory mechanism may be impaired. Unilateral selective vestibular
neurectomy (SVN) may convert the fluctuating or partial loss to a complete cessation of input
and facilitate compensation. Bilateral SVN is often complicated by oscillopsia (p. 570) – AKA Dandy’s syndrome, with difficulty in maintaining balance in the dark due to loss of the vestibulo-ocular reflex – and is to be avoided.

**Indications**

The two conditions for which SVN is most commonly employed are Meniere’s disease (see below) and partial vestibular injury (viral or traumatic). SVN may be indicated in disabling cases refractory to medical or non-destructive surgical treatment when vestibular studies demonstrate continued or progressive uncompensated vestibular dysfunction.3

SVN preserves hearing and in Meniere’s disease is >90% effective in eliminating episodic vertiginous spells (≈ 80% success rate in non-Meniere’s cases), but is unlikely to improve stability with rapid head movement.

**Surgical approaches for SVN**

1. retrolabyrinthine, AKA postauricular approach: anterior to sigmoid sinus. Primary choice in patients with Meniere’s disease who have not had previous endolymphatic sac (ELS) procedures since it permits simultaneous SVN and decompression of the endolymphatic sac. Requires mastoidectomy with skeletonization of the semicircular canals and ELS. The dural opening is bounded anteriorly by the posterior semicircular canal, posteriorly by the sigmoid sinus. Water-tight dural closure is difficult

2. retrosigmoid, AKA posterior fossa, AKA suboccipital approach: posterior to sigmoid sinus. The original approach plied by Dandy in pre-microsurgical era, usually sacrificed hearing, and occasionally facial nerve function. Better results today with microscopic techniques. Indicated for cases other than Meniere’s disease where there is no need for identification of the ELS. Also the best approach for positive identification of eighth nerve

3. middle fossa (extradural) approach: the fibers of the vestibular division may be more segregated from the cochlear fibers in the IAC than in the CPA, thus permitting more complete section of the vestibular nerve. May be appropriate for failed response to SVN by the above approaches. Disadvantages: requires temporal lobe retraction, does not allow exposure of ELS, and higher morbidity and risk of damage to facial nerve than retrolabyrinthine approach

**Surgical considerations for selective vestibular neurectomy**

(Also Fig. 1.7)

1. the vestibular nerve is in the superior half of the eighth nerve complex, and is slightly more gray in color than the cochlear division (due to less myelin5). They may be separated by a small vessel or by an indentation in the bundle

2. facial (VII) nerve:
   a) whiter than the VIII nerve complex
   b) lies anterior and superiorly to the VIII nerve
   c) EMG monitoring of the facial nerve is recommended
   d) direct stimulation confirms the identification

3. any vessels present on eighth nerve bundle must be preserved to save hearing (primarily, the artery of the auditory canal must be preserved)

4. if no plane of cleavage can be defined between vestibular & cochlear divisions, the superior half of the nerve bundle is divided

5. the endolymphatic sac lies ≈ midway between the posterior edge of the internal auditory meatus and the sigmoid sinus

**33.2 Meniere’s disease**

**33.2.1 General information**

**Key concepts**

- increased endolymphatic pressure
- clinical triad: vertigo, tinnitus & fluctuating hearing loss
- surgical options for failure of medical management include endolymphatic shunt or selective vestibular neurectomy

http://e-surg.com
Probably due to a derangement of endolympathic fluid regulation (a consistent finding is endolympathic hydrops: increased endolympathic volume and pressure with dilatation of endolympathic spaces), with resultant fistulization into the perilymphatic spaces.

### 33.2.2 Epidemiology

Incidence $\approx 1$ per 100,000 population. Most cases have onset between 30–60 years of age, rarely in youth or in the elderly. May become bilateral in 20%.

### 33.2.3 Clinical

#### Clinical triad

1. attacks of violent vertigo (due to vestibular nerve dysfunction): usually the earliest and the most disabling symptom. Nausea, vomiting, and diaphoresis are frequent concomitants. Severe attacks may cause prostration. Vertigo may persist even after complete deafness. Balance is normal between attacks
2. tinnitus: often described as resembling the sound of escaping steam, not a true “ringing”
3. fluctuating low frequency hearing loss: may fluctuate for a period of weeks to years, and may progress to permanent deafness if untreated (a sensation of fullness in the ear is commonly described, however, this is nonspecific and may occur with hearing loss for any reason)

#### Other clinical features

Drop attacks (“otolithic crises of Tumarkin”) occasionally occur.

- **Attack duration:** $\approx 5$–30 minutes (some say 2–6 hours), with a “post-ictal” period of fatigue lasting several hrs.
- **Frequency:** varies from one or two attacks a year to several times per week.
- **Two subtypes differ from classical form:** vestibular Meniere’s (episodic vertigo with normal hearing) and cochlear Meniere’s (few vestibular symptoms).
- **Natural course of syndrome is characterized by periods of remission.** Eventually the vertiginous attacks either progress in severity, or “burn out” (being replaced by constant unsteadiness’).

#### Differential diagnosis

Also see Differential diagnosis: Dizziness and vertigo (p. 572) for more details.

1. benign (paroxysmal) positional vertigo: AKA cupulolithiasis. Self limited (most cases last < 1 year).
   - No hearing loss
2. disabling positional vertigo: constant disabling positional vertigo or dysequilibrium, $\approx$ constant nausea, no vestibular dysfunction nor hearing loss (tinnitus may be present)
3. vestibular schwannoma: usually slowly progressive ataxia instead of episodic severe vertigo.
   - BAER latencies usually abnormal. CT or MRI usually positive
4. vestibular neuronitis: sudden onset of vertigo with gradual improvement
5. vertebrobasilar insufficiency (VBI) (p. 1305): less distinct vestibular symptoms, and prominence of nonvestibular symptoms

#### Diagnostic studies

1. electronystagmography (ENG) with bithermal caloric stimulation usually abnormal, may show blunted thermal responses
2. audiogram: low frequency hearing loss, fairly good preservation of discrimination and loudness recruitment, negative tone decay on impedance testing
3. BAER usually shows normal latencies
4. radiographic imaging (CT, MRI, etc.): no findings in Meniere’s disease
5. in bilateral cases, a VDRL should be checked to R/O luetic disease

#### Treatment

**Medical treatment**

1. reduced intake of salt (strict salt restriction is as effective as any medication) and caffeine
2. diuretics: taken daily until ear fullness abates, then PRN ear pressure (usually once or twice weekly suffices)
a) acetazolamide: Diamox® sequels 500 mg p.o. q d × 1 week, increase to BID if symptoms persist. D/C if paresthesias develop. Do not use during 1st trimester of pregnancy

3. vestibular suppressants
   a) diazepam (Valium®): probably the most effective
   b) meclizine HCl (Antivert®): Adult dose for vertigo associated with the vestibular system (during attacks): 25–100 mg/day PO divided. Dose for motion sickness: 25–50 mg PO one hr prior to stimulus. Supplied: 12.5, 25 & 50 mg tabs. Side effects: drowsiness

4. vasodilators: postulated to be mediated by increased cochlear blood flow: inhalation of 5–10% CO₂ works well, but relief is short lived

Surgical treatment
Reserved for incapacitating cases refractory to medical management. When functional hearing exists, procedures that spare hearing are preferred because of high incidence of bilateral involvement. Procedures include:
1. endolymphatic shunting procedures: to mastoid cavity (Arenberg shunt) or to subarachnoid space. Reserved for cases with serviceable hearing. ~65% success rate (see below). If symptoms are relieved ≥1 year, then a recurrence would be treated by shunt revision, if<1 year then vestibular neurectomy
2. direct application of corticosteroids to the inner ear
3. nonselective vestibular ablation (in cases with nonserviceable hearing on the side of involvement)
   a) surgical labyrinthectomy
   b) middle ear perfusion with gentamicin
   c) translabyrinthine section of the 8th nerve
4. selective vestibular neurectomy (p.572), in cases with serviceable hearing

Outcome
Endolymph shunting procedures
Outcomes from 112 endolymphatic shunting procedures are shown in Table 33.1.

Neurectomy procedures
Vestibulocochlear nerve section (based on early posterior fossa surgery by Dandy; entire eighth nerve bundle was sectioned in 587 patients; all were deaf post-op): 90% relieved of vertigo, 5% unchanged and 5% worse; 9% incidence of facial paralysis (3% incidence of permanent paralysis).
Selective vestibular nerve section (sparing cochlear portion, 95 patients from Dandy): 10% had improved hearing, 28% unchanged, 48% worse, 14% deaf.
Retro labyrinthine approach: in 32 patients with Meniere’s syndrome (25 failed endolymph shunt) responding to survey, 85% had complete relief of vertigo, 6% improved, 9% no relief (one of whom responded to middle fossa neurectomy).5

Complications and untoward effects
Patients with little vestibular nerve function pre-op (determined by ENG) usually have little difficulty immediately following vestibular neurectomy; patients with more function may have a transient worsening post-op until they accommodate.
Among 42 patients undergoing retro labyrinthine approach: none lost hearing as a result of surgery, no facial weakness, one CSF rhinorrhea requiring re-operation, and one meningitis with good outcome.5

Table 33.1 Outcome in 112 endolymphatic-subarachnoid shunts7

*improved hearing considered serviceable (50 dB pure tone, 70% speech discrimination); additional 14 patients had improved but non-serviceable hearing
†5 patients had recurrence of vertigo after 1–3 years
In post-op failures, check ENG. If any vestibular nerve function is demonstrated on operated side, then the nerve section was incomplete; consider re-operating.

33.3 Facial nerve palsy

33.3.1 Severity grading

Severity of facial palsy is often graded with the House and Brackmann scale (see Table 41.3).

33.3.2 Localizing site of lesion

Central facial palsy (AKA supranuclear facial palsy)

The cortical representation for facial movement occurs in the motor strip along the lateral aspect (just above the most inferior opercular portion of the precentral gyrus). The keys to differentiating central paralysis (due to supranuclear lesions) from peripheral facial palsy are that central palsies:
1. are confined primarily to the lower face due to some bilateral cortical representation of upper facial movement
2. may spare emotional facial expression (e.g. smiling at a joke)

Nuclear facial palsy

The motor nucleus of the seventh nerve is located at the pontomedullary junction. Nuclear VII palsy results in paralysis of all VII nerve motor function. In nuclear facial palsies, other neurologic findings also often occur from involvement of adjacent neural structures by the underlying process (stroke, tumor…), e.g. in Millard-Gubler syndrome (p.99), there is ipsilateral abducens palsy + contralateral limb weakness. Tumors invading the floor of the 4th ventricle (e.g. medulloblastoma) may also cause nuclear facial palsy (from involvement of facial colliculus in the floor of 4th ventricle).

Facial nerve lesion

Motor fibers ascend within the pons and form a sharp bend (“internal genu”) around the sixth nerve (abducens) nucleus, forming a visible bump in the floor of the 4th ventricle (facial colliculus). The seventh nerve exits from the brain stem at the ponto-medullary junction (Fig. 2.6) where it may be involved in CPA tumors. It enters the supero-anterior portion of the internal auditory canal (Fig. 1.7). The geniculate ganglion (“external genu”) is located within the temporal bone. The first branch from the ganglion is the greater superficial petrosal nerve (GSPN) which passes to the pterygopalatine ganglion and innervates the nasal and palatine mucosa and the lacrimal gland of the eye; lesions proximal to this point produce a dry eye. The next branch is the branch to the stapedius muscle; lesions proximal to this point produce hyperacusis. Next, the chorda tympani joins the facial nerve bringing taste sensation from the anterior two-thirds of the tongue. Basal skull fractures may injure the nerve just proximal to this point. Travelling with the chorda tympani are fibers to the submandibular and sublingual glands. The facial nerve exits the skull at the stylomastoid foramen. It then enters the parotid gland, where it splits into the following branches to the facial muscles (cranial to caudal): temporal, zygomatic, buccal, mandibular, and cervical. Lesions within the parotid gland (e.g. parotid tumors) may involve some branches but spare others.

33.3.3 Etiologies

These etiologies produce primarily facial nerve palsy, also see Multiple cranial nerve palsies (cranial neuropathies) (p.1399). Note: 90-95% of all cases of facial palsy are accounted for by Bell’s palsy, herpes zoster oticus, and trauma (basal skull fractures).9
1. Bell’s palsy (p.577)
2. herpes zoster oticus (auris) (p.578)
3. trauma: basal skull fracture
4. birth:
   a) congenital
      • *bilateral facial palsy (facial diplegia) of Möbius syndrome (p.1399): unique in that it affects upper face more than lower face
      • *congenital facial diplegia may be part of facioscapulohumeral or myotonic muscular dystrophy
   b) traumatic
5. otitis media: with acute otitis media, facial palsy usually improves with antibiotics. With chronic suppurative otitis surgical intervention is required
6. central facial paralysis and nuclear facial paralysis: see Localizing site of lesion above
7. neoplasm: usually causes hearing loss, and (unlike Bell’s palsy) slowly progressive facial paralysis
   a) most are either benign schwannomas of the facial or auditory nerve, or malignancies metastatic to the temporal bone. Facial neurons as account for ≈5% of peripheral facial nerve palsies; the paralysis tends to be slowly progressive
   b) parotid tumors may involve some branches but spare others
   c) Masson’s vegetable intravascular hemangioendothelioma (p. 770)
8. *neurosarcoidosis (p.189): VII is the most commonly affected cranial nerve
9. diabetes: 17% of patients >40 yrs old with peripheral facial palsy (PPF) have abnormal glucose tolerance tests. Diabetics have 4.5 times the relative risk of developing PPF than nondiabetics
10. *stage II Lyme disease (p.334) 12: facial diplegia is a hallmark
11. *Guillain-Barré syndrome: facial diplegia occurs in ≈50% of fatal cases
12. occasionally seen in Klippel-Feil syndrome
13. *isolated 4th ventricle (p.402): compression at the facial colliculus

* Items with an asterisk are often associated with facial diplegia (i.e. bilateral facial palsy), see also multiple cranial neuropathies (p.1399).

33.3.4 Bell’s palsy

General information
Bell’s palsy (BP), AKA idiopathic peripheral facial palsy (PFP), is the most common cause of facial paralysis (50–80% of PF Ps). Incidence: 150–200/1-million/yr.
Etiology: by definition, PFP is called Bell’s palsy when it is not due to known causes of PFP (e.g. infection, tumor or trauma) and there are no other neurological (e.g. involvement of other cranial nerves) or systemic manifestations (e.g. fever, diabetes, possibly hypertension). Thus, true BP is idiopathic, and is a diagnosis of exclusion. Most cases probably represent a viral inflammatory demyelinating polyneuritis usually due to the herpes simplex virus. Facial palsy due to Lyme disease can usually be recognized on clinical grounds. Severity may be graded on the House & Brackmann grading scale (see Table 41.3).

Presentation
A viral prodrome is frequent: URI, myalgia, hypesthesia or dysesthesia of the trigeminal nerve, N/V, diarrhea… Paralysis may be incomplete and remain so (Type I); it is complete at onset in 50%(Type II), the remainder progress to completion in 1 week. Usually exhibits distal to proximal progression: motor branches, then chorda tympani (loss of taste and decreased salivation), then stapedial branch (hyperacusis), then geniculate ganglion (decreased tearing). Associated symptoms are shown in Table 33.2, and are usually, but not always, ipsilateral. Herpes zoster vesicles develop in 4% of patients 2–4 days after onset of paralysis; and in 30% of patients 4–8 days after onset. During the recovery phase excessive lacrimation may occur (aberrant nerve regeneration).

Evaluation
Patients with PFP should be examined at an early stage to optimize outcome.
Electrodiagnostics: EMG may detect re-innervation potentials, aids prognostication. Nerve conduction study: electrical stimulation of the facial nerve near the stylomastoid foramen while recording EMG in facial muscles (a facial nerve may continue to conduct for up to ~1 week even after complete transection).

Management

General measures
Eye protection: protection of the eye is critical. Artificial tears during the day, eye ointment at night, avoid bright light (using dark glasses during the day).

Medical management
Steroids: prednisolone 25 mg p.o. BID × 10 days, started within 72 hours of onset of symptoms, improves the chances of complete recovery at 3 & 9 months.
Acyclovir: does not help (alone or in combination with prednisolone).¹⁸

Surgical management
Surgical decompression: controversial. The definitive study has not been done. Rarely utilized. Indications may include:
1. complete facial nerve degeneration without response to nerve stimulation (although this absence is also used as an argument against surgery⁹)
2. progressively deteriorating response to nerve stimulation
3. no clinical nor objective (nerve testing) improvement after 8 wks (however, in cases where the diagnosis of Bell’s palsy is felt to be certain, the active disease will have abated by ≈ 14 days after onset⁹)

Prognosis
Essentially all cases show some recovery (if none by 6 mos, other etiologies should be sought). Extent of recovery: 75–80% of cases recover completely, 10% partial, remainder poor. If recovery begins by 10–21 d, tends to be complete; if not until 3–8 wks → fair, if not until 2–4 mos → poor recovery. If paralysis is complete at onset, 50% will have incomplete recovery. Cases of incomplete paralysis at onset that do not progress to complete paralysis → complete recovery; incomplete paralysis at onset that progresses to complete → incomplete recovery in 75% A worse prognosis is associated with: more proximal involvement, hyperacusis, decreased tearing, age > 60 yrs, diabetes, HTN, psycho-neuroses, and aural, facial or radicular pain.

33.3.5 Herpes zoster oticus facial paralysis
Symptoms are more severe than Bell’s palsy, herpetic vesicles are usually present, and antibody titers to varicella-zoster virus rise. These patients have a higher risk of facial nerve degeneration.

33.3.6 Surgical treatment of facial palsy
General information
For cases with focal injury to the facial nerve (e.g. trauma, injury during surgery for CPA tumor…), dynamic reconstruction by nerve anastamoses are usually considered superior to static methods.¹⁹ For non-focal causes, e.g. Bell’s palsy, only “static” methods may be applicable. A functional neural repair is not possible if the facial muscles have atrophied or fibrozed.

Surgical options
Surgical treatment options include:
1. for intracranial injury to facial nerve (e.g. during CPA tumor surgery): intracranial reapproximation (with or without graft) offers the best hope for the most normal facial reanimation
   a) timing
      • at time of tumor removal (for a divided facial nerve during removal of vestibular schwannoma²⁰,²¹,²²): the best result that can be achieved with this is House-Brackmann Grade III. The operation fails to produce good results in ≈ 33% of cases²²
      • in delayed fashion, especially if the nerve was left in anatomic continuity
   b) techniques
      • direct reanastamosis: difficult due to the frail nature of the VII nerve (especially when it has been stretched by a tumor)
      • cable graft: e.g. using greater auricular nerve²³ or sural nerve

http://e-surg.com
2. extracranial facial nerve anastomosis
   a) hypoglossal nerve (Cr. N. XII)-facial nerve anastomosis (see below)
   b) spinal accessory nerve (Cr. N. XI)-facial nerve anastomosis (see below)
   c) phrenic nerve-facial nerve anastomosis
   d) glossopharyngeal (Cr. N. IX)-facial nerve anastomosis
   e) crossface grafting (VII-VII): results have not been very good

3. “mechanical” or “static” means
   a) facial suspension: e.g. with polypropylene (Marlex®) mesh
   b) eye closure techniques (protects the eye from exposure and reduced tearing)
      • tarsorrhaphy: partial or complete
      • gold weights in eyelid
      • stainless-steel spring in eyelid

Timing of surgery
If the facial nerve is known to be interrupted (e.g. transected during removal of vestibular schwannoma) then early surgical treatment is indicated. When the status of the nerve is unknown or if in continuity but not functioning, then several months of observation and electrical testing should be allowed for spontaneous recovery. Very late attempts at anastomosis have less chance for recovery due to facial muscle atrophy.

Hypoglossal nerve-facial nerve (XII-VII) anastomosis

General information
Cannot be used bilaterally in patients with facial diplegia or in those with other lower cranial nerve deficits (or potential for same). In spite of some suggestions to the contrary, sacrificing the XII nerve does create some morbidity (tongue atrophy with difficulty speaking, mastication and swallowing in \( \approx 25\% \) of cases, exacerbated when the facial muscles do not function on that side; aspiration may occur if vagus (Cr. N. X) dysfunction coexists with loss of XII).

Not as effective as it would theoretically seem possible. The resultant facial reanimation is often less than ideal (may permit mass movement). To avoid severe disappointment, the patient should thoroughly understand the likely side effects and that the facial movement will probably be much less than normal, often with poor voluntary control.

Usually performed in conjunction with anastomosis of the descendens hypoglossi to the distal hypoglossal nerve to try and reduce hemiatrophy of the tongue. Atrophy may also be reduced by using a “jump graft” without completely interrupting XII.

Technique
Position: supine, head turned slightly to the opposite side. Skin incision: 6–8 cm incision from just above the mastoid process obliquely downward across the neck to 2 cm below the angle of the jaw. The platysma is opened, and the tip of the mastoid is exposed by incising the insertion of the SCM and using a periosteal elevator. Incise the deep fascia; avoid the parotid gland, which is retracted superiorly. Rongeur the anterior third of the mastoid process (wax any exposed air cells) and identify the facial nerve as it exits the stylomastoid foramen between the mastoid process and the styloid process. Retract the posterior belly of the digastric inferiorly to aid the exposure.

The SCM is retracted laterally until the carotid sheath is identified, revealing the hypoglossal nerve. It loops around the occipital artery at this level (where it gives off the descendens hypoglossi) to pass between the carotid artery and jugular vein. The nerve is freed proximally to the point where it enters the carotid sheath and distally to the submandibular triangle where it is sharply divided.

The facial nerve is divided at the stylomastoid foramen and is approximated to the proximal hypoglossal nerve. The descendens hypoglossi is divided as far distally as possible and is then anastomosed to the distal stump of the hypoglossal nerve.

Variations
1. interposition jump grafts: spares function in the XII nerve (to minimize glottic denervation, the incision of XII should be distal to the descendens hypoglossi)
   a) using cutaneous nerve jump graft
   b) using muscle interposition jump graft
2. mobilizing the intratemporal portion of VII out of the fallopian canal (as previously described) and then anastamosing it using a bevelled cut to a partially incised XII
Outcome
Results are better if performed early, although good results can occur up to 18 mos after injury. In 22 cases, 64% had good results, 14% fair, 18% poor, and 1 patient had no evidence of reinnervation. In 59% of cases, evidence of reinnervation was seen by 3–6 mos, in the remaining patients with reinnervation improvement was noted by 8 mos. Recovery of forehead movement occurs in only ≈ 30% return of tone precedes movement by ≈ 3 months.

Spinal accessory nerve-facial nerve (XI-VII) anastomosis

General information
First described in 1895 by Sir Charles Ballance. Sacrifices some shoulder movement rather than use of tongue. Initial concerns about significant shoulder disability and pain resulted in the technique of using only the SCM branch of XI, however these problems have not occurred in the majority of patients even with use of the major division.

Technique
See reference.

Skin incision: curves across the mastoid tip along the anterior margin of the SCM. Strip and remove the anterior third of the mastoid process (wax any exposed air cells), identify the facial nerve and divide it as close to its exit from the stylomastoid foramen as possible. Locate the XI nerve 3–4 cm below the mastoid tip, and divide it distal to the SCM division. Mobilize the free end and anastomose it to the distal stump of VII. Results in loss of trapezius function, which may not cause deficit even if done bilaterally. Alternatively, the SCM branch of XI may be used, sparing the trapezius function, however the shorter length may be difficult to work with and in some individuals there may only be multiple small branches to the SCM.

33.4 Hearing loss
Two anatomic types: conductive and sensorineural.

33.4.1 Conductive hearing loss
1. Patients tend to speak with normal or low volume voice
2. Etiologies: anything that interferes with ossicular movement. Included:
   a) Otitis media with middle ear effusion
   b) Otosclerosis
3. Clinical findings with unilateral hearing loss (see Table 33.3):
   a) Weber test will lateralize to side of hearing loss (Weber test: place a vibrating 256 or 512 Hz tuning fork on the center of the forehead; the sound will lateralize – sound louder – on the side of conductive hearing loss, or opposite to the side of SNHL)
   b) Rinne test will be abnormal (BC>AC) on the side of hearing loss, called a negative Rinne (Rinne test: place a vibrating 256 or 512 Hz tuning fork on the mastoid process, when sound is no longer heard, move the fork to just outside the ear to see if air conduction [AC] is > bone conduction [BC])
4. Middle ear impedance measurements are abnormal

</tr>
</tbody>
</table>

<sup>a</sup>normal, or symmetric hearing loss
33.4.2 Sensorineural hearing loss (SNHL)

1. Patients tend to speak with loud voice
2. clinical findings with unilateral hearing loss (Table 33.3):
   a) Weber test will lateralize to side of better hearing (Weber test: place a vibrating 256 or 512 Hz tuning fork on the center of the forehead; the sound will lateralize – sound louder – on the side of conductive hearing loss, or opposite to the side of SNHL)
   b) Rinne test will be normal (AC>BC), called a positive Rinne (Rinne test: place a vibrating 256 or 512 Hz tuning fork on the mastoid process, when sound is no longer heard, move the fork to just outside the ear to see if air conduction (AC) is > bone conduction (BC))
3. further divided into sensory or neural. Distinguished by otoacoustic emissions (only produced by a cochlea with functioning hair cells) or BAERs
   a) sensory: loss of outer hair cells in the cochlea. Etiologies: cochlear damage (usually causes high-frequency hearing loss) from noise exposure, ototoxic drugs (e.g. aminglycosides), senile cochlear degeneration, viral labyrinthitis. Speech discrimination may be relatively preserved
   b) neural: due to compression of the 8th cranial nerve. Etiologies: CP angle tumor (e.g. vestibular schwannoma). Typically much greater loss of word discrimination out of proportion to pure tone audiogram abnormalities

Sensory hearing loss may be distinguished from neural hearing loss by
1. otoacoustic emissions which are only produced by a cochlea with functioning hair cells
2. or BAERs
3. an elevated stapedial reflex threshold out of proportion to PTA abnormalities is also highly diagnostic of a retrocochlear (neural) lesion

34 General Information, Classification and Tumor Markers

34.1 Classification of nervous system tumors

WHO classification of tumors of the nervous system

The 2007 WHO classification identifies 7 categories of tumors of the nervous system (see Table 34.1) and a modified outline appears below along with the unofficial category “intra-cranial and/or intraspinal embryonal remnants”, and pituitary adenomas (not part of the CNS). Also to be considered: cysts (neurocysticercosis...), tumor-like masses (e.g. giant aneurysms), and local extension of regional tumors. Cytogenetic and molecular genetic information are playing an ever increasing role in the rapidly evolving classification of many brain tumors.

Table 34.1 Overview of WHO classification of nervous system tumors

| 1. | tumors of neuroepithelial tissue |
| 2. | tumors of cranial and paraspinal nerves |
| 3. | tumors of the meninges |
| 4. | lymphomas and hematopoietic neoplasms |
| 5. | germ cell tumors |
| 6. | tumors of the sellar region |
| 7. | metastatic tumors |

G. METASTATIC TUMORS (p. 800)
Those commonly involving brain include:

I. Lung cancer: especially small-cell (p. 802)
II. Breast
III. Melanoma (p. 803)
IV. Renal cell (p. 805)
V. Lymphoma
VI. GI

H. LOCAL EXTENSIONS FROM REGIONAL TUMORS

I. Paraganglioma (chemodectoma)
   1. glomus jugulare tumor (p. 654)
II. Notochord chordoma (p. 778)
III. Carcinoma

I. CYSTS AND TUMOR-LIKE LESIONS

I. Rathke’s cleft cyst (p. 756)
II. Extodermal rests
   1. epidermoid cyst (p. 761)
   2. cholesteatoma (p. 761)
%ICD-O=morphology code of the International Classification of Diseases for Oncology (http://codes.iarc.fr). The extension after the slash is the “behavior code”: /0 = benign, /1 = low or uncertain malignant potential or borderline malignancy, /2 = in situ lesions, /3 = malignant tumors
%represents a significant portion of what is usually considered to be primary brain tumors
%the term “glioma” is occasionally used to refer to all glial tumors (e.g. “low-grade glioma” is often used when discussing low-grade tumors of any glial lineage), although in its usual sense glioma (especially “high grade gliomas”) refers only to astrocytic tumors
\*WHO II” means World Health Organization (WHO) grade II, “WHO III” means WHO grade III, etc.
\*these tumors are not part of the 2007 WHO classification5

34.2 Brain tumors – general clinical aspects

34.2.1 General information

For details of presentation, see sections below for supratentorial and infratentorial tumors. Most brain tumors present with:
- Progressive neurologic deficit (68%): usually motor weakness (45%).
- Headache: was a presenting symptom in 54% (see below).
- Seizures in 26% Often focal in onset (due to cortical irritation in the area of the tumor), may generalize secondarily.

34.2.2 Focal neurologic deficits associated with brain tumors

In addition to nonfocal signs and symptoms (e.g. seizures, increased ICP...), as with any destructive brain lesion, tumors may produce progressive deficits related to the function of the involved brain. Some characteristic “syndromes”:
1. frontal lobe: abulia, dementia, personality changes. Often nonlateralizing, but apraxia, hemiparesis or dysphasia (with dominant hemisphere involvement) may occur
2. temporal lobe: auditory or olfactory hallucinations, déjà vu, memory impairment. Contralateral superior quadrantanopsia may be detected on visual field testing
3. parietal lobe: contralateral motor or sensory impairment, homonymous hemianopsia. Agnosias (with dominant hemisphere involvement) and apraxias may occur; see Clinical syndromes of parietal lobe disease (p. 97)
4. occipital lobe: contralateral visual field deficits, alexia (especially with corpus callosum involvement with infiltrating tumors)
5. posterior fossa: (see above) cranial nerve deficits, ataxia (truncal or appendicular)

34.2.3 Headaches with brain tumors

General information

Headache (H/A) may occur with or without elevated ICP. H/A are present equally in patients with primary or metastatic tumor (= 50% of patients\(^6\)). Classically described as being worse in the morning (possibly due to hyperventilation during sleep), this may actually be uncommon.\(^6\) Often exacerbated by coughing, straining, or (in 30%) bending forward (placing head in dependent position). Associated with nausea and vomiting in 40% may be temporarily relieved by vomiting (possibly due to hyperventilation during vomiting). These features along with the presence of a focal neurologic
deficit or seizure were thought to differentiate tumor H/A from others. However, H/A in 77% of brain tumor patients were similar to tension H/A, and in 9% were migraine-like. Only 8% showed the “classic” brain tumor H/A, two-thirds of these patients had increased ICP.

Etiologies of tumor headache

The brain itself is not pain sensitive. H/A in the presence of brain tumor may be due to any combination of the following:

1. increased intracranial pressure (ICP): which may be due to
   a) tumor mass effect
   b) hydrocephalus (obstructive or communicating)
   c) mass effect from associated edema
   d) mass effect from associated hemorrhage
2. invasion or compression of pain sensitive structures:
   a) dura
   b) blood vessels
   c) periosteum
3. secondary to difficulty with vision
   a) diplopia due to dysfunction of nerves controlling extra-ocular muscles
   • direct compression of III, IV, or VI
   • abduccens palsy from increased ICP, see diplopia (p. 592)
   • internuclear ophthalmoplegia due to brainstem invasion/compression
   b) difficulty focusing: due to optic nerve dysfunction from invasion/compression
4. extreme hypertension resulting from increased ICP (part of Cushing’s triad)
5. psychogenic: due to stress from loss of functional capacity (e.g. deteriorating job performance)

34.2.4 Supratentorial tumors

See reference.7

Signs and symptoms include:

1. those due to increased ICP (see below):
   a) from mass effect of tumor and/or edema
   b) from blockage of CSF drainage (hydrocephalus): less common in supratentorial tumors (classically occurs with colloid cyst, may also occur with entrapped lateral ventricle)
2. progressive focal deficits: includes weakness, dysphasia (which occurs in 37–58% of patients with left-sided brain tumors8): see below
   a) due to destruction of brain parenchyma by tumor invasion
   b) due to compression of brain parenchyma by mass and/or peritumoral edema and/or hemorrhage
   c) due to compression of cranial nerve(s)
3. headache: see below
4. seizures: not infrequently the first symptom of a brain tumor. Tumor should be aggressively sought in an idiopathic first time seizure in a patient >20 years (if negative, the patient should be followed with repeat studies at later dates). Rare with posterior fossa tumors or pituitary tumors
5. mental status changes: depression, lethargy, apathy, confusion
6. symptoms suggestive of a TIA (dubbed “tumor TIA”) or stroke, may be due to:
   a) occlusion of a vessel by tumor cells
   b) hemorrhage into the tumor: any tumor may hemorrhage, see Hemorrhagic brain tumors (p.1335)
   c) focal seizure
7. in the special case of pituitary tumors (p. 718):
   a) symptoms due to endocrine disturbances
   b) pituitary apoplexy (p. 720)
   c) CSF leak

Booking the case: Craniotomy for supratentorial tumor

Also see defaults & disclaimers (p.27). If awake craniotomy is required, see Booking the case: Awake craniotomy (p.1433).

1. position: (depends on location of tumor)
2. pre-op embolization (by neuroendovascular interventionalist) for some vascular tumors including some meningiomas
3. equipment:
   a) microscope
   b) ultrasonic aspirator
   c) image guidance system
4. blood availability: type and cross 2 U PRBC
5. post-op: ICU
6. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery through the skull to remove as much of the tumor as is safely possible
   b) alternatives: nonsurgical management, radiation therapy for some tumors
   c) complications: usual craniotomy complications (p. 28) plus inability to remove all of the tumor

34.2.5 Infratentorial tumors

Signs and symptoms
Seizures are rare (unlike the situation with supratentorial tumors, (seizures arise from irritation of cerebral cortex).
1. most posterior fossa tumors present with signs and symptoms of increased intracranial pressure (ICP) due to hydrocephalus (HCP). These include:
   a) headache: (see below)
   b) nausea/vomiting: due either to increased ICP from HCP, or from direct pressure on the vagal nucleus or the area postrema (so-called “vomiting center”)
   c) papilledema: estimated incidence is ≈ 50–90% (more common when the tumor impairs CSF circulation)
   d) gait disturbance/ataxia
   e) vertigo
   f) diplopia: may be due to VI nerve (abducens) palsy which may occur with increased ICP in the absence of direct compression of the nerve
2. S/S indicative of mass effect in various locations within the p-fossa
   a) lesions in cerebellar hemisphere may cause: ataxia of the extremities, dysmetria, intention tremor
   b) lesions of cerebellar vermis may cause: broad based gait, truncal ataxia, titubation
   c) brainstem involvement usually results in multiple cranial nerve and long tract abnormalities, and should be suspected when nystagmus is present (especially rotatory or vertical)

Evaluation
Posterior fossa (infratentorial) tumors
See Posterior fossa lesions (p. 905) for differential diagnosis (includes non-neoplastic lesions as well.
In pediatric patients with a posterior fossa tumor, an MRI of the lumbar spine should be done pre-op to rule-out drop mets (post-op there may be artifact from blood).
In adults, most intraparenchymal p-fossa tumors will be metastatic, and work-up for a primary should be undertaken.

Treatment of associated hydrocephalus
In cases with hydrocephalus at the time of presentation, some authors advocate initial placement of VP shunt or EVD prior to definitive surgery (waiting ≥ 2 wks before surgery) because of possibly lower operative mortality. Theoretical risks of using this approach include the following:
1. placing a shunt is generally a lifelong commitment, whereas not all patients with hydrocephalus from a p-fossa tumor will require a shunt
2. possible seeding of the peritoneum with malignant tumor cells e.g. with medulloblastoma. Consider placement of tumor filter (may not be justified given the high rate of filter occlusion and the low rate of “shunt metastases”)
3. some shunts may become infected prior to the definitive surgery
4. definitive treatment is delayed, and the total number of hospital days may be increased
5. upward transtentorial herniation (p. 303) may occur if there is excessively rapid CSF drainage

Either approach (shunting followed by elective p-fossa surgery, or semi-emergent definitive p-fossa surgery) is accepted. At Children’s Hospital of Philadelphia, dexamethasone is started and the surgery is performed on the next elective operating day, unless neurologic deterioration occurs necessitating emergency surgery.
Some surgeons place a ventriculostomy at the time of surgery. CSF is drained only after the dura is opened (to avoid upwards herniation) to help equilibrate the pressures between the infra- and supra-tentorial compartments. Post-op, the external ventricular drain EVD is usually set at a low height (≈ 10 cm above the EAM) for 24 hours, and is progressively raised over the next 48 hrs and should be D/C'd by ≈ 72 hrs post-op.

**Booking the case: Craniotomy for infratentorial tumor**

- **Also see defaults & disclaimers** (p. 27) and retromastoid surgery for vestibular schwannomas (p. 681).
- **1. position:** (typically either prone or park bench, depending on tumor type/location and surgeon preference)
- **2. pre-op embolization** (by neuroendovascular interventionalist) for some vascular tumors such as hemangioblastoma
- **3. equipment:**
  - a) microscope
  - b) ultrasonic aspirator
  - c) image guidance system (optional)
- **4. blood availability:** type and cross 2 U PRBC
- **5. post-op:** ICU
- **6. consent (in lay terms for the patient – not all-inclusive):**
  - a) procedure: surgery through the skull remove as much of the tumor as is safely possible
  - b) alternatives: nonsurgical management, radiation therapy for some tumors
  - c) complications: usual craniotomy complications (p. 28) plus inability to remove all of the tumor, hydrocephalus, CSF leak

### 34.3 Pediatric brain tumors

#### 34.3.1 General information

Among all childhood cancers, brain tumors are the second only to leukemias in incidence (20%), and are the most common solid pediatric tumor, comprising 40–50% of all tumors. Annual incidence: 2–5 cases per 100,000.

#### 34.3.2 Types of tumors

The common pediatric brain tumors are gliomas (cerebellum, brain stem, and optic nerve), pineal tumors, craniopharyngiomas, teratomas, granulomas, and primitive neuroectodermal tumors (PNETs, primarily medulloblastoma).

- **Meningiomas:** 1.5% of meningiomas occur in childhood and adolescence (usually between 10–20 years), comprising 0.4–4.6% of intracranial tumors; see Meningiomas (p. 690).

#### 34.3.3 Infratentorial vs. supratentorial

It has traditionally been taught that most pediatric brain tumors (≈ 60%) are infratentorial, and that these are equally divided among brain stem gliomas, cerebellar astrocytomas, and medulloblastomas. In reality, the ratio of supratentorial to infratentorial tumors is dependent on the specific age group studied, as illustrated in Table 34.3. Table 34.4 shows the breakdown for pooled data from 1350 pediatric brain tumors.

- Astrocytomas are the most common supratentorial tumor in pediatrics as in adulthood.

#### 34.3.4 Intracranial neoplasms during the first year of life

Brain tumors presenting during the first year of life is a different subset of tumors than those presenting later in childhood. In a busy neurosurgical unit in a children’s hospital, they represented ≈ 8% of children admitted with brain tumors, an average of only ≈ 3 admissions per year. 90% of brain tumors in neonates are of neuroectodermal origin, teratoma being the most common. Some of these tumors may be congenital. Other supratentorial tumors include: astrocytoma,
choroid plexus tumors, ependymomas, and craniopharyngiomas. Posterior fossa tumors include medulloblastoma and cerebellar astrocytoma. Many of these tumors escape diagnosis until they are very large in size due to the elasticity of the infant skull, the adaptability of the developing nervous system to compensate for deficits, and the difficulty in examining a patient with limited neurologic repertoire and inability to cooperate. The most common presenting manifestations are vomiting, arrest or regression of psychomotor development, macrocrania, poor feeding/failure to thrive. They may also present with seizures.

34.4 Medications for brain tumors

34.4.1 Steroid use in brain tumors

The beneficial effect of steroids in metastatic tumors is often much more dramatic than with primary infiltrating gliomas.

- Dexamethasone (Decadron®) dose for brain tumors:
  - for patients not previously on steroids:
    - adult: 10 mg IVP loading, then 6 mg PO/IVP q 6 hrs. In cases with severe vasogenic edema, doses up to 10 mg q 4 hrs may be used
    - peds: 0.5–1 mg/kg IVP loading, then 0.25–0.5 mg/kg/d PO/IVP divided q 6 hrs. NB: avoid prolonged treatment because of growth suppressant effect in children
  - for patients already on steroids:
    - for acute deterioration, a dose of approximately double the usual dose should be tried
    - see also “stress doses” (p.146)

34.4.2 Prophylactic anticonvulsants with brain tumors

20–40% of patients with a brain tumor will have had a seizure by the time their tumor is diagnosed. Antiepileptic drugs (AEDs) are indicated in these patients. 20–45% more will ultimately develop a seizure. Prophylactic AEDs do not provide substantial benefit (reduction of risk >25% for seizure-free survival) and there are significant risks involved. Practice guidelines for AED use with brain tumors is shown below. Prophylactic AEDs are not indicated for isolated posterior fossa tumors.
Practice guideline: Prophylactic anticonvulsants with brain tumors

Level I: prophylactic AEDs should not be used routinely in patients with newly diagnosed brain tumors.

Level II: in patients with brain tumors undergoing craniotomy, prophylactic AEDs may be used, and if there has been no seizure, it is appropriate to taper off AEDs starting 1 week post-op.

34.5 Chemotherapy for brain tumors

34.5.1 General information

General information is presented here. Chemotherapy for some specific tumors is also included in the section devoted to that tumor where appropriate. Some agents used for CNS tumors: see Table 34.5.22,23

34.5.2 Alkylating agents

Temozolomide (Temodar®) is a derivative of Dacarbazine (DTIC®) and is an oral alkylating agent. Temozolomide is a prodrug which undergoes rapid non-enzymatic conversion at physiologic pH to the active metabolite monomethyl triazenoimidazole carboxamide (MTIC). The cytotoxic effect of MTIC is associated with alkylation (adding an alkyl group, the smallest of which is a methyl group) of DNA at various sites primarily at the O6 and N7 positions on guanine. Some tumors can repair this damage via a protein (AGT) that is coded for by the O-6-methylguanine-DNA methyltransferase (MGMT) gene.

34.5.3 Nitrosoureas

Excellent BBB penetration (see below). Significant hematopoietic, pulmonary and renal toxicity.

34.5.4 Blood-brain barrier (BBB) and chemotherapy agents

Traditionally, the BBB has been considered to be a major hindrance to the use of chemotherapy for brain tumors. In theory, the BBB effectively excludes many chemotherapeutic agents from the CNS, thereby creating a “safe haven” for some tumors, e.g. metastases. This concept has been challenged. Regardless of the etiology, the response of most brain tumors to systemic chemotherapy is usually very modest, with a notable exception being a favorable response of oligodendrogliomas (p.640) and gliomas lacking MGMT activity. Considerations regarding chemotherapeutic agents in relation to the BBB include:

1. some CNS tumors may partially disrupt the BBB, especially malignant gliomas
2. lipophilic agents (e.g. nitrosoureas) may cross the BBB more readily
3. selective intraarterial (e.g. intracarotid or intervertebral) injection: produces higher local concentration of agents which increases penetration of the BBB, with lower associated systemic toxicities than would otherwise occur
4. the BBB may be iatrogenically disrupted (e.g. with mannitol) prior to administration of the agent
5. the BBB may be bypassed by intrathecal administration of agents via LP or ventricular access device, e.g. methotrexate for CNS lymphoma (p.713)
6. biodegradable polymer wafers containing the agent may be directly implanted

34.5.5 Imaging studies following surgical removal of tumor

At many academic centers, it is common to get a noncontrast CT scan within 6–12 hours of surgery to assess for acute complications (primarily blood – within brain or epidural or subdural hematoma, amount of pneumocephalus, hydrocephalus…).

Then to assess the extent of tumor removal, a post-op brain CT or MRI without and with contrast should either be obtained within 2–3 days, or should be delayed at least 30 days. The non-contrast scan is important to help differentiate blood from enhancement. The contrast images demonstrates areas of enhancement, which may represent residual tumor. After ≈ 48 hours, contrast enhancement due to post-operative inflammatory vascular changes ensues, which may be difficult to differentiate from tumor. This usually subsides by ≈ 30 days, but may persist for 6–8 weeks. This recommendation regarding the timing of post-op imaging does not apply to pituitary tumors (p.718). The effect of steroids on contrast enhancement is controversial, and may depend on many factors (including tumor type).

34.6 Intraoperative pathology consultations (“frozen section”)

34.6.1 Accuracy of intraoperative pathology consultations

Accuracy of intraoperative pathologic diagnosis can be increased by:
- Providing the pathologist with information regarding: patient demographics, clinical history, imaging results, relevant previous pathologic diagnoses, and clinical impression
- Larger specimen sizes when possible
- Avoiding artifact created by excessive crushing or coagulation

Frozen section diagnoses should be considered preliminary. The final diagnosis differs from the frozen section in approximately 3–10 % of cases. If the frozen section interpretation does not correlate with the clinical impression, direct discussion with the pathologist may be advisable.

34.6.2 Techniques for intraoperative tissue preparation

Touch preparation. The specimen is gently “touched” with a glass slide which is then rapidly fixed, stained and dehydrated for examination. This technique is particularly useful for tumors with discohesive cells (e.g. lymphoma, pituitary adenoma).

Smear or squash preparation. A small portion of specimen is smeared or compressed with moderate pressure between two glass slides, rapidly fixed, stained, and dehydrated for examination. This technique can be particularly useful for: multiple sclerosis (identifying histiocytes),
visualizing long cell processes in gliomas, and identifying cytoplasmic inclusions or intranuclear pseudoinclusions).\(^{35}(p\ 5–6)\) The cohesive nature often seen in tumors such as metastases and meningiomas is apparent, as are areas of necrosis.

Frozen section. A portion of tissue is rapidly frozen in liquid nitrogen and cut into 4–6 micron sections, mounted on a slide, rapidly fixed, stained, and dehydrated for examination. Unlike touch and smear preparations, this allows more accurate assessment of lesion architecture, cellularity, and interface with adjacent brain tissue. Disadvantages include use of greater tissue with less available for permanent histology (important with small biopsies), as well as artifacts such as freezing ice crystal artifact (which, when present, suggests lesional tissue has been biopsied but limits interpretation of cellularity).\(^{35}(p\ 6)\) When possible, some tissue should be preserved for processing without freezing to avoid artifacts.

At the time of frozen section interpretation, consideration for additional studies such as tissue cultures or flow cytometry should be entertained. With minute specimens, a discussion is warranted whether frozen section is required to preserve tissue for permanent studies.

### 34.6.3 Selected frozen section pitfalls or potential critical diagnoses

- **Differentiating low grade gliomas from normal or reactive brain tissue can be challenging.**\(^{32,33}\)
  - Increased cellularity (best evaluated at low power), nuclear atypia when present, and increased perineuronal satellitosis can be helpful, though not always readily observed.\(^{35}(p\ 72–3, p\ 174–7)\)
  - **Pearl:** Secondary structures of Scherer may be useful in identifying gliomas in challenging cases and include increased perineuronal and perivascular satellitosis (limited perineuronal satellitosis is normal) and accumulation of neoplastic cells in the subpial molecular layer with subpial tumor spread.\(^{36}\)
- **Metastasis vs Gliona:** Usually not problematic on frozen section, except occasionally with markedly atypical gliomas with limited sampling.\(^{32,33,34}\) In such rare cases immunohistochemistry is helpful.
- **Astrocytoma vs oligodendroglioma:** Usually not a critical distinction at the time of frozen section diagnosis. However, in part due to frozen section artifact imparted to the nuclei, oligodendrogliomas can be interpreted as astrocytomas in the frozen section room.\(^{32}\) Smear preparations can at times be helpful due to decreased “frozen” artifact. Also, perineuronal satellitosis may in some cases be more pronounced in oligodendrogliomas.
  - **Pearl:** The “fried egg” appearance in oligodendrogliomas is an artifact of formalin fixation for permanent sections and is NOT present on frozen sections, also hindering intraoperative interpretation.
- **Glioma grading:** Sampling bias, particularly in biopsy specimens, can lead to undergrading (i.e. mitotic figures underrepresented in the biopsy material, vascular proliferation or necrosis not present in the biopsy). However, overgrading of gliomas at the time of intraoperative consultation also can occur, including with low grade childhood gliomas such as pilocytic astrocytomas.\(^{32}\)
- **Radionecrosis vs recurrent glioblastoma:** Despite the fact that a history of prior radiation therapy is usually known at the time of intraoperative consultation, differentiation of the two entities can at times be difficult.\(^{32}\) Both lesions often are present simultaneously. Identifying obvious tumor cells and palisading necrosis suggests recurrent/residual glioblastoma. Radiation necrosis, which affects primarily white matter, is supported by large areas of geographic necrosis, sclerosis/hyalinization of vessels or fibrinoid necrosis of vessel walls, perivascular lymphocytes, calcifications, and the presence of macrophages.
- **Ischemic infarct:** May see ischemic red neuron change (if the biopsy includes gray matter), as well as histiocytes (similar to demyelinating lesions). Necrosis may mimic the center of ring enhancing lesions (such as glioblastoma or metastasis), though tumor necrosis will typically involve vessels and lack a macrophage response.\(^{35}(p\ 663–4)\)
- **Demyelinating lesions (e.g. tumeffactive MS):** Primarily affects white matter with discrete borders. Identifying histiocytes at the time of frozen section is critical for the diagnosis. The histiocytes can mimic astrocytes of gliomas on frozen section preparation; smear preparations are particularly helpful in the distinction.
- **Lymphoma (PCNSL) and small cell carcinoma:** Accurate frozen section diagnosis may be critical as both conditions typically require only biopsy unless there is significant mass effect. The two entities may resemble each other on frozen section as well as resembling astrocytomas, oligodendrogliomas, and other types of metastatic carcinomas.\(^{32,33,34,35}(p\ 395–7)\)
  - **Touch preparations** can be particularly useful in identifying PCNSL.
- **Spindle cell tumor/meningioma:** It has been demonstrated that at times distinguishing between meningioma and spindled cell lesions such as schwannomas can be difficult at the time of
intraoperative consultation. Classic features of meningiomas (whorls, psammoma bodies, intranuclear pseudoinclusions) may be absent, and freeze artifact can create Antoni B appearing areas in meningiomas. In addition, underdiagnosis of malignant meningiomas and sarcomas at the time of frozen section has been noted.

- Spinal cord astrocytoma vs. ependymoma: On occasion these entities can be difficult to distinguish during intraoperative consultation, especially as most spinal cord biopsies for frozen interpretation are minute. Due to the critical surgical implications of the accuracy of the frozen section diagnosis for intramedullary spinal gliomas, a careful discussion should be had between the surgeon and pathologist at the time of intraoperative consultation (refer to section on tumors of the spine and spinal cord).

34.6.4 Tissue preparation for permanent sections

Tissue is processed overnight through a variety of alcohol/xylene steps to remove water. This allows for embedding into paraffin so that thin sections can be cut for slide mounting. The specimens are then rehydrated by essentially reversing the alcohol/xylene steps in preparation for staining, and then dehydrated again for permanent slide coverslipping. This produces better histology with fewer artifacts, allows for processing of larger specimen volumes for evaluation, and allows for application of special stains as needed.

Fresh specimens. Tissue should be sent “fresh” (i.e. without preservatives such as formalin) when the following techniques are needed:
- electron microscopy
- flow cytometry: e.g. when lymphoma is suspected
- muscle
- cultures (typically: aerobic, anaerobic, acid fast and fungal) should be sent in situations where infection is a consideration

34.7 Select commonly utilized stains in neuropathology

34.7.1 Organism and special stains

1. Organism stains:
   - tissue Gram stains (Brown & Brenn, Brown & Hopps)
   - fungi (Periodic acic-Schiff: PAS, Gomori methenamine silver: GMS)
   - acid fast bacilli (Ziehl-Neelsen, Kinyoun, FITE)

2. Special stains:
   - luxol fast blue: stains myelin; absence of staining highlights demyelinating lesions. Presence within histiocytes demonstrates ingestion of myelin as seen in MS
   - trichrome and reticulin stain: Both delineate the sarcomatous component of gliosarcomas. A reticulin stain demonstrates the connective tissue around acini of the normal pituitary gland, a feature that is lost with pituitary adenomas

34.7.2 Immunohistochemical stains

General information

Staining patterns: An individual tumor may lack a marker that is typically representative of its type. Therefore, a positive stain is typically more significant than a negative stain. General staining patterns are shown in Table 34.6.

Glial fibrillary acidic protein (GFAP)

Polypeptide, MW = 49,000 Daltons. Stains intermediate filaments classically identified in astrocytes/astrocytic tumors. However, it is also typically expressed in ependymomas, oligodendroglomas (especially in minigemistocytes and gliofibrillary oligodendrocytes), and some choroid plexus papillomas. GFAP is only rarely found outside the CNS in such tissues as Schwann cells, epithelium of the lens, certain liver cells, chondrocytes, etc. It would be unusual for a metastatic lesion to demonstrate staining for GFAP. However, GFAP expression may be limited in certain subsets of GBM (e.g. small cell GBM).
S-100 protein

A low molecular weight (21,000 Daltons) calcium-binding protein that stains a variety of tissues including glia, neurons, chondrocytes, stellate cells of the adenohypophysis, myoepithelial cells, etc. Stains a variety of CNS neoplasms such as gliomas (though less specific than GFAP), PNET, ependymomas, chordomas, and craniopharyngiomas. Primary uses in neuropathology include to support the diagnosis of metastatic melanoma, and, in the peripheral nervous system, to confirm the diagnosis of schwannoma or neurofibroma (less intense staining in the latter).

Clinically has been measured in serum (see below).

Cytokeratins (high and low molecular weight)

A variety of stains (low e.g. CAM 5.2) & high molecular weight keratin, CK7, CK20, etc.) which stain epithelial cells. Useful to distinguish metastatic carcinoma (positive staining) from primary CNS tumors (note: cytokeratins can be expressed in choroid plexus papillomas, and GBM can express cytokeratins in rare cases). Different keratin staining combinations can be used to suggest possible sites of origin for metastatic tumors.

Epithelial membrane antigen (EMA)

Stains cell membranes in many carcinomas; useful to distinguish hemangioblastoma (negative) from metastatic renal cell carcinoma (positive). Also, meningiomas typically demonstrate positive staining, as do ependymomas.

MIB-1 (AKA monoclonal mouse anti-human Ki-67 antibody)

The Ki-67 antigen is expressed in all phases of the cell cycle except G0. Available since the early 1990s, it is a valuable marker of cell proliferation but can only be used with fresh-frozen specimens. MIB-1 is a monoclonal antibody developed using recombinant parts of the Ki-67 protein as an immunogen, and can be used on paraffin-embedded sections of fixed tissue. Cells leaving the G0/G1-phase and entering the S-phase (performing DNA synthesis) stain positive with MIB-1.

abbreviations: GFAP = glial fibrillary acidic protein, EMA = epithelial membrane antigen, CAM5.2 = cytokeratin CAM5.2, CgA = chromogranin A, syn = synaptophysin

*a “+” or a “–” sign indicates presence or absence of the stain respectively; “0” entries indicate that the stain is not decisive for that particular tumor.
immunohistochemical stain. This stain can be used to compute a semi-quantitative score. A high MIB-1 labeling index denotes high mitotic activity which often correlates with degree of malignancy. Often used in lymphomas, endocrine tumors, carcinoids, etc. See also use in astrocytomas (p.617) and in meningiomas (p.694).

Neuroendocrine stains

Includes:

In neuropathology, utilized in central neurocytoma, medulloblastoma, PNET, pineocytoma, ganglion cell tumors, paragangliomas, and choroid plexus tumors. Metastases that are positive for neuroendocrine stains include small-cell carcinoma of the lung (most common), malignant pheochromocytoma, and Merkel cell tumor.

Includes:

1. chromogranin: stains synaptic vesicles. Perhaps less commonly utilized than synaptophysin in primary CNS tumor
2. synaptophysin: stains synaptic vesicles; has higher sensitivity but lower specificity than chromogranin. Often positive for central neurocytoma which typically lacks chromogranin staining.
3. CD56 (Neural cell adhesion molecule): a family of glycoproteins present in nervous tissue as well as other tissues such as thyroid, liver, etc. Frequently used to confirm neuroendocrine differentiation.
4. neuron specific enolase (NSE): sensitive but not specific for neuronal or neuroendocrine differentiation despite its name (often referred to as "neuron non-specific enolase"). Due to this, it is less often utilized as a neuroendocrine marker.

Cluster of differentiation (CD) markers

A number of immunohistochemical stains that detect antigens on the surface of leukocytes, though many stain other cell types as well. Examples include:

- CD45: General leukocyte marker
- CD3 and CD5: T-cells
- CD20: B-cells
- CD38 and CD138: Plasma cells
- CD68: Histiocytes
- CD56 (Neural cell adhesion molecule): Classically stains natural killer cells, but also a neuroendocrine marker (see above)

Metastases that are positive for neuroendocrine stains include: small-cell carcinoma of the lung, malignant pheochromocytoma, Merkel cell tumor. Metastatic small-cell tumors to the brain staining positive for neuroendocrine stains are almost all due to lung primaries (all other primaries are a distant possibility).

34.7.3 Tumor markers used clinically

Human chorionic gonadotropin (hCG)

A glycoprotein, MW = 45,000. Secreted by placental trophoblastic epithelium. Beta chain (β-hCG) is normally present only in the fetus or in gravid or postpartum females, otherwise it indicates disease. Classically associated with choriocarcinoma (uterine or testicular), also found in patients with embryonal cell tumors, teratocarcinoma of testis, and others.

CSF β-hCG is 0.5–2% of serum β-hCG in non-CNS tumors. Higher levels are diagnostic of cerebral mets from uterine or testicular choriocarcinoma, or primary choriocarcinoma or embryonal cell carcinoma of pineal (p.658) or suprasellar region.

Alpha-fetoprotein

Alpha-fetoprotein (AFP) is a normal fetal glycoprotein (MW = 70,000) initially produced by the yolk sac, and later by the fetal liver. It is found in the fetal circulation throughout gestation, and drops rapidly during the first few weeks of life, reaching normal adult levels by age 1 yr. It is detectable only in trace amounts in normal adult males or nonpregnant females. It is present in amniotic fluid
in normal pregnancies, and is detectable in maternal serum starting at ≈ 12–14 weeks gestation, increasing steadily throughout pregnancy until ≈ 32 weeks.\(^\text{39}\)

Abnormally elevated serum AFP may occur in Ca of ovary, stomach, lung, colon, pancreas, as well as in cirrhosis or hepatitis and in the majority of gravid women carrying a fetus with an open neural tube defect; see Prenatal detection of neural tube defects (p.290). Serum AFP >500 ng/ml usually means primary hepatic tumor.

CSF-AFP is elevated in some pineal region germ-cell tumors (p.659). 16–25% of patients with testicular tumors get cerebral mets and elevated CSF AFP levels are reported in some.

**Carcinoembryonic antigen (CEA)**

A glycoprotein, MW = 200,000. Normally present in fetal endodermal cells. Originally described in the early 1960s in the serum of patients with colorectal adeno-Ca, now known to be elevated in many malignant and nonmalignant conditions (including cholecystitis, colitis, diverticulitis, hepatic involvement from any tumor, with 50–90% of terminal patients having elevation).

CSF CEA: levels >1 ng/ml are reported with leptomeningeal spread of lung Ca (89%), breast Ca (60–67%), malignant melanoma (25–33%), and bladder Ca. May be normal even in CEA secreting cerebro- mets if they don’t communicate with the subarachnoid space. Only carcinomatous meningitis from lung or breast Ca consistently elevates CS CEA in the majority of patients.

**S-100 protein**

Serum S-100 protein levels rise after head trauma, and possibly after other insults to the brain. Levels may also be elevated in Creutzfeldt-Jakob disease.

35 Syndromes Involving Tumors

35.1 Neurocutaneous disorders

35.1.1 General information

Formerly called phakomatoses. Neurocutaneous disorders (NCD) are a group of conditions, each with unique neurologic findings and benign cutaneous lesions (NB: both skin and the CNS derive embryologically from ectoderm), usually with dysplasia of other organ systems (often including the eyes). With the exception of ataxia-telangiectasia (not discussed here) all exhibit autosomal dominant inheritance. There is also a high rate of spontaneous mutations. These syndromes should be kept in mind in a pediatric patient with a tumor, and other stig mata of these syndromes should be sought.

NCDs that are more likely to come to the attention of the neurosurgeon:
1. neurofibromatosis: see below
2. tuberous sclerosis (p.606)
3. von Hippel-Lindau disease (p.703)
4. Sturge Weber syndrome (p.608)
5. racemose angioma (Wyburn-Mason syndrome): midbrain and retinal AVMs

35.1.2 Neurofibromatosis

General information

Neurofibromatosis (NFT) is the most common of the NCDs. There are as many as 6 distinct types, the two most common of which (NF1 & NF2) are compared in Table 35.1 (variant forms also occur).

* malignant peripheral nerve sheath tumor
Schwannoma vs. neurofibroma

While similar in many ways, these tumors differ histologically. Schwannomas (nee: neurilemmomas) arise from schwann cells which produce myelin. Neurofibromas consist of neurites (axons or dendrites of immature or developing neurons), Schwann’s cells, and fibroblasts within a collagenous or myxoid matrix. In contrast to schwannomas which displace axons (centrifugal), neurofibromas are unencapsulated and engulf the nerve of origin (centripetal). Neurofibromas may occur as solitary lesions, or, may be multiple as part of NF1 in the setting of which there is potential for malignant transformation. Both tumors have Antoni A (compact) and Antoni B (loose) fibers, but neurofibromas tend to have more Antoni B fibers. A patient ≤30 years of age with a vestibular schwannoma is at increased risk of having NF2.

Neurofibromatosis 1
(NF1 AKA von Recklinghausen’s disease)
See reference.

General information
More common than NF2, representing >90% of cases of neurofibromatosis.

Clinical
Diagnostic criteria: see Table 35.2.

Associated conditions
1. Schwann-cell tumors on any nerve (but bilateral VSs are virtually nonexistent)
2. spinal and/or peripheral-nerve neurofibromas
3. multiple skin neurofibromas
4. aqueductal stenosis (p. 258)
5. macrocephaly: secondary to aqueductal stenosis and hydrocephalus, increased cerebral white matter
6. intracranial tumors: hemispheric astrocytomas are the most common, solitary or multicentric meningiomas (usually in adults). Gliomas associated with NF1 are usually pilocytic astrocytomas. Brain stem astrocytomas include both contrast-enhancing pilocytic lesions and those that are non-enhancing and radiologically diffuse
7. unilateral defect in superior orbit → pulsatile exophthalmos
8. neurologic or cognitive impairment: 30–60% have mild learning disabilities
9. kyphoscoliosis (seen in 2–10% often progressive which then requires surgical stabilization)
10. visceral manifestations from involvement of autonomic nerves or ganglia within the organ. Up to 10% of patients have abnormal gastrointestinal motility/neuronal intestinal dysplasia related to neuronal hyperplasia within submucosal plexus
11. ≈20% develop plexiform neurofibromas: tumors from multiple nerve fascicles that grow along the length of the nerve. Almost pathognomonic for NF1
12. syringomyelia

Table 35.2 Diagnostic criteria for NF1

<table>
<thead>
<tr>

</tr>
<tr>
<td>a first degree relative (parent, sibling or offspring) with NF1 by above criteria</td>
</tr>
</tbody>
</table>

*café au lait spots: hyperpigmented oval light brown skin macules (flat). May be present at birth, increase in number and size during 1st decade. Are present in >99% of NF1 cases. Rare on face
13. malignant tumors that have increased frequency in NFT: neuroblastoma, ganglioglioma, sarcoma, leukemia, Wilms tumor, breast cancer

14. pheochromocytoma: is occasionally present

15. “unidentified bright objects” (UBOs) on brain or spinal MRI in 53–79% of patients (bright on T2WI, isointense on T1WI) that may be hamartomas, heterotopias, foci of abnormal myelination or low grade tumors. Tend to resolve with age

Genetics
Simple autosomal dominant inheritance with variable expressivity but almost 100% penetrance after age 5 years. The NF1 gene is on chromosome 17q11.2 which codes for neurofibromin (neurofibromin is a negative regulator of the Ras oncogene). Loss of neurofibromin as in NF1 results in elevation of growth-promoting signals. The spontaneous mutation rate is high, with 30–50% of cases representing new somatic mutations.

Counselling: prenatal diagnosis is possible by linkage analysis only if there are 2 or more affected family members. 70% of NF1 gene mutations can be detected using protein truncation analysis.

Management
1. optic gliomas
   a) unlike optic gliomas in the absence of NFT, these are rarely chiasmal (usually involving the nerve), are often multiple, and have a better prognosis
   b) most are non progressive, and should be followed ophthalmologically and with serial imaging (MRI or CT)
   c) surgical intervention probably does not alter visual impairment. Therefore, surgery is reserved for special situations (large disfiguring tumors, pressure on adjacent structures...)

2. other neural tumors in patients with NF1 should be managed in the same manner as in the general population
   a) focal, resectable, symptomatic lesions should be surgically removed
   b) intracranial tumors in NF1 may often be unresectable, and in these cases chemotherapy and/or radiation therapy may be appropriate, with surgery reserved for cases with increasing ICP
   c) when malignant degeneration is suspected (rare, but incidence of sarcomas and leukemias is increased), biopsy with or without internal decompression may be indicated

Neurofibromatosis 2 (NF2 AKA bilateral acoustic NFT)
See reference.

General information
AKA MISME Syndrome (Multiple Inherited Schwannomas, Meningiomas, and Ependymomas).

Clinical
Diagnostic criteria: see Table 35.3.

Other clinical features:
1. seizures or other focal deficits
2. skin nodules, dermal neurofibromas, café au lait spots (less common than in NF1)
3. multiple intradural spinal tumors are common (less common in NF1); including intramedullary (especially ependymomas) and extramedullary (schwannomas, meningiomas...)
4. retinal hamartomas

<table>
<thead>
<tr>

</tr>
<tr>
<td>2. multiple meningiomas and either of the following: schwannoma, glioma, or posterior lens opacity</td>
</tr>
</tbody>
</table>
5. antigenic nerve growth factor is increased (does not occur with NF1)
6. despite its name, is not associated with neurofibromas

Two subtypes:
1. the more common, severe form with younger age of onset (2nd to 3rd decade), with rapid progression of hearing loss and multiple associated tumors
2. milder form, presents later in life, with slower deterioration in hearing and fewer associated tumors

Genetics
Autosomal dominant inheritance. NF2 is due to a mutation at chromosome 22q12.2 Which results in the inactivation of schwannomin (AKA merlin, a semi-acronym for moesin-, ezrin, and radixin-like proteins), a tumor suppression peptide. NF2 patients with nonsense and frameshift mutations are more likely to have intramedullary tumors (but not any other type of tumor) compared with other mutation types.

Management considerations
1. bilateral vestibular schwannomas:
   a) chance of preserving hearing is best when tumor is small. Thus, one should attempt to remove smaller tumor. If hearing is serviceable in that ear after surgery, then consider removing the second tumor, otherwise follow the second tumor as long as possible and perform a subtotal removal in an attempt to prevent total deafness
   b) stereotactic radiosurgery therapy may be a treatment option
2. most NF2 patients will become deaf at some time during their life
3. prior to surgery, obtain MRI of cervical spine to R/O intraspinal tumors that may cause cord injuries during other operations
4. NB: pregnancy may accelerate the growth of eighth nerve tumors

35.1.3 Tuberous sclerosis complex

General information

**Key concepts**

- most cases are due to spontaneous mutation. Inherited cases are autosomal dominant. Incidence: 1 in 6K-10K live births
- clinical triad: seizures, mental retardation and sebaceous adenomas; the full clinical triad is seen in <1/3 of cases
- typical CNS finding: subependymal nodules (“tuber”) – a hamartoma
- common associated neoplasm: subependymal giant cell astrocytoma
- 2 tumor suppressor genes: TSC1 (on chromosome 9q34) codes for hamartin, and TSC2 (on chromosome 16p13) encodes tuberin
- CT shows intracerebral calcifications (usually subependymal)

Tuberous sclerosis complex (TSC), AKA Bourneville’s disease, is a neurocutaneous disorder characterized by hamartomas of many organs including the skin, brain, eyes and kidneys. In the brain, the hamartomas may manifest as cortical tubers, glial nodules located subependymally or in deep white matter, or giant cell astrocytomas. Associated findings include pachygyria or microgyria.

Epidemiology/genetics/epigenetics

Incidence: 1 in 6,000–10,000 live births.\(^12\) Point prevalence: 10.6 per 100,000 persons (from Rochester, MN\(^13\)).

Autosomal dominant inheritance, however spontaneous mutation account for the majority of cases.\(^14\) Two distinct tumor suppressor genes have been identified: TSC1 (located on chromosome 9q34) codes for hamartin, and TSC2 (on chromosome 16p13) codes for tuberin. Only 1 gene needs to be affected to develop TSC. These proteins work together to inhibit activation of rapamycin (mTOR).

Genetic counseling for unaffected parents with one affected child: 1–2% chance of recurrence.
Pathology

Subependymal nodules ("tubers") are benign hamartomas that are almost always calcified, and protrude into the ventricles.

Subependymal giant cell astrocytoma (SEGA): a transformation lesion. Almost always located at the foramen of Monro. Occurs in 5–15% of patients with TSC. Histology shows fibrillary areas alternating with cells containing generous amounts of eosinophilic cytoplasm. Areas of necrosis and abundant mitotic figures may be seen, but are not associated with the typical malignant aggressiveness that these features usually denote.

Clinical

Diagnostic criteria are shown in Table 35.4.

In the infant, the earliest finding is of "ash leaf" macules (hypomelanotic, leaf shaped) that are best seen with a Wood’s lamp. Infantile myoclonus may also occur.

In older children or adults, the myoclonus is often replaced by generalized tonic-clonic or partial complex seizures which occurs in 70–80% Facial adenomas are not present at birth, but appear in >90% by age 4 yrs (these are not really adenomas of the sebaceous glands, but are small hamartomas of cutaneous nerve elements that are yellowish-brown and glistening and tend to arise in a butterfly malar distribution usually sparing the upper lip).

Retinal hamartomas occur in ≈50% (central calcified hamartoma near the optic disc or a more subtle peripheral flat salmon-colored lesion). A distinctive depigmented iris lesion may also occur.

Evaluation

Plain skull x-rays

May show calcified cerebral nodules.

CT scan

See reference.

Intracerebral calcifications are the most common (97% of cases) and characteristic finding. Primarily located subependymally along the lateral walls of the lateral ventricles or near the foramina of Monro.

Low density lesions that do not enhance are seen in 61% Probably represent heterotopic tissue or defective myelination. Most common in occipital lobe.

Hydrocephalus (HCP) may occur even without obstruction. In the absence of tumor, HCP is usually mild. Moderate HCP usually occurs only in the presence of tumor.

Subependymal nodules are usually calcified, and protrude into the ventricle ("candle guttering" described the appearance on pneumoencephalography).

</tr>
</tbody>
</table>
Paraventricular tumors (mostly giant cell astrocytomas) see pathology) are essentially the only enhancing lesion in TSC.

MRI
Subependymal tubers are high on T2 and low on T1 and only ≈ 10% enhance. Low signal in subependymal lesions may represent calcification. SEGA enhance intensely (enhancing subependymal lesion are almost always SEGAs). Radial bands sign: abnormal signal intensity extending in a radial manner, representing cells of varying degrees of neuronal and astrocytic differentiation as well as difficult to classify cells.¹⁹

Treatment
Paraventricular tumors should be followed. Tubers grow minimally, but SEGA progress should be removed if they are symptomatic. A transcallosal approach or ventriculoscopy removal are options. Infantile myoclonus may respond to steroids. Seizures are treated with AEDs. Surgery for intractable seizures may be considered when a particular lesion is identified as a seizure focus. Better seizure control, not cure, is the goal in TSC. Patients ≥ 3 years of age with increasing size of SEGA lesions have had sustained reduction of SEGA volume on everolimus.²⁰

35.1.4 Sturge–Weber syndrome
General information

Key concepts
- cardinal signs: 1) localized cerebral cortical atrophy and calcifications, 2) ipsilateral port-wine facial nevus (usually in distribution of V1)
- contralateral seizures usually present
- plain skull films classically show “tram-tracking” (double parallel lines)

AKA encephalotrigeminal angiomatosis. A neurocutaneous disorder consisting of:
1. cardinal features:
   a) localized cerebral cortical atrophy and calcifications (especially cortical layers 2 and 3, with a predilection for the occipital lobes):
      • calcifications appear as curvilinear double parallel lines (“tram-tracking”) on plain x-rays
      • cortical atrophy usually causes contralateral hemiparesis, hemiatrophy, and homonymous hemianopia (with occipital lobe involvement)
   b) ipsilateral port-wine facial nevus (nevus flammeus) usually in distribution of 1st division of trigeminal nerve (rarely bilateral)
2. other findings that may be present:
   a) ipsilateral exophthalmos and/or glaucoma, coloboma of the iris
   b) oculomeningeal capillary hemangioma
   c) convulsive seizures: contralateral to the facial nevus and cortical atrophy. Present in most patients starting in infancy
   d) retinal angiomas

Genetics
Most cases are sporadic. Other cases are suggestive of recessive inheritance, with chromosome 3 being implicated.

Treatment
Treatment is supportive. Anticonvulsants are used for seizures. Lobectomy or hemispherectomy may be needed for refractory seizures. XRT: complications are common and benefits are lacking. Laser surgery for the cutaneous nevus is disappointing; better results obtain from masking the nevus with a skin colored tattoo.
35.1.5 Neurocutaneous melanosis (NCM)

Background
1. a rare, congenital, nonheritable phakomatosis in which large or numerous congenital melanocytic nevi are associated with benign and/or malignant melanocytic tumors of the leptomeninges\textsuperscript{21}
2. pathogenesis: neuroectodermal defect during morphogenesis involving melanoblasts of skin and pia mater originating from neural crest cells\textsuperscript{21}

Clinical features
1. two-thirds of patients with NCM have giant congenital melanocytic nevi\textsuperscript{21}: pigmented nevi that are large, hairy, or both. (The chances that nevi represents NCM is higher when the nevi are located on head, posterior neck or paravertebral)
2. one-third have numerous lesions without a single giant lesion\textsuperscript{21}
3. virtually all have large cutaneous melanocytic (pigmented) nevi located on the posterior torso\textsuperscript{22}
4. neurologic manifestations: usually before age 2 years. Signs of intracranial hypertension (lethargy, vomiting…), focal seizures, motor deficits or aphasia\textsuperscript{21}
5. hydrocephalus: in almost 66\%. Usually due to obstruction of CSF flow or reduced absorption as a result of thickened leptomeninges\textsuperscript{21}

Clinical diagnostic criteria
See reference.\textsuperscript{23}
1. large or multiple congenital melanocytic nevi with meningeal melanosis or melanoma
2. absence of cutaneous melanoma, except in patients with benign meningeal lesions (i.e. must rule-out meningeal metastases from cutaneous melanoma)
3. no evidence of meningeal melanoma, except in patients with benign cutaneous lesions

Associated conditions
NCM is sometimes associated with
1. neurocutaneous syndromes\textsuperscript{21}
   a) Sturge-Weber syndrome (p.608)
   b) von Recklinghausen’s neurofibromatosis (NF1) (p.604)
2. posterior fossa cystic malformations: e.g. Dandy Walker malformation (p.256); occurs in up to 10\%. These cases have worse prognosis due to malignant transformation\textsuperscript{21}
3. intraspinal lipoma and syringomyelia\textsuperscript{21}

Diagnostic testing
1. MRI: T1 and T2 signal shortening produced by melanin. IV gadolinium may demonstrate enhancement of tumor-infiltrated meninges\textsuperscript{21}
2. histological exam of CNS lesions shows leptomeningeal melanosis (benign) which develops from the melanocytes of the pia matter. Melanoma (malignant) occurs in 40–62\% of cases but distinction has little prognostic significance because of the poor outcome of the symptomatic NCM patient even in the absence of melanoma\textsuperscript{21}

Management
The benefit of resecting skin lesions is questionable in the presence of leptomeningeal lesions.\textsuperscript{24}
NCM appears refractory to radiation therapy and chemotherapy\textsuperscript{24}
   - Neurosurgical involvement is usually limited to\textsuperscript{23};
     1. shunting for hydrocephalus
     2. palliative operative decompression if early in the course
     3. biopsy for tissue diagnosis in questionable cases

Prognosis
1. when neurological signs are present, prognosis is poor regardless of whether or not malignancy is present
2. >50\% of patients die within 3 years after the first neurologic manifestation\textsuperscript{21}
35.2 Familial tumor syndromes

35.2.1 General information

Several familial syndromes are associated with CNS tumors as shown in Table 35.5.

35.2.2 Turcot syndrome

A rare inherited disorder characterized by multiple colorectal neoplasms (carcinomas or benign adenomatous polyps) together with neuroepithelial tumors of the CNS (GBM, AA, MB, pineoblastoma, gangliogioma & ependymoma).12 Type 1: GBM without familial polyposis (but often with non-polyposis colorectal cancer). Mean survival of Turcot patients with GBM is 27 months (longer than sporadic cases). Type 2: MB & familial adenomatous polyposis.

35.2.3 Li-Fraumeni syndrome

Rare (<400 families identified) inherited autosomal dominant mutation of the TP53 tumor suppressor gene. Patients have increased incidence of multiple types of tumors, including: sarcoma & osteosarcoma, breast cancer, astrocytoma and PNET, adrenocortical carcinoma, leukemia.

36 Astrocytomas

36.1 Incidence, risk factors

Astrocytic tumors are the most common primary intra-axial brain tumor. The average annual age adjusted incidence from 2006 – 2010 was 5.17 per 100,000,\(^1\) approximately 16,000 new cases/year in the U.S.

The best-established causes for brain tumors are syndromic (familial diseases...) and post-radiation therapy.

The controversy of cell phones as a risk factor: The substantial increase in the number of mobile phone subscriptions since the early 1990’s has not been observed to be associated with increased incidence of brain tumor in the US.\(^2,3,4\) Nonetheless, primarily due to lack of data for extremely long exposure (>15 years), in May 2011, the WHO issued a warning of possible cancer risk in relation to the use of devices that emit nonionizing electromagnetic radiation, such as cellular phones.\(^5\)

36.2 Classification and grading of astrocytic tumors

36.2.1 Classification by general morphology or behavior

In general
- Circumscribed vs. Diffuse
- Non-infiltrative vs. Infiltrative\(^6\)
- Special vs. Ordinary

Detailed classification:
1. Infiltrating astrocytoma
   a) Diffuse astrocytoma (AKA low grade astrocytoma): WHO II. Genetic hallmark: frequent TP53 mutation. Histological variants:
      - fibrillary: the most common subtype
      - gemistocytic
      - protoplasmic: rare
   b) Mixed oligoastrocytoma WHO II
   c) Anaplastic astrocytoma WHO III
   d) Anaplastic oligoastrocytoma WHO III
   e) Glioblastoma multiforme WHO IV
2. Non-infiltrative astrocytoma
   a) Juvenile Pilocytic astrocytoma WHO I
   b) Subependymal giant cell astrocytoma (Tuberous Sclerosis) WHO I
   c) Desmoplastic infantile astrocytoma WHO I
   d) Pilomyxoid astrocytoma WHO II
3. Unique astrocytoma (unique variant that the prognosis does not conform to the grading):
   a) Pleomorphic xanthoastrocytoma WHO II
   b) Gemistocytic astrocytoma WHO II

In diffuse/infiltrative tumors, since complete surgical excision is rarely attainable, there is higher recurrence rate and poorer prognosis in general.

Special vs Ordinary:
- dividing tumors according to favorable or poor behavior is not considered to be a contemporary classification system
- Special – favorable outcome, younger age group, includes pilocytic astrocytoma, microcytic cerebellar and subependymal giant cell astrocytoma
- Ordinary – poorer outcome, includes in WHO Grade II-IV or St.Anne/Mayo Grade I-IV group

36.2.2 Grading and neuropathology

General information

The grading of astrocytomas has been historically fraught with disagreement, and a number of grading systems have been proposed over the years. The first system of Bailey and Cushing was a 3-tiered system, the Kernohan system was 4-tiered, and since then a number of 3-tiered systems like the
Rin gertz system,\textsuperscript{7} have been proposed. As a result, there is a lack of uniformity in, for example, what constitutes a glioblastoma from series to series over time. The current trend has been to use one of two different systems, the WHO definition or the St. Anne/Mayo system, both of which appear below.

Grading of astrocytomas remains controversial. Some special concerns:
1. sampling error: may have different degrees of malignancy in different areas
2. dedifferentiation (p.615): tumors tend to progress in malignancy over months or years
3. histological criteria that affect prognosis include: cellularity, presence of giant cells, anaplasia, mitosis, vascular proliferation with or without endothelial proliferation, necrosis, and pseudopalisading\textsuperscript{8}
4. in addition to histology, issues that affect clinical behavior (many of which are not factored into most grading systems) include:
   a) patient age
   b) extent of tumor
   c) topography: tumor location, especially in relation to critical structures

Obsolete grading systems

Rin gertz’s system. The obsolete Rin gertz’s system developed three grades for ast rocytoma malignancy.\textsuperscript{7} Necrosis was used to divide the intermediate grade from the glioblastoma multiforme. The Rin gertz three-tiered grading system was more clinically correlated with the prognosis for astrocytomas.

Kernohan system. The obsolete Kernohan system,\textsuperscript{9} originally devised at the Mayo Clinic, divided these tumors into 4 grades (grade IVA K A glioblastoma multiforme) based on the degree of presence of a number of features such as anaplasia, nuclear pleomorphism, number of mitoses. The Kernohan system determined tumor grade according to the proportion of normal tissue remaining in the invading tumor and the type of invading edge of the tumor into normal tissue. Prognostically, this system distinguished only 2 clinically different groups (grades I/II, and grades III/IV) and is not used today. It is presented for completeness when reviewing older literature.

Current grading systems

The 2 main systems in use today are shown below, and differ primarily in the definition of Grade I.

WHO system. The World Health Organization (WHO) system is shown in Table 36.1.\textsuperscript{10} In the WHO system, grade I is reserved for special types of astrocytomas that are more circumscribed, including pilocytic astrocytomas, while the more typical astrocytic neoplasms are graded II through IV. The approximate equivalence to the Rin gertz system, Kernohan grade, and St Anne-Mayo grading is also shown in Table 36.2.

WHO 2007 Grading of astrocytomas for specific types of astrocytomas:

1. Grade I
   - Subependymal giant cell astrocytoma (SEGA)
   - Pilocytic astrocytoma

2. Grade II
   - Pilomyxoid astrocytoma
   - Diffuse astrocytoma
   - Pleomorphic xanthoastrocytoma

3. Grade III – anaplastic astrocytoma

4. Grade IV
   - Glioblastoma
   - Giant cell glioblastoma
   - Gliosarcoma

St. Anne/Mayo grading system. Grading systems such as those described above are very dependent upon subjective impression of histological findings. The classification system known as the St. Anne/Mayo (SA/M) system addresses histological considerations, and is reproducible and prognostically significant. It is restricted to "ordinary" astrocytomas, as grade has not been shown to correlate with clinical behavior in pilocytic or microcystic cerebellar astrocytomas. It is similar to the WHO system except that SA/M grade I astrocytomas are a very rare diffuse astrocytoma without atypia.

The SA/M system assesses the presence or absence of 4 criteria (see Table 36.3) and then assigns a grade based on the number of criteria present (Table 36.4). When the presence of any criteria is uncertain, it is considered to be absent.

The criteria tended to occur in a predictable sequence: nuclear atypia occurred in all grade 2 tumors, mitotic activity was seen in 92% of grade 3 tumors (and in none of the grade 2 tumors), necrosis and endothelial proliferation were restricted almost only to grade 4 tumors (they were seen in only 8% of grade 3 tumors).

The frequencies of occurrence among 287 “ordinary” astrocytomas were: grade 1 = 0.7% (a very rare tumor), grade 2 = 16% grade 3 = 17.8% and grade 4 = 65.5%

Median survival was as follows: (there were only two grade 1 patients, one survived 11 years and the other was still alive after 15 years), grade 2 = 4 years, grade 3 = 1.6 years, and grade 4 = 0.7 years (8.5 months).

Relative frequency of astrocytoma grades. Glioblastoma comprise approximately 54% of all gliomas and about 6% of anaplastic astrocytoma. Less common ones like anaplastic oligodendroglialoma and anaplastic oligoastroglioma, together with the scarcer tumors such as anaplastic ependymoma and anaplastic ganglioglioma make up 7.2% of all gliomas.

Future directions of astrocytoma grading

Guideline for future WHO classification:\(^1\): In order to align with new developments in glioma molecular genetics, a consensus was reached amongst world leaders in neuropathology. Guidelines for the next WHO classification were issued:

- diagnostic entities should be defined as narrowly as possible to optimize interobserver reproducibility, clinicopathological predictions and therapeutic planning
- diagnoses should be “layered” with histologic classification, WHO grade and molecular information listed below an “integrated diagnosis”
- determinations should be made for each tumor entity as to whether molecular information is required, suggested or not needed for its definition
- some pediatric entities should be separated from their adult counterparts
- input for guiding decisions regarding tumor classification should be solicited from experts in complementary disciplines of neuro-oncology
- entity-specific molecular testing and reporting formats should be followed in diagnostic reports.

It is hoped that these guidelines will facilitate the forthcoming update of the fourth edition of the WHO classification of central nervous system tumors

Low-grade astrocytoma (WHO II) comments

AKA low-grade diffuse astrocytoma. Three histopathological types:
1. fibrillary astrocytoma: the most common histological subtype of Grade II
2. gemistocytic astrocytoma: particularly prone to progress to Grade II & IV
3. protoplasmic astrocytoma

These tumors tend to occur in children and young adults. Most present with seizures. There is a predilection for temporal, posterior frontal and anterior parietal lobes.\(^1\)\(^4\) They demonstrate low degrees of cellularity and preservation of normal brain elements within the tumor. Calcifications are rare. Anaplasia and mitoses are absent (a single mitosis is allowed). Blood vessels may be slightly increased in number. The ultimate behavior of these tumors is usually not benign. The most important favorable prognosticator is young age. Poor prognosis is associated with findings of increased ICP, altered consciousness, personality change, significant neurologic deficits,\(^1\)\(^3\) short duration of symptoms before diagnosis (suggesting rapid progression), and enhancement on imaging studies.

Dedifferentiation

The major cause of morbidity with low-grade astrocytomas is dedifferentiation to a more malignant grade. Low grade fibrillary astrocytomas tend to undergo malignant transformation more quickly (with six-fold increased rapidity) when diagnosed after age 45 years than when diagnosed earlier\(^1\)\(^6\) (see Table 36.5). Gemistocytic astrocytomas tend to dedifferentiate more rapidly than fibrillary astrocytomas.\(^1\)\(^7\)\(^8\)% of fibrillary astrocytomas have a mutation of the TP53 gene located on chromosome 17p; these tumors are more likely to dedifferentiate. Once dedifferentiation occurs, median survival is 2–3 years beyond that event. Genetic markers that correlate with a higher degree of malignant degeneration include\(^1\)\(^7\)\(^8\):

- loss of heterozygosity on chromosomes 10 & 17
- alteration in tumor suppressor genes at 9p, 13q, 19q & 22q
- changes in epidermal growth factor receptor (EGFR) and platelet-derived growth factor (PDGF)
- transformation of the p53 suppressor gene
- isocitrate dehydrogenase (IDH) mutations (p.616) – genetic aberrations that lead to epigenetic machinery dysfunction

| Table 36.5 Dedifferentiation rate for low grade astrocytomas |
|---------------------------------|---------------------------------|
| Patients diagnosed @ age <45 yrs | Patients diagnosed @ age ≥45 yrs |
| mean time to de-differentiation | 44.2 ± 17 mos | 7.5 ± 5.7 mos |
| time to death | 58 mos | 14 mos |
Malignant astrocytomas (WHO III and IV) comments

This category encompasses anaplastic astrocytoma (AA) and glioblastoma (GBM). Although both are "malignant", AA and GBM have distinct differences. Among 1265 patients with malignant astrocytomas, the mean age was 46 yrs for AA and 56 yrs for GBM. Mean duration of symptoms pre-op: 5.4 mos for GBM, and 15.7 mos for AA. Malignant astrocytomas may develop from low grade astrocytomas via dedifferentiation (see above), however they may also arise de novo.

Infratentorial glioblastoma (GBM) is rare, and often represents subarachnoid dissemination of a supratentorial GBM (used as an argument for irradiation in all patients with p-fossa GBM).

Glioblastoma (multiforme) (WHO IV) comments

The most common primary brain tumor, it is also the most malignant astrocytoma. Current nomenclature omits "multiforme".

Histological findings associated with GBM (not all may be present, and this list does not follow any of the standard grading systems above):
- gemistocytic astrocytes
- neovascularization with endothelial proliferation
- areas of necrosis
- pseudopalisading around areas of necrosis

36.3 Molecular genetics and epigenetics

36.3.1 Molecular pathways in the development of glioblastomas

Genome-wide profiling studies have shown remarkable genomic diversities among glioblastomas. Molecular studies have helped identify at least 3 different pathways in the development of glioblastomas.

- 1st pathway: dysregulation of growth factor signaling through amplification and mutational activation of receptor tyrosine kinase (RTK) genes. RTKs are a diverse group of transmembrane proteins that act as receptors for growth factors like epithelial growth factor (EGF), vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF). They can also act as receptors for cytokines, hormones and other signaling pathways.
- 2nd pathway: the activation of the phosphatidylinositol-3-OH kinase (PI3K)/AKT/mTOR, which is an intracellular signaling pathway. It is essential in regulating cell survival.
- 3rd pathway: the inactivation of the p53 and retinoblastoma (Rb) tumor suppressor pathways.

36.3.2 Transcriptional silencing

O6-Methylguanine-DNA methyltransferase (MGMT) Methylation: MGMT is an independent prognosticator for response of malignant gliomas to chemotherapy with alkylating chemotherapeutic agents (e.g. nitrosourea or temozolomide) which damage tumor DNA by attaching an alkyl group to the guanine base. The MGMT gene is located on chromosome 10q26 and codes for a DNA repair enzyme that specifically removes the mutagenic alkyl O6 methylguanine and restores guanine residues to their native state. The loss of MGMT expression is likely to be caused by transcriptional silencing through hypermethylation of the CpG islands on the genome and this hypermethylation phenomenon is frequently (45% to 75%) present in glioblastomas.

In short: Loss of MGMT expression makes alkylating agent (e.g. Temozolodar) more effective.

36.3.3 IDH 1/2 mutation

IDH1 Arg132 mutations and IDH2 Arg140 and Arg172 mutations accounting for >90% of aberrations. IDH1 and IDH2 mutations reduce the enzymatic capacity of these proteins to bind isocitrate, their substrate, and convert it into α-ketoglutarate (α-KG), generating carbon dioxide and replenishing NADH and NADPH as side products. This is one of the irreversible steps in the tricarboxylic acid cycle important for cellular respiration. Mutant IDH1 (cytoplasmic) and IDH2 (mitochondrial) enzymes also show a modified enzymatic capacity to convert α-KG into 2-hydroxyglutarate (2-HG), a small onco-metabolite. Equally important, IDH1 and IDH2 mutations stratify individuals into molecular subtypes with distinct clinical outcomes – the mutations are associated with lower-grade astrocytomas, oligodendrogliomas (grade II/III) and secondary gliomas with better overall survival, progression-free survival and chemosensitivity than glioblastomas that are wild type for both genes.
36.3.4 Primary vs. secondary glioblastoma

Primary vs. secondary glioblastoma: First described in 1940 by German pathologist Scherer. 

- **primary glioblastoma**: the majority of GBMs. Arise without evidence (clinical or histological) of a less malignant precursor. More common in older patients (mean age = 55 years) after a short (<3 month) clinical history. Characterized by EGFR amplification (~40% of cases) and/or overexpression (60%), PTEN mutations (30%), p16INK4a deletion (30–40%), MDM2 amplification (<10%), and/or overexpression (50%), and in 50–80% of cases, loss of heterozygosity (LOH) on the entire chromosome 10.

- **secondary glioblastoma**: develop by malignant degeneration of WHO grade II or III astrocytoma. Patients are younger (mean age = 40 years) and have a slower clinical course. Secondary glioblastomas are less frequent than primary glioblastomas. 60% have TP53 mutations (present in >90% of the less malignant precursors). Malignant degeneration is characterized by allelic loss of chromosomes 19q and 10q. MGMT promoter methylation appears to occur with a higher frequency in secondary than in primary glioblastoma.

36.3.5 Subclassification of GBM

With the widespread use of molecular technology over the past two decades, considerable achievements have been made to identify the heterogeneity of glioblastoma, even though it is still under a single disease entity. Based on molecular genetic data from The Cancer Genome Atlas (TCGA) Research Network, Verhaak et al used gene expression analysis to further sub-classify GBM into 4 subtypes: I. Classical, II. Mesenchymal, III. Proneural, and IV. Neural.

36.4 Miscellaneous pathological features

- **Glial fibrillary acidic protein (GFAP)**. Most astrocytomas stain positive for GFAP (astrocytomas that may not stain GFAP positive: some poorly differentiated gliomas, purely gemistocytic astrocytomas since fibrillary astrocytes are required to stain positive).

- **Cysts**. Gliomas may have cystic central necrosis, but may also have an associated cyst even without necrosis. When fluid from these cysts is aspirated it can be differentiated from CSF by the fact that it is usually xanthochromic and often clots once removed from the body (unlike e.g. fluid from a chronic subdural). Although they may occur with malignant gliomas, cysts are more commonly associated with pilocytic astrocytomas (p.630).

- **MIB-1 index**. It has been suggested that a MIB-1 index ≥7–9% is indicative of an anaplastic tumor, while MIB-1 <5% favors a low-grade tumor. However, variability between observers and institutions precludes using the MIB-1 index as a sole discriminant between grade II & III astrocytomas.

36.5 Neuroradiological grading and findings

Astrocytomas typically arise in white matter (e.g. centrum semiovale) and traverse through white matter tracts (see below). See also MR-spectroscopy findings (p.233).

CT scan & MRI grading. Grading gliomas by CT or MRI is imprecise, but may be used as a preliminary assessment (see Table 36.6). Neuroradiologic grading is not applicable to pediatric patients or special astrocytomas (e.g. pilocytic astrocytomas).

<table>
<thead>
<tr>

</tr>
<tr>
<td>III</td>
<td>complex enhancement*</td>
</tr>
<tr>
<td>IV</td>
<td>necrosis (ring enhancement)</td>
</tr>
</tbody>
</table>

*however, some may not enhance
Low-grade gliomas. Usually hypodense on CT. Most are hypointense on T1WI MRI, and show high intensity changes on T2WI that extend beyond the tumor volume. Most do not enhance on CT or MRI (although up to 40% do, and these may have a worse prognosis). The UCSF preoperative grading system for low-grade infiltrating gliomas assigns 1 point for the presence of each of 4 parameters shown in Table 36.7. The points are summed and the prognosis is shown in Table 36.8 (this scale needs to be validated at other institutions). Another study found poor prognosis associated with: age ≥ 40 years, tumor ≥ 6 cm dia, tumor crossing midline and the presence of neurologic deficit.

Malignant gliomas. Anaplastic astrocytomas (AA) may not enhance (31% of highly anaplastic and 59% of moderately anaplastic astrocytomas do not enhance on CT; MRI not studied). Calcifications and cysts occur in 10–20% of AA. Most glioblastomas enhance, but some rare ones do not.

Ring-enhancement with glioblastoma (GBM). The nonenhancing center may represent necrosis or associated cyst (see above). The enhancing ring is cellular tumor, however, tumor cells also extend ≥ 15 mm beyond the ring.

Positron emission tomography (PET) scan. Low grade fibrillary astrocytomas appear as hypometabolic “cold” spots with fluorodeoxyglucose PET scans. Hypermetabolic “hot” spots suggest high-grade astrocytomas and help distinguish high grade glioma that do not enhance on MRI from lower grade (II) astrocytomas.

Angiographic appearance. AAs usually appear as an avascular mass. Tumor blush and AV-shunting with early draining veins are more characteristic of GBM.

### 36.6 Spread
Gliomas may spread by the following mechanisms (note: <10% of recurrent gliomas recur away from the original site):

1. tracking through white matter
   a) corpus callosum (CC)
      • through genu or body of CC → bilateral frontal lobe involvement (“butterfly glioma”)
      • through splenium of CC → bilateral parietal or occipital lobes
   b) cerebral peduncles → midbrain involvement
   c) internal capsule → encroachment of basal ganglion tumors into centrum semiovale
   d) uncinate fasciculus → simultaneous frontal and temporal lobe tumors
   e) interthalamic adhesion → bilateral thalamic gliomas

2. CSF pathways (subarachnoid seeding): 10–25% frequency of meningeal and ventricular seeding by high grade gliomas\textsuperscript{47}
3. rarely, gliomas may spread systemically

### 36.7 Multiple gliomas

Discussion of multiple gliomatous masses has to acknowledge the concept that astrocytoma is a multifocal disease, not a focal one. Some terms are probably artificial, e.g. since gliomatosis cerebri probably represents a diffuse infiltrating glial tumor with areas that may dedifferentiate into higher grade and then is called multincentric glioma.

Settings in which multiple gliomatous masses are encountered:
1. conventional glioma that has spread by one of the mechanisms previously described (see above)
2. gliomatosis cerebri: a diffuse, infiltrating astrocytoma that invades almost all of the cerebral hemispheres and brainstem. Usually low-grade,\textsuperscript{39} areas of anaplasia and glioblastoma may also occur\textsuperscript{48} and may present as focal mass.\textsuperscript{49} Occurs most frequently in 1st 2 decades
3. multiple primary gliomas: some of the following terms are inconsistently used interchangeably: “multincentric”, “multifocal”, and “multiple.” Reported range of occurrence is 2–20% of gliomas\textsuperscript{50, 51} (lower end of range ≈ 2–4% is probably more accurate, the higher end of the range is probably accounted for by infiltrative extension\textsuperscript{52}(p 3117))
   a) commonly associated with neurofibromatosis and tuberous sclerosis
   b) rarely associated with multiple sclerosis and progressive multifocal leukoencephalopathy
4. meningeal gliomatosis: dissemination of glioma throughout the CSF, similar to carcinomatous meningitis (p.811). Occurs in up to 20% of autopsies on patients with high-grade gliomas. May present with cranial neuropathies, radiculopathies, myelopathy, dementia, and/or communicating hydrocephalus

In a series of 25 patients with multincentric glioma,\textsuperscript{53} glioblastoma was the most common pathology (48%), followed by anaplastic astrocytoma (20%), and glioblastoma with simultaneous AA (20%).

Treatment considerations for multiple gliomas. There is little data available. In a nonrandomized study of 25 patients with multifocal glioma,\textsuperscript{53} the 16 patients who underwent debulking did better than the 9 who did not. However, there was significant selection bias in choosing patients suitable for craniotomy.

Biopsy is generally required/recommended to confirm the diagnosis.

\[\Sigma\]

Once the diagnosis of multiple gliomatous masses has been ascertained, local therapies (e.g. surgery, interstitial radiation...) are impractical. Whole brain radiation and possibly chemotherapy are indicated. An exception would be to consider debulking tumor to prevent herniation in a patient deteriorating from mass effect.

### 36.8 Treatment

#### 36.8.1 Low-grade astrocytomas (WHO grade II)

**Treatment options**
1. no treatment: follow serial neurologic exams and imaging studies, with intervention reserved for cases showing progression
2. radiation
3. chemotherapy
4. surgery
5. combinations of radiation and chemotherapy, with or without surgery

**Analysis**

No well-designed study has shown that any approach for supratentorial WHO grade II infiltrating astrocytomas in adults is clearly superior to any other. Some treatments may simply expose the...
patient to the risk of treatment side effects. The argument holds that these tumors are slow growing, and that until progression on imaging or malignant degeneration is documented, that it may be no worse to not treat the patient.\textsuperscript{\ref{54}} Although this view has been challenged,\textsuperscript{\ref{55}} a definitive study has yet to be performed. The following are associated with more aggressive tumors and should prompt consideration for some form of treatment:

1. extremely young patients, or patients $\geq 50$ yrs age; increasing age at diagnosis is associated with more rapid dedifferentiation (p.615)
2. large tumors that enhance (tumor size is one of the most important prognosticators\textsuperscript{\ref{56}})
3. symptomatic patients, especially those with short clinical history
4. evidence of progression on imaging studies
5. Astrocytic/Astrocytic-dominant mixed glioma histology
6. Biopsy only without resection

**Surgery for low grade gliomas**

4 objectives in performing surgery for low grade gliomas\textsuperscript{\ref{57}}:

1. To obtain histological confirmation/molecular genetic analysis
2. To improve neurological condition
3. To reduce risk of tumor growth
4. To prevent malignant transformation

Surgery is the principal treatment for low-grade glioma in most circumstances. Although there is no randomized control trial (RCT) comparing tumor resection to biopsy alone in low-grade glioma, current opinion advocates early resection. A recent Norway study showed a significant lower overall survival in a center favoring watchful waiting approach. More aggressive excision is associated with better outcome\textsuperscript{\ref{58,59,60}} and later malignant transformation to anaplastic types.\textsuperscript{\ref{59}} Even in recurrent low-grade glioma, surgical resection is associated with a survival benefit.

**Intraoperative Mapping and Awake Craniotomy**

Complete resection is often not possible due to the infiltrative nature of low-grade gliomas and its frequent location near or at eloquent areas. Resection can be safely maximized by means of intraoperative mapping and awake-surgeries.\textsuperscript{\ref{61}} A meta-analysis of 8091 patients showed the use of intraoperative stimulation brain mapping achieved more gross total removal with less late severe neurological deficits, and is recommended as a standard for glioma surgery especially if eloquent areas are involved.\textsuperscript{\ref{62}} Multicentric gliomas, previously considered not resectable can also be resected with aid of awake intraoperative map-ping.\textsuperscript{\ref{63}} Despite this advances, the role of surgery remains limited for gliomatosis cerebri or very deep-seated lesions.

Surgery is the principal treatment in the following situations of low-grade astrocytomas:

1. surgical biopsy or partial resection is recommended in almost all cases to establish the diagnosis since clinical and radiographic data are not definitive\textsuperscript{\ref{14}}
2. pilocytic astrocytomas
   a) cerebellar tumors occurring in children & young adults (p.630)
   b) supratentorial pilocytic astrocytomas
3. when herniation threatens from large tumors or tumor cysts
4. tumors causing obstruction of CSF flow
5. may help in seizure control with refractory seizures
6. in an attempt to delay adjuvant therapy and its side-effects in children (especially XRT in those $< 5$ yrs old)\textsuperscript{\ref{14}}
7. for prevention of malignant transformation

The role of surgery is limited in the following situations of low-grade astrocytomas:

1. disseminated (poorly circumscribed) tumors
2. multifocal tumors
3. location in eloquent brain

**Adjuvant therapy for low-grade gliomas**

Radiation therapy (XRT). Early radiotherapy (54 Gy in fractions of 1.8 Gy) is recommended as adjuvant therapy and is shown to prolong median progression free survival from 3.4 to 5.3 years but does not affect overall survival.\textsuperscript{\ref{64}} In patients with the tumor radically resected, early RT did not prolong PFS and is recommended to be deferred until progression. Following incomplete resection, early RT significantly prolongs PFS and disease specific survival.\textsuperscript{\ref{65}} Two prospective trials found no
difference in OS or PFS between different XRT doses (EORTC trial\textsuperscript{56}; 45 Gy in 5 weeks vs. 59.4 Gy in 6.6 weeks; Intergroup study\textsuperscript{56} 50.4 vs. 64.8 Gy). Side effects from WBXRT include: leukoencephalopathy and cognitive impairment; see Radiation injury and necrosis (p.1560). The frequency of side effects may\textsuperscript{66} or may not\textsuperscript{67} be higher at higher XRT doses.

Chemotherapy. Usually reserved for tumor progression. Temozolomide (Temodar\textsuperscript{®}) may be effective in progressive WHO grade II astrocytomas (off label use).\textsuperscript{68} Effectiveness of PCV (procarbazine, CCNU, and vincristine) was assessed by RTOG 9802. It showed no significant difference in 5-yr OS rates (RT+PCV versus RT: 72\% versus 63\% but on post hoc analysis of survival for patients surviving to 2 years, RT+PCV group had higher 5-yr OS than RT alone.\textsuperscript{59}

\textbf{36.8.2 Malignant astrocytomas (WHO grades III and IV)}

\textbf{Surgery for newly diagnosed high-grade gliomas}

The aim of surgery in high-grade gliomas is cytoreduction, to relieve mass effect, and to obtain adequate tissue for histological and molecular study. Cytoreductive surgery followed by external beam radiation and concurrent temozolomide has become the standard against which other treatments are compared.\textsuperscript{70}

\textbf{Extent of resection.} The extent of tumor removal and (in an inverse relationship) the volume of residual tumor on post-op imaging studies\textsuperscript{71} have a significant effect on time to tumor progression and median survival.\textsuperscript{72} It was demonstrated that excision for 97 percent or more was associated with increased survival time.\textsuperscript{73} Whenever feasible, gross total resection of tumor with preservation of eloquent and critical structures should be the goal. Recent advances in tumor localization, intraoperative monitoring and mapping have allowed more effective and safer resection.

5-aminolevulinic-acid (5-ALA) guided resection. In addition to techniques of stereotactic localization using preoperative imaging as well as intraoperative brain mapping, techniques to enhance visual identification of tumor intraoperatively may be used and include 5-aminolevulinic-acid (5-ALA). 5-ALA is metabolized into fluorescent porphyrins, which accumulate in malignant glioma cells. This property permits use of ultraviolet illumination during surgery as an adjunct to map out the tumor. This has been proven with RCT where use of 5-ALA leads to more complete resection (65\% vs 36\% p<0.0001), which translates into a higher 6-month progression free survival (41\% vs 21.1\% p=0.0003) but no effect on OS.\textsuperscript{74}

Partial resection of a GBM carries significant risk of post-operative hemorrhage and/or edema (wounded glioma syndrome) with risk of herniation. Furthermore, the benefit of subtotal resection is dubious. Retrospective evidence suggested survival benefits in gross total resection but not with incomplete resection.\textsuperscript{75} Therefore, surgical excision should only be considered when the goal of gross total removal is feasible.

As a result of the above, the following are usually not candidates for surgical debulking
1. extensive dominant lobe GBM
2. lesions with significant bilateral involvement (e.g. large butterfly gliomas)
3. elderly patients
4. Karnofsky score <70 (in general, with infiltrating tumors, the neurologic condition on steroids is as good as it is going to get, and surgery rarely improves this)
5. multicentric gliomas

\textbf{Stereotactic biopsy.} Due to sampling error, stereotactic biopsy may underestimate the occurrence of GBM by as much as 25\% Indications for stereotactic biopsy (instead of initial resection) in suspected malignant astrocytomas\textsuperscript{76}:
1. tumors located in eloquent or inaccessible areas of brain
2. patients in poor medical condition precluding general anesthesia
3. to ascertain a diagnosis when one is not definitely established (including when considering a more definitive operation). Some CNS lymphomas mimic GBM radiographically (and without immunostaining, some have also been mistaken pathologically) biopsy should be given serious consideration (to avoid operating on a lymphoma which may be best treated with XRT & intra-thecal chemotherapy)

\textbf{Technique:} Yield of biopsy is highest when targets within the low density (necrotic) center and enhancing rim are chosen.\textsuperscript{44}
Patients with left-sided tumors and dysphasia are at significant risk of worsening of language function following stereotactic biopsy (the risk of deterioration is low if there is no dysphasia before biopsy).  

**Adjuvant therapy after cytoreductive surgery for newly diagnosed GBM (Stupp regimen)**

Temozolomide is an oral alkylating agent that is given as a prodrug which undergoes rapid non-enzymatic conversion at physiologic pH to the active metabolite monomethyl triazenoimidazole carboxamide (MTIC). The cytotoxic effect of MTIC is associated with alkylation (methylation) of DNA at various sites including the O6 and N7 positions on guanine.

Cytoreductive surgery followed by the Stupp regimen has become the standard for newly diagnosed GBM.  

Stupp regimen included concomitant chemoradiotherapy and adjuvant chemotherapy. Chemoradiotherapy started within six weeks after histological diagnosis of GBM. Radiotherapy in the Stupp regimen consists of fractionated focal irradiation at a dose of 2 Gy per fraction once daily five days per week over a period of six weeks, for a total dose of 60 Gy, with a 2-3 cm margin of clinical target volume. The is is compared to the usual XRT regime for malignant gliomas of 50-60 Gy (usually 50 Gy to a margin 2-3 cm greater than the enhanced volume on MRI with a boost to the enhancing volume to bring the total to 60 Gy). Concomitant chemotherapy consists of temozolomide 75 mg/m²/day, 7 days per week till the end of radiotherapy. Four weeks later, six cycles of adjuvant chemotherapy starts. Each cycle consists of 5-days of temozolomide repeated every 28 days. The dose was 150 mg/m²/day for first cycle and stepped up to 200 mg/m²/day. The median survival was 14.6 months with the Stupp regimen compared to 12.1 months with radiotherapy alone with median survival benefit of 2.1 months. The five-year survival rate was 9.8% for the Stupp regimen in contrast to 1.9%  

Regard less of extent of resection and MGMT status, patients received the Stupp regimen had longer median survival. Patients with MGMT promoter region methylation had median survival time of 23.4 months compared to 12.6 months in the non-methylated group. In the MGMT unmethylated group, the Stupp regimen only improved median survival from 11.8 months to 12.6 months. Some groups do extend the adjuvant chemotherapy after the standard six-month regimen until tumor progression is observed, in one study this extended the median survival time from 16.5 months to 24.6 months.

**Side effects:** Temozolomide may cause myelosuppression. It should not be given unless the neutrophil count ≥ 1.5 x 10⁹/L and platelet count ≥ 100 x 10⁹/L. For all patients with newly diagnosed GBM for concomitant temozolomide and radiotherapy, prophylaxis against Pneumocystis carinii pneumonia is required for the 42-day regimen.

Other treatment protocols for GBM. Gliadel® wafer carmustine (BCNU) 7.7 mg in a 200 mg prosthetic polymer carrier (wafer) that can be applied to resection cavity after tumor excision. The wafers are degraded by hydrolysis and the drug is released over 2-3 wks. This exposes the tumor to 113 times the concentration of BCNU compared to IV administration. Following tumor removal, up to 8 of the 1.4 cm × 1 mm (dime-sized) wafers are applied to the tumor resection bed at the time of surgery.

It increases median survival to 13.8 months compared with 11.6 months in placebo groups for newly diagnosed GBM. It showed no survival benefit for recurrent disease. Side effects: seizures, cerebral edema, healing abnormalities, intracranial infection.

Some other regimens that have not proven to be successful for GBM:

- AVAglio: a phase III trial with addition of bevacizumab to the Stupp regimen for newly diagnosed GBM and RTOG 0825 (another trial of similar design) showed improved PFS, but no significant improvement on OS.  
- CENTRIC: a phase III trial studied another antiangiogenic (cilengitide, an integrin inhibitor) to the standard temozolomide and radiation therapy. There was no improvement in either PFS or OS.  
- RTOG 93-05: stereotactic radiosurgery followed by conventional chemoradiation did not improve the median survival of GBM patient compared to those without stereotactic radiotherapy.  
- Brachytherapy has shown no significant benefit as an adjunct to EBRT in the initial treatment of malignant astrocytomas.  
- Whole brain XRT has not been shown to increase survival compared to focal XRT, and the risk of side effects is greater.  
- Combination chemotherapy of procarbazine, lomustine and vincristine (PCV) was used before the proven benefit of the Stupp regimen. But randomized trial did not show any benefit.  
- RTOG 0525: a phase 3 trial of dose-dense temozolomide at 100 mg/m² day 1-21 of a 28-day cycle showed no significant benefit over standard dosing for median OS or median PFS.
Treatment protocols for anaplastic astrocytoma (WHO Grade III)

For newly diagnosed anaplastic astrocytoma, surgery followed by radiotherapy was the standard treatment with median OS 5.7 yrs. In a retrospective review, radiotherapy followed by chemoradiation, concurrent chemoradiation using temozolomide did not achieve better median OS nor PFS compared with radiotherapy alone.\(^{50}\) On the other hand, temozolomide was approved by FDA in 1999 for anaplastic astrocytoma refractory to both a nitrosourea and procarbazine. The median duration of all response was 50 weeks, median PFS was 4.4 months and median OS was 15.9 months.\(^{91,92}\)

36.8.3 Pseudoprogression

Since temozolomide has become the new standard of care in the treatment of GBM, there has been an increasing awareness of progressive contrast-enhancing areas on MRI that mimics tumor progression, typically seen \(\leq 3\) months after treatment. This phenomenon of pseudoprogression occurs in up to 28-60% of patients after XRT + temozolomide treatment. Histologically it resembles radiation necrosis and is believed to be associated with tumor kill by radiation. Increased tumor kill with chemotherapy results in more pseudoprogression. 91% in methylated MGMT patients vs. 41% in the unmethylated group.\(^{93}\)

Management: The MRI findings usually improve without treatment,\(^{24}\) and steroids may help control symptoms.

Diagnosis: There is no definitive diagnostic test. MR perfusion has been tried to distinguish pseudoprogression from true progression but is not reliable. DWI with higher apparent diffusion coefficient (ADC), MR spectroscopy, and PET have also not achieved high sensitivity and specificity. Monitoring with serial MRIs and clinical exams seems to be an effective strategy.

36.8.4 Treatment for recurrent GBM

Less than 10% of recurrent gliomas recur away from the original tumor site.\(^{46}\)  
1. Surgery: reoperation extends survival by an additional 36 weeks in patients with GBM, and 88 weeks in AA.\(^{95,96}\) (duration of high quality survival was 10 weeks and 83 weeks respectively, and was lower with pre-op Karnofsky score <70). In addition to Karnofsky score, significant prognosticators for response to repeat surgery include: age and time from the first operation to reoperation (shorter times \(\rightarrow\) worse prognosis).\(^{97}\) Morbidity is higher with reoperation (5-18%); the infection rate is \(\approx 3\) x that for first operation, wound dehiscence is more likely.

2. Chemotherapy  
   a) temozolomide:  
      • in a 2013 Cochrane review,\(^{98}\) chemotherapy with temozolomide was not associated with extension of PFS nor OS

\(^a\)\(\geq 50\%\) corticosteroid dose reduction, relative to baseline
The RESCUE study looked at continuous dose-intense temozolomide at 50 mg/m$^2$/day showed one year survival ranged 14.8–28.6% depended on the timing of progression and the start of dose-intense treatment.

Bevacizumab (Avastin®) – a monoclonal antibody against VEGF. FDA approved in May, 2009 for progressive GBM following prior treatment based on two trials: the BRAIN study, AVF3708g and NCI 06-C-0064E. Given as 10 mg/kg every 2 weeks until disease progression. The reported 6-month PFS rate was 36.0%. The median response durations were 3.9 months and 4.2 months from the two trials. The median OS was 9.3 months. Side effects: gastrointestinal perforations, wound healing complications, hemorrhage, fistula formation, arterial thromboembolic events, hypertension.

Summary: For recurrent GBM, surgery is still the mainstay of treatment; in general, surgery is recommended only for patients with KPS ≥70.

### 36.9 Outcome

Survival with various grades of astrocytoma

In general, with “optimal treatment” the survival of the various grades of astrocytoma are approximately given in Table 36.10 (more details may be found in other sections – see also Table 36.13 and below for recursive partitioning analysis (RPA) for GBM).

**Low-grade astrocytomas (WHO grade II)**

- For low grade infiltrating gliomas, see prognosis based on pre-op grading (Table 36.7).
- Malignant astrocytomas (WHO grades III & IV)
  - Prognostic indicators:
    1. patient age: consistently found to be the most significant prognosticator, with younger patients faring better.
    2. histological features
    3. performance status, e.g. Karnofsky score (KPS) at presentation (p.1358)
    4. Mental Status changes and symptoms <3 months portends a worse prognosis
    5. MGMT Methylation status

**MGMT Promotor Methylation Survival Outcome (Table 36.11)**

Analysis of 206 patients for MGMT methylation: Median overall survival for MGMT methylation positive patients treated with temozolomide and RT was 21.7 month, RT only 15.3 months; no survival difference between treatments in patients with unmethylated MGMT.

- Stupp Regime vs. radiotherapy alone, survival outcome $^{70,78}$
- EORTC–NCIC Trial, 573 patients, 5-year Follow-up (Table 36.12)

Recursive partitioning analysis (RPA) with glioblastoma (Table 36.13)$^{105}$: RPA classification developed to compare survival categories and determine homogenous patient subsets. Useful for refining stratification and phase III study design. Can determine which patient subsets will benefit from specific treatments (and which may be spared unnecessary treatment).

37 Other Astrocytic Tumors

37.1 Pilocytic astrocytomas

37.1.1 General information

Key concepts

- a subgroup of astrocytomas with better prognosis (10-year survival: 94%) than infiltrating fibrillary or diffuse astrocytomas
- age ≤ 20 yrs in 75% which is lower than for typical astrocytomas
- common locations: cerebellar hemisphere, optic nerve/chiasm, hypothalamus
- radiographic appearance: discrete appearing, contrast enhancing lesion, often cystic with mural nodule
- pathology: compacted and loose textured astrocytes with Rosenthal fibers and/or eosinophilic granular bodies
- danger of overgrading and overtreating if not recognized. Histology alone may be inadequate for diagnosis; knowledge of radiographic appearance is critical

Background and terminology

Pilocytic astrocytoma (PCA) is the currently recommended nomenclature for these tumors that have been previously referred to variously as cystic cerebellar astrocytomas, juvenile pilocytic astrocytomas, optic gliomas, and hypothalamic gliomas. However, since treatment decisions vary based on location and neural involvement, it is still helpful to discuss differences in management of these subtypes.

PCAs differ markedly from infiltrating fibrillary astrocytomas in terms of their ability to invade tissue and for malignant degeneration.

37.1.2 Location

PCAs arise throughout the neuraxis and are more common in children and young adults:

1. optic gliomas & hypothalamic gliomas:
   a) PCAs arising in the optic nerve are called optic gliomas (p.631)
   b) when they occur in the region of the chiasm they cannot always be distinguished clinically or radiographically from so-called hypothalamic gliomas (p.632) or gliomas of the third ventricular region

2. cerebral hemispheres: tends to occur in older patients (i.e. young adults) than optic nerve/hypothalamic lesions. These PCAs are potentially confused with fibrillary astrocytomas possessing more malignant potential. PCAs are often distinguished by a cystic component with an enhancing mural nodule (would be atypical for a fibrillary astrocytoma), & some PCAs have dense calcifications

3. brainstem gliomas (p.633): usually are fibrillary infiltrating type and only a small proportion are pilocytic. Those that are PCAs may comprise the majority of the prognostically favorable group described as “dorsally exophytic”

4. cerebellum: formerly referred to as cystic cerebellar astrocytoma (p.630)

5. spinal cord: PCAs may also occur here, but little information is available on these. Again, patients tend to be younger than with spinal cord fibrillary astrocytomas

37.1.3 Pathology

PCAs are composed of loosely knit tissue comprised of stellate astrocytes in microcystic regions containing eosinophilic granular bodies intermixed with regions of compact tissue consisting of elongated and fibrillated cells often associated with Rosenthal fiber formation (Rosenthal fibers: sausage or corkscrew shaped cytoplasmic eosinophilic inclusion bodies consisting of glial filament aggregates resembling hyaline; stain bright red on Masson trichrome smears).

These latter two distinctive features facilitate the diagnosis. Another characteristic finding is that the tumors easily break through the pia to fill the overlying subarachnoid space. PCAs may also
infiltrate into the perivascular spaces. Vascular proliferation is common. Multinucleated giant cells with peripherally located nuclei are common, especially in PCAs of the cerebellum or cerebrum. Mitotic figures may be seen, but are not as ominous as with fibrillary astrocytomas. Areas of necrosis may also be seen. In spite of well-demarcated margins grossly and on MRI, at least 64% of PCAs infiltrate the surrounding parenchyma, especially the white matter (the clinical significance of this is uncertain, one study found no statistically significant decrease in survival).

Differentiating from a diffuse or infiltrating fibrillary astrocytoma: Unless some of the distinctive findings described above are seen, pathology alone may not be able to differentiate. This may be especially problematic with small specimens obtained e.g. with stereotactic biopsy. Factors that suggest the diagnosis include young age, and knowledge of the radiographic appearance is often critical (see below).

Malignant degeneration: Malignant degeneration has been reported, often after many years. This may occur without radiation therapy (XRT), although in most cases XRT had been administered.

37.1.4 Radiographic appearance

On CT or MRI, PCAs are usually well circumscribed, 94% enhance with contrast (unlike most low-grade fibrillary astrocytomas), frequently have a cystic component with a mural nodule, and have little or no surrounding edema. Although they may occur anywhere in the CNS, 82% are periventricular. Calcifications are only occasionally present. 4 main imaging patterns of cerebellar or cerebral PCAs are shown in Table 37.1.

37.1.5 Epidemiology

Usually presents during second decade of life (ages 10–20). 75% occur in age <20 years. No evidence of gender predilection.

37.1.6 Pilocytic astrocytoma of the cerebellum

General information

Key concepts

- often cystic, half of these have mural nodule
- usually presents during the second decade of life (ages 10–20 yrs)
- also, see Key concepts for pilocytic astrocytomas in general (p.629)

Formerly referred to by the nonspecific and confusing term cystic cerebellar astrocytoma. One of the more common pediatric brain tumors (≈ 10%), comprising 27–40% of pediatric p-fossa tumors. They may also occur in adults, where the mean age is lower and the post-operative survival is longer than for fibrillary astrocytomas.

Presentation

Signs and symptoms of pilocytic astrocytoma (PCA) of the cerebellum are usually those of any p-fossa mass, i.e. those of hydrocephalus or cerebellar dysfunction; see Posterior fossa (infratentorial) tumors (p.592).

Pathology
The classic “juvenile pilocytic astrocytoma” of the cerebellum is a distinctive entity with its macroscopic cystic architecture and microscopic spongy appearance.1 For other microscopic findings, see above.

These tumors may be solid, but are more often cystic (hence the older term “cystic cerebellar astrocytoma”), and tend to be large at the time of diagnosis (cystic tumors: 4–5.6 cm dia; solid tumors: 2–4.8 cm dia). Cysts contain highly proteinaceous fluid (averaging ≈ 4 Hounsfield units higher density than CSF on CT).

50% of cystic tumors have a mural nodule and a cyst lining of reactive, non-neoplastic cerebellar tissue or ependymal lining (non-enhancing on CT), whereas the remaining 50% lack a nodule and have a cyst wall of poorly cellular tumor12 (enhances on CT).

Histological classification of Winston
The Winston classification system13 is shown in Table 37.2. 72% of cerebellar PCAs tended to cluster with either Type A or B characteristics, 18% in his series had both, and 10% had neither.

Treatment guidelines
The natural history of these tumors is slow growth. Treatment of choice is surgical excision of the maximal amount of the tumor that can be removed without producing deficit. In some, invasion of brainstem or involvement of cranial nerves or blood vessels may limit resection. In tumors composed of a nodule with a true cyst, excision of the nodule is sufficient; the cyst wall is non-neoplastic and need not be removed. In tumors with a so-called “false cyst” where the cyst wall is thick and enhances (on CT or MRI), this portion must be removed also. Because of the high 5 and 10 year survival rates together with the high complication rate of radiation therapy over this time interval – see Radiation injury and necrosis (p.1560) -, and the fact that many incompletely resected tumors enlarge minimally if at all over periods of 5, 10 or even 20 years, it is recommended to not radiate these patients post-op. Rather, they should be followed with serial CT or MRI and be re-operated if there is recurrence.14 Radiation therapy is indicated for non-resectable recurrence (i.e. reoperation is preferred if possible) or for recurrence with malignant histology. Chemotherapy is preferable to XRT in younger patients.15

Also, see Posterior fossa (infratentorial) tumors (p.592) for guidelines regarding hydrocephalus, etc.

Prognosis
Children with Winston Type A cerebellar PCAs had 94% 10-yr survival, whereas those with Type B had only 29% 10-yr survival.

Tumor recurrence is relatively common, and although it has been said that they generally occur within ≈ 3 yrs of surgery,16 this is controversial and very late recurrences (violating Collins’ law, which says that a tumor may be considered cured if it does not recur within a time period equal to the patient’s age at diagnosis + 9 months) are well known.14 Also, some tumors excised partially fail to show further growth, representing a form of cure.

About 20% of cases develop hydrocephalus requiring treatment following surgery.17 So-called “drop metastases” are rare with PCAs.

37.1.7 Optic glioma
General information
Accounts for ≈ 2% of gliomas in adults, and 7% in children. The incidence is higher (≈ 25%) in neurofibromatosis (NFT) (p.603).

Table 37.2 Classification of cerebellar astrocytoma

<table>
<thead>
<tr>
<th>Classification of cerebellar astrocytoma</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Type A: microcysts, leptomeningeal deposits, Rosenthal fibers, foci of oligodendroglioma</td>
</tr>
<tr>
<td>• Type B: perivascular pseudorosettes, high cell density, mitosis, calcification</td>
</tr>
<tr>
<td>• common features of types A &amp; B: hypervascularity, endothelial proliferation, parenchymal desmoplasia, pleomorphism</td>
</tr>
</tbody>
</table>
May arise in any of the following patterns:
1. one optic nerve (without chiasmal involvement)
2. optic chiasm: less commonly involved in patients with NFT than in sporadic cases
3. multicentric in both optic nerves sparing the chiasm: almost only seen in NFT
4. may occur in conjunction with or be part of a hypothalamic glioma (see below)

Pathology
Most are composed of low-grade (pilocytic) astrocytes. Rarely, a malignant chiasmal glioma occurs.

Presentation
Painless proptosis is an early sign in lesions involving one optic nerve. Chiasmal lesions produce variable and nonspecific visual defects (usually monocular) without proptosis. Large chiasmal tumors may cause hypothalamic and pituitary dysfunction, and may produce hydrocephalus by obstruction at the foramen of Monro. Gliosis of the optic nerve head may be seen on fundoscopy.

Evaluation
Plain x-rays: not usually helpful, although in some cases dilatation of the optic canal can be seen in optic canal views.
CT/MRI: CT scan is excellent for imaging structures within the orbit. MRI is helpful for demonstrating chiasmal or hypothalamic involvement. On CT or MRI, involvement of the optic nerve produces contrast enhancing fusiform enlargement of the nerve usually extending > 1 cm in length.

Treatment
Tumor involving a single optic nerve, sparing the chiasm, producing proptosis and visual loss should be treated with a transcranial approach with excision of the nerve from the globe all the way back to the chiasm (a transorbital (Kronlein) approach is not appropriate since tumor may be left in the nerve stump). In addition to the anticipated blindness in the involved eye, this may produce a junctional scotoma (p.730).
Chiasmal tumors are generally not treated surgically except for biopsy (especially when it is difficult to distinguish an optic nerve glioma from a hypothalamic glioma), CSF shunting, or to remove the rare exophytic component to try and improve vision.
Further treatment: Chemotherapy\(^\text{15}\) (especially in younger patients) or XRT is used for chiasmal tumors, for multicentric tumors, post-op if tumor is found in the chiasmal stump end of the resected nerve, and for the rare malignant tumor. Typical XRT treatment planning is for 45 Gy given in 25 fractions of 1.8 Gy.

37.1.8 Hypothalamic glioma
Pilocytic astrocytomas of the hypothalamus and third ventricular region occur primarily in children. Radiographically, the lesion may have an intraventricular appearance. Many of these tumors have some chiasmal involvement and the distinction from optic nerve glioma cannot be made (see above).
May present with so-called “diencephalic syndrome”, a rare syndrome seen in peds, usually caused by an infiltrating glioma of the anterior hypothalamus. Classically: cachexia (loss of subcutaneous fat) associated with hyperactivity, over-alertness and an almost euphoric affect. May also see: hypoglycemia, failure to thrive, macrocephaly.
When complete resection is not possible, further treatment may be needed as outlined under optic gliomas (above).

37.1.9 Pilomyxoid astrocytoma (PMA)
WHO grade II. Related to pilocytic astrocytomas (PCA) but more aggressive with greater tendency to recur and spread in CSF.\(^\text{18}\) May be an infantile form of PCA with a case report of “maturation” to a typical PCA.\(^\text{19}\) Typical onset in infancy (10 months).
Histologically: dominant mucoid matrix, monomorphic bipolar cells, and angiocentric cell arrangement. By definition, does not contain Rosenthal fibers.
May also occur in spinal cord, with a case report of extraneural peritoneal mets spread through a VP shunt.\(^\text{20}\)
37.1.10 Brainstem glioma

General information

Key concepts

- not a homogeneous group. MRI can differentiate malignant from benign lesions
- trend: lower grade tumors tend to occur in the upper brainstem, and higher grade tumors in the lower brainstem/medulla
- usually presents with multiple cranial nerve palsies and long tract findings
- most are malignant, have poor prognosis, and are not surgical candidates
- role of surgery primarily limited to dorsally exophytic lesions and shunting

Brainstem gliomas (BSG) tend to occur during childhood and adolescence (77% are < 20 yrs old, they comprise 1% of adult tumors\(^2\)). BSG are one of the 3 most common brain tumors in pediatrics – see Pediatric brain tumors (p. 593) – comprising ≈ 10–20% of pediatric CNS tumors.\(^2\)

Presentation

See reference.\(^22\)

- Upper brainstem tumors tend to present with cerebellar findings and hydrocephalus, whereas lower brainstem tumors tend to present with multiple lower cranial nerve deficits and long tract findings. Due to their invasive nature, signs and symptoms usually do not occur until the tumor is fairly extensive in size.
- Signs and symptoms:
  1. gait disturbance
  2. headache (p. 590)
  3. nausea/vomiting
  4. cranial nerve deficits: diplopia, facial asymmetry
  5. distal motor weakness in 30%
  6. papilledema in 50%
  7. hydrocephalus in 60% usually due to aqueductal obstruction (often late, except with periaque ductal tumors, e.g. below)
  8. failure to thrive (especially in age ≤ 2 yrs)

Pathology

BSG is a heterogeneous group. There may be a tendency towards lower grade tumors in the upper brainstem (76% were low-grade) versus the lower brainstem (100% of the glioblastomas were in the medulla).\(^23\) A cystic component is seen rarely. Calcifications are also rare. 4 growth patterns that can be identified by MRI\(^24\) that may correlate with prognosis\(^25\):

1. diffuse: all are malignant (most are anaplastic astrocytomas, the rest are glioblastomas). On MRI these tumors extend into the adjacent region in vertical axis (e.g. medullary tumors extend into pons and/or cervical cord) with very little growth towards obex, remaining intraaxial
2. cervicomedullary: most (72%) are low-grade astrocytomas. The rostral extent of these tumors is limited to the spinomedullary junction. Most bulge into the obex of the 4th ventricle (some may have an actual exophytic component)
3. focal: extent limited to medulla (does not extend up into pons nor down into spinal cord). Most (66%) are low-grade astrocytomas
4. dorsally exophytic: may be an extension of “focal” tumors (see above). Many of these may actually be low grade gliomas including:
    a) pilocytic astrocytomas (p. 629)
    b) gangliogliomas (p. 651): very rare, only 13 cases reported as of 1984. Compared to other BSGs, these patients tend to be slightly older and the medulla is involved more frequently.\(^26\)

Evaluation

MRI

The diagnostic test of choice. MRI evaluates status of ventricles, gives optimal assessment of tumor (CT is poor in the posterior fossa) and detects exophytic component. TIWI: almost all are
CT
Most do not enhance on CT, except possibly an exophytic component. If there is marked enhancement, consider other diagnoses (e.g. high grade vermal astrocytoma).

Treatment
Surgery
Biopsy: should not be performed when the MRI shows a diffuse infiltrating brainstem lesion (does not change treatment or outcome).

Treatment is usually non-surgical. Exceptions where surgery may be indicated:
1. Tumors with a dorsally exophytic component: see below these may protrude into 4th ventricle or CP angle, tend to enhance with IV contrast, tend to be lower grade
2. Some success has been achieved with non-exophytic tumors that are not malignant astrocytomas (surgery in malignant astrocytomas is without benefit) (detailed follow-up is lacking)
3. Shunting for hydrocephalus

Dorsally exophytic tumors
These tumors are generally histologically benign (e.g. gangliogliomas) and are amenable to radical subtotal resection. Prolonged survival is possible, with a low incidence of disease progression at short-term follow-up.

Surgical goals in exophytic tumors include:
1. Enhanced survival by subtotal removal of exophytic component: broad attachment to the floor of 4th ventricle is typical and usually precludes complete excision (although some “safe entry” zones have been described). An ultrasonic aspirator facilitates debulking
2. Establishing diagnosis: radiographic differentiation of exophytic brainstem gliomas tumors from other lesions (e.g. medulloblastoma, ependymoma and dermoids) may be difficult
3. Tumors that demonstrate recurrent growth after resection remained histologically benign and were amenable to re-resection

Complications of surgery generally consisted of exacerbation of pre-operative symptoms (ataxia, cranial nerve palsies…) which usually resolved with time.

Medical
No proven chemotherapeutic regimen. Steroids are usually administered. In pediatrics, there is some indication of response to Temodar® (temozolomide) (p. 595).

Radiation
Traditionally given as 45–55 Gy over a six week period, five days per week. When combined with steroids, symptomatic improvement occurs in 80% of patients.

Possible improved survival with so called “hyperfractionation” where multiple smaller doses per day are used.

Prognosis
Most children with malignant BSG will die within 6–12 months of diagnosis. XRT may not prolong survival in patients with grade III or IV tumors. A subgroup of children have a more slowly growing tumor and may have up to 50% five-year survival. Dorsally exophytic tumors comprised of pilocytic astrocytomas may have a better prognosis.

37.1.11 Tectal gliomas

General information
A topically defined diagnosis generally consisting of low-grade astrocytomas. Considered a benign subgroup of brainstem glioma. Because of location, tends to present with hydrocephalus. Was dramatically referred to as “the smallest tumor in the body that can lead to the death of the patient”. Focal neurologic findings are rare – diplopia, visual field deficits, nystagmus, Parinaud’s syndrome (p. 99), ataxia, seizures… – and are often reversible after the hydrocephalus is corrected.
Epidemiology
Comprises ≈ 6% of surgically treated pediatric brain tumors.\(^\text{31}\) Presents primarily in childhood. Median age of patients becoming symptomatic = 6–14 years.\(^\text{31}\)

Pathology
Since many of these are not biopsied, meaningful statistical analysis is not possible. Pathologies identified include: WHO II diffuse astrocytoma, pilocytic astrocytomas, WHO II ependymoma, anaplastic astrocytoma, oligodendroglioma & oligoastrocytoma.

Radiographic evaluation
CT scan detects hydrocephalus, but may miss the tumor in ≈ 50%.\(^\text{32}\) Calcification on CT has been described in 9–25%.\(^\text{32,33}\) MRI is the study of choice for diagnosis and follow-up. Typically appears as a mass projecting dorsally from the quadrigeminal plate. Isointense on T1WI, iso- or hyperintense on T2WI.\(^\text{31,34}\) Enhancement with gadolinium occurs in 18% and is of uncertain prognostic significance.

Treatment
General information
Due to the indolent course, open surgery is not recommended. Options include:
1. VP shunt: the standard treatment for years. Long-term results are good with a functioning shunt
2. endoscopic third ventriculostomy: may avoid the need for a shunt. Endoscopic biopsy may be done at the same time through the same burr hole if it is technically feasible (requires a dilated foramen of Monro, which is often present). Long-term results unknown
3. endoscopic aqueductoplasty (with or without stenting): an option for some. Long-term results unknown

Stereotactic radiosurgery: May be offered for tumor progression (criteria are not defined: radiographic progression may not be associated with clinical deterioration).\(^\text{34}\) Dosing should be limited to ≤ 14 Gray at the 50–70% isodose line to avoid radiation-induced side effects.\(^\text{36}\)

Prognosis
Tumor progression: described in 15–25%
Follow-up: no accepted guidelines. Serial neurologic exams and MRIs every 6–12 months has been suggested.\(^\text{31}\)

37.2 Pleomorphic xanthoastrocytoma (PX A)
37.2.1 General information

Key concepts
- low-grade glioma, possibly from subpial astrocytes → superficial location, >90% supratentorial, most common in children or young adults
- mural nodule with cystic component in 25%, meninges involved in >67%
- pathology: pleomorphic cells (xanthomatous (lipid laden) cells, fibrillary and giant multinucleated astrocytes). Usually circumscribed, occasionally invasive
- WHO grade II unless high mitotic index or necrosis, which is WHO grade III
- treatment: maximal safe resection. XRT or chemo = only for grade III

A low-grade glioma thought to arise from subpial astrocytes which may explain their superficial location and abundance of reticulin fibers. Over 90% are supratentorial. Predilection for temporal lobes (50%), followed by parietal, occipital & frontal lobes. Most have a cystic component (may be multiloculated, but >90% have a large, single cyst).
37.2.2 Epidemiology

≈ 1% of astrocytomas. Usually occurs in children or young adults (most are <18 years age). No gender difference.

37.2.3 Clinical

Usual presentation: seizures. May also produce focal deficit or increased ICP.

37.2.4 Differential diagnosis

1. imaging: meningioma is also superficial with dural tail, may also resemble low grade fibrillary astrocytoma
2. pathology: may be confused with anaplastic astrocytoma

37.2.5 Pathology

WHO grade II (MIB is usually <1%) unless there is a high mitotic index or necrosis which qualifies as WHO grade III “PXA with anaplastic features”.37 Compact, superficial tumor with marked cellular pleomorphism (fibrillary and giant multinucleated astrocytes, large xanthomatous (lipid laden) GFAP staining cells (bespeaking glial origin)), abundant reticulin and frequent perivascular chronic inflammatory cells. The reticulin fibers surround two cell types:

1. spindle cells: fusiform cell shape with elongate nuclei
2. pleomorphic cells: round cells with heterochromic, pleomorphic nuclei that may be mono-
nucleated or multinucleated. Variable intracellular lipid content

Usually circumscribed, occasionally infiltrates cortex. Marked cellular pleomorphism may cause these tumors to be mistaken for anaplastic astrocytoma. Vascular proliferation and necrosis are absent,39 most but not all lack mitotic figures. Some PXAs undergo anaplastic change.39 There have also been several reported cases of malignant transformation to anaplastic astrocytoma or glioblastoma.40

37.2.6 Imaging

The cyst, when present, may partially enhance on CT or MRI. A mural nodule is present in 25%. May have “dural tail” (67% show leptomeningeal involvement, 13% show involvement of all 3 meningeal layers). Peritumoral edema may be mild to moderate, calcifications are rare.41

CT: solid portion of tumor is ill-defined and may be isodense to grey matter.

MRI: T1WI: hypointense cystic component with ill-defined isointense solid component that strongly enhances with gadolinium. T2WI: hyperintense cystic component with ill-defined isointense solid component.

37.2.7 Treatment

1. surgery: primary treatment
   a) gross total resection if it can be accomplished without unacceptable neurologic deficit, otherwise subtotal resection
   b) extent of resection: most strongly associated with recurrence free survival42
   c) incomplete resections should be followed since these tumors may grow very slowly over many years before retreatment is necessary, and repeat excision should be considered

2. radiation therapy: controversial
   a) literature suggests either no difference in overall survival or possibly a trend toward pro-
      longed survival38
   b) considered with: residual disease, high mitotic index, or necrosis

3. chemotherapy: role not defined

37.2.8 Prognosis

Overall survival with gross total resection or subtotal resection, with or without radiation and che-
motherapy: 5 years = 80%; 10 years = 71%.37

Extent of resection, mitotic index, and necrosis appear to be the best predictors of outcome.41,42
References

38 Oligodendroglial Tumors and Tumors of the Ependyma, Choroid Plexus, and Other Neuroepithelial Tumors

38.1 Oligodendroglial tumors

38.1.1 General information

Key concepts

- frequently presents with seizures
- predilection for the frontal lobes
- histology: classic features of “fried egg” cytoplasm (on permanent pathology) & “chicken wire” vasculature are unreliable. Calcifications are common
- grading: controversial. Recommendation: low grade and high grade
- recommended treatment: surgery for mass effect or low grade lesions (high-grade lesions are controversial). Chemotherapy for all (with or without surgery), XRT only for anaplastic transformation

38.1.2 Epidemiology

Oligodendroglioma (ODG) have long been thought to comprise only \( \approx 2-4\% \) of primary brain tumors\(^1,2\) or \( 4-8\% \) of cerebral gliomas\(^3\); but recent evidence indicates these tumors have been under-diagnosed (many are misinterpreted as fibrillary astrocytomas, especially the infiltrative portion of these tumors) and ODGs may represent up to \( 25-33\% \) of glial tumors.\(^3,4\) Ratio of male:female = 3:2. Primarily a tumor of adults: average age \( \approx 40 \) years (peak between 26–46 years), but with a smaller earlier peak in childhood between 6–12 years.\(^5\) CSF metastases reportedly occur in up to 10\% but 1\% may be a more realistic estimate.\(^1\) Spinal ODGs comprise only \( \approx 2.6\% \) of intramedullary tumors of the cord and filum.

38.1.3 Clinical

Classic presentation of ODG: a patient with seizures for many years prior to the diagnosis being made when they would present with an apoplectic event due to peritumoral intracerebral hemorrhage. This scenario is less common in the CT/MRI era.

Seizures are the presenting symptoms in \( \approx 50-80\% \) of cases.\(^1,5\) The remainder of presenting symptoms are nonspecific for ODG, and are more often related to local mass effect and less commonly to ↑ ICP. Presenting symptoms are shown in Table 38.2.

38.1.4 Evaluation

Calcifications are seen in \( 28-60\% \) of ODGs on plain radiographs,\(^1\) and on \( 90\% \) of CTs.

38.1.5 Pathology

General information

73% of tumors have microscopic calcifications. Isolated tumor cells consistently penetrate largely intact parenchyma, an associated solid tumor component may or may not be present. The solid portion, when present, classically demonstrates lucent perinuclear halos giving a “fried egg” appearance (actually an artifact of formalin fixation, which is not present on frozen section and may make diagnosis difficult on frozen). A “chicken-wire” vascular pattern has also been described. These features are felt to be unreliable, and cells with monotonous round nuclei (often in cellular sheets) with an eccentric rim of eosinophilic cytoplasm lacking obvious cell processes are more consistent features.

16% of hemispheric ODGs are cystic (cysts form from coalescence of microcysts from micro-hemorrhages, unlike astrocytomas which actively secrete fluid). 33–41% have a component of ependymal or neoplastic astrocytic cells (so called oligoastrocytomas or mixed gliomas or collision tumors (p.645)).

GFAP staining: Since most ODGs contain microtubules instead of glial filaments, ODGs usually do not stain for GFAP (p.598) although some do. In mixed gliomas, the astrocytic component may stain for GFAP.

Grading

A work-in-progress. Historically, a number of attempts at grading ODGs have been proposed and then abandoned because of lack of prognostic significance (for a review, see reference). For example, the system of Smith et al. was based on 5 histopathologic features which have been shown not to be independent determinants of tumor progression (only pleomorphism has been shown to be statistically correlated with survival). Necrosis does not appear to reliably predict a poor prognosis.

For prognostic purposes, it is suggested that ODGs be stratified into two groups:

- oligodendroglioma (WHO grade II) or low grade
- anaplastic oligodendroglioma (WHO grade III) or high grade.

Although there is not uniform agreement on the means for differentiating the two, the factors shown in Table 38.3 should be taken into account as they have been demonstrated to have prognostic significance. Using the spatial grading system for low grade gliomas, no ODGs are of the Type 1 tumor (solid tumor without infiltrative component).

* for information on the MIB-1 index (p. 599)
Tumors composed of at least 51% oligodendroglial elements are graded on 5 histologic features:

1. maximal nuclear/cytoplasmic ratio: the normal oligodendroglial cell ratio is considered low (↓), anything above that is coded as high (↑)
2. maximal cell density: coded according to predominant appearance of sample. Cell density similar to white matter is low (↓), sheets of cells with little or no intervening extracellular neuropil is high (↑)
3. pleomorphism: coded according to predominant appearance of sample. Coded as present (+) if there is large variability in nuclear and cytoplasmic size and shape
4. endothelial proliferation: coded present (+) if 1 or more instance noted
5. necrosis: coded present (+) if 1 or more instance of coagulation necrosis and/or areas of debris filled with macrophages noted

Tumor grade is then determined from Table 38.4.

### 38.1.6 Treatment

#### General information

Recommendation (see text for details). Following an appropriate surgical procedure (if indicated), chemotherapy is the primary treatment modality. XRT is reserved for anaplastic transformation, if it should occur.

### Chemotherapy

Most ODGs respond to some form of chemotherapy, usually in <3 mos, often with a reduction in size. The response is variable in degree and duration. No pathological or clinical feature of high-grade ODGs has been identified that reliably predicts response to chemotherapy. However, allelic loss of chromosome 1p, and combined loss of chromosome arms 1p and 19q, are associated with response to chemo; and losses of both 1p and 19q were associated with longer tumor-free survival after chemo.

The most experience is with PCV (procarbazine 60 mg/m² IV, CCNU AKALomustine (CeeNU ®) 110 mg/m² PO, and vincristine 1.4 mg/m² IV, all given on a 29 day cycle repeated every 6 weeks). Also studied: temozolomide for recurrent anaplastic oligoastrocytoma showed some efficacy.

### Surgery

Indications for surgery:

1. ODGs with significant mass effect regardless of grade: surgery decreases the need for corticosteroids, reduces symptoms and prolongs survival.
2. tumors without significant mass effect:
   a) low-grade ODGs and oligoastrocytoma: surgery is recommended for resectable lesions. Gross total removal should be attempted when possible (survival is improved even more than with astrocytomas\textsuperscript{19}), but not at the expense of neurologic function
   b) high-grade ODGs: data for improved survival is less convincing, and some studies show no advantage of gross total removal over partially resected or biopsied-only high-grade lesions.\textsuperscript{8} Older dogma was that aggressive removal leads to longer survival,\textsuperscript{19} and results in fewer side effects than “partial debulking” operations\textsuperscript{20}

Grossly, the tumor appears as a pink to red, friable mass. There may be a false plane of demarcation between tumor and what appears to be normal brain.

Postoperative radiation

Benefits of postoperative irradiation is controversial.\textsuperscript{5} In a retrospective analysis with no set selection criteria, survival was better in patients receiving $>45$ Gy.\textsuperscript{21} In another series, no difference in 5 year survival following surgery was seen with or without XRT (amount of radiation not specified).\textsuperscript{22} Radiation side effects of memory loss, dementia and personality changes are more common with the longer survival seen in many of these cases.\textsuperscript{23}

38.1.7 Prognosis

Pure ODGs have a better prognosis than mixed oligoastrocytomas which are better than pure astrocytomas (an oligodendroglial component, no matter how small, confers a better prognosis).

With the Smith grading system (see above), median survival in 323 cases was as follows: grade A was 94 months, grades B & C were not statistically different and were 51 and 45 months respectively, and grade D was 17 months.

10 year survival of 10–30% has been quoted for tumors that are completely or predominantly ODGs.\textsuperscript{21} As a group, median survival for surgically treated lesions is given as 35 months post-op (mean 52 months).\textsuperscript{1}

The presence of calcifications is debated as a prognosticator; in one series, calcified ODG on plain films had a longer median survival of 108 months (vs. 58 months for non-calcified).\textsuperscript{1}

Frontal lobe ODGs survived longer than those in temporal lobes (37 months vs. 28 months post-operative survival),\textsuperscript{1} possibly due to increased ease of radical resection with the former.

Chromosomal 1p loss (or combined 1p and 19q loss) is also associated with longer survival.\textsuperscript{14,24}

38.2 Oligoastrocytic tumors

38.2.1 Molecular biology

May show changes typical for diffuse astrocytoma (TP53 mutation & LOH on 17p) or for ODG (LOH on 1p and 19q). No molecular genetic markers have been identified to distinguish oligoastrocytoma from either astrocytoma or ODG. Unlike ODG, the prognostic/therapeutic value of LOH on 1p is less clear.\textsuperscript{24}

Oligoastrocytoma (WHO grade II)

Two distinct neoplastic cell types, 1 type resembles oligodendroglioma cells, and the other resembles cells in diffuse astrocytomas. Some cells may have features of both. The 2 cell types may be segregated or diffusely admixed.

Anaplastic oligoastrocytoma (WHO grade III)

Increased cellularity, nuclear atypia, pleomorphism, and high mitotic activity. Necrosis and microvascular proliferation may be present. Differentiating from GBM may be difficult since GMS may have areas resembling anaplastic ODG (the term “glioblastoma with oligodendroglioma component” is a disputed term suggested for these – unproven suggestion that survival may be better than for ordinary GBM\textsuperscript{25}).
38.3 Ependymal tumors

38.3.1 Ependymoma

General information regarding intracranial and spinal ependymomas

Ependymomas arise from ependymal cells lining the cerebral ventricles and the central canal of the spinal cord. They may occur anywhere along the neuraxis, in pediatrics they are most common in the posterior fossa (see below), in adults they tend to be intraspinal (p.788).

Epidemiology

- intracranial: comprises only ≈ 5–6% of intracranial gliomas, 69% occur in children,26 comprise 9% of pediatric brain tumors.27 Incidence of pediatric intracranial ependymomas: ≈ 200 cases/yr in the U.S.
- spinal: ≈ 60% of spinal cord gliomas (the most common primary intramedullary spinal cord glioma below the mid-thoracic region – see Intramedullary spinal cord tumors (p.787) – 96% occur in adults,26 especially those of filum terminale; see myxopapillary ependymoma below).

The mean age at diagnosis is shown in Table 38.5. Ependymomas have the potential to spread via the CSF through the neuraxis (including to the spinal cord), a process known as “seeding”, resulting in so-called “drop mets” in the spinal cord in 11% The incidence is higher with higher grade.27 Systemic spread occurs on rare occasion.

Pathology

Although they are usually circumscribed with a covering layer of ependyma, ependymomas may be invasive.

Classification is a work in progress. Ependymomas from different locations (p-fossa, supratentorial, spinal cord) are genetically distinct.28 The World Health Organization (WHO) classification of ependymal tumors:

1. ependymoma (WHO II) – variants:
   a) cellular
   b) papillary: “classic lesion” occurring in brain or spinal cord. Can metastasize in up to 30% of cases. Dark, small nuclei. 2 cytoplasmic patterns:
      - differentiation along glial line: these form perivascular pseudorosettes (areas of radiating processes lacking nuclei surrounding blood vessels) which, when they occur, are diagnostic
      - cuboidal cells: these can form true rosettes (where the cytoplasmic processes extend to form a lumen-like structure with no central blood vessel – as if trying to recreate an ependymal lining e.g. of a ventricle). True rosettes are classically associated with ependymomas, however, perivascular pseudorosettes are more common
   c) clear cell
   d) tanycytic: rare. Tumor cells appear similar to “ependymoglia” or “tanycytes” (stretched cells present to a limited degree in the normal CNS). True rosettes are absent. No preference for age, sex or location within CNS. Treatment of choice: gross total resection29

2. myxopapillary ependymoma: (WHO I) distinctive, occurs only in filum terminale. Papillary, with microcystic vacuoles and mucousubstance

Table 38.5 Mean age at diagnosis of ependymoma26

3. subependymomas: (WHO I) typically occur in anterior lateral ventricles or posterior fourth ventricle, with prominent role of subependymal glial cells. Not uncommon at autopsy, rarely surgical. Classically do not enhance; see Ependymal and subependymal enhancement (p. 1385).

4. anaplastic ependymomas: (WHO III) pleomorphism, multinucleation, giant cells, mitotic figures, vascular changes and areas of necrosis; the term ependymoblastoma has occasionally been used for more anaplastic lesions, but this term is best reserved for a distinct, rare childhood primitive neuroectodermal tumor (p. 666). It is unclear if the degree of anaplasia has any effect on outcome.

**General Information for Intracranial Ependymomas**

**Key Concepts**

- Usually benign tumors, often fibrillary with epithelioid appearance. Perivascular pseudorosettes or true rosettes may be seen in classic (papillary) form.
- Most often occur in the floor of the 4th ventricle, presenting with hydrocephalus (increased ICP) and cranial nerve VI & VII palsies.
- Evaluation: includes imaging the entire neuraxis (usually with enhanced MRE: cervical, thoracic, lumbar & brain) because of potential for seeding through CSF.
- Worse prognosis the younger the patient (especially age < 24 months).
- Treatment: the best outcomes are associated with gross total removal (no enhancing tumor on post-op MRI) followed by XRT. XRT may be withheld for age < 3.
- Do LP ≈ 2 weeks post-op to send ≈ 10 cc of CSF for cytology for prognostication.

Usually well circumscribed and benign (although anaplastic (malignant) ependymomas do occur), commonly arises in the floor of the fourth ventricle (60–70% are infratentorial, all of these occur near 4th ventricle, 26 they comprise 25% of tumors in region of 4th ventricle (p 2792)). Children with p-fossa ependymomas often have anaplastic tumors with a higher risk of spread through the neuraxis. Supratentorial ependymomas are often cystic. Rarely occur outside the CNS in: mediastinum, lung or ovaries. Although not as malignant histologically as medulloblastomas, ependymomas have a worse prognosis due to their propensity to invade the obex which precludes complete removal.

**Clinical**

**Symptoms**

Mostly those of posterior fossa mass with increased ICP (from hydrocephalus) and cranial nerve involvement.

- Symptoms of increased ICP:
  1. headache: 80%
  2. N/V: 75%
  3. ataxia or vertigo: 60%
  4. seizures: only in ≈ 30% of supratentorial lesions; comprise only 1% of patients with intracranial tumors presenting with seizures.

**Signs**

Cranial nerve involvement: invasion of the floor of the 4th ventricle may involve the facial colliculus producing facial nerve palsy (p. 576) (involvement of internal genu of VII) and abducens palsy (from VI nucleus).

**Evaluation**

MRI: imaging study of choice. Image the entire craniocerebral axis with and without contrast because of possibility of drop mets. Usually appears as a mass in the floor of fourth ventricle, often with obstructive hydrocephalus. May be difficult to distinguish from medulloblastoma (MBS) radiographically, see differentiating features (p. 1365).

CT: not as detailed for evaluation of posterior fossa.

Myelogram: water-soluble contrast myelography is about as sensitive as gadolinium enhanced MRI in detecting “drop mets.” Myelography also provides CSF for cytology for staging purposes.
Treatment

Surgical resection

Goal of surgery: maximal possible resection of intracranial portion without causing neurological deficits (since extent of resection is an important prognosticator). Gross total resection may not possible when invasion of the floor is extensive, or when tumor extends through the foramen of Luschka (bradycardia may prevent GTR).

2 weeks postoperatively, perform LP to look for “drop mets”: 10 cc of CSF is sent for cytology to quantitate (if any) number of malignant cells (may be used to follow treatment). If LP is positive, then by definition there are drop mets. If negative, it is not as helpful (sensitivity is not high). CSF from an EVD is not as sensitive as LP.

Lesions in fourth ventricle region are approached via midline suboccipital craniectomy.

Radiation therapy (XRT)

Ependymomas rank 2nd only to medulloblastomas in radiosensitivity. XRT is administered after surgical excision (survival is improved with post-op XRT\textsuperscript{26,31}: 50% survival time was 2 yrs longer with XRT than without,\textsuperscript{26} and 5-year survival increased from 20–40% without XRT to 40–80% with XRT\textsuperscript{31}), however, for patients age <3 years, see below.

1. cranial XRT
   a) traditional therapy: 45–48 Gy to tumor bed\textsuperscript{11} (recurrence treated with additional 15–20 Gy)\textsuperscript{30 (p 2797)}
   b) recent recommendations: 3-D conformal XRT with higher doses (59.4 Gy delivered to tumor bed +1 cm margins)\textsuperscript{32}
   c) intensity modulated proton beam therapy appears equivalent in terms of local control, but may be better at sparing normal tissue\textsuperscript{33}

2. spinal XRT: most radiate only if drop mets or if positive CSF cytology (however, prophylactic spinal is controversial\textsuperscript{34})
   a) low dose XRT to entire spinal axis (median dose =30 Gy in one series\textsuperscript{31})
   b) boost to any regions showing drop mets

3. XRT is undesirable in age <3 due to side effects. XRT was avoided in ≈ 30% of patients <3 years age with comparable survival when XRT was reserved for treatment failures.\textsuperscript{35,36} This concept of selective XRT may be applicable to older children as well\textsuperscript{37}

Chemotherapy

Role is very limited.

1. has little impact on newly diagnosed cases. Adjuvant chemo after XRT in patients >3 years showed no benefit
2. may reduce vascularity of ependymomas which may facilitate GTR (sometimes in a second stage operation)
3. may be considered for infants <≈ 3 years age to delay use of XRT (see above)
4. chemo at the time of recurrence may arrest tumor progression for short periods

Outcome

Operative mortality\textsuperscript{30 (p 2797)}: 20–50% in early series; more recently: 5–8%

Operative morbidity: advise patients/families pre-op of the likelihood need for post-op gastric feeding tube (G-tube) and trachestomty (these may be temporary).

Age: peds vs. adults: 5-year survival is 20–30% in the pediatric group,\textsuperscript{27,38} compared with up to 80% in adults. Patients 24–35 months old did better (5-year survival =73%) than those younger than 24 months (26%-5-YS) or those older than 36 months (36%-5-YS).\textsuperscript{39}

Pathology: prognosis is worse with anaplastic ependymoma (WHO III) than with “standard” grade (WHO II).\textsuperscript{40,41} However, excluding WHO III tumors, malignant features in an ependymoma do not necessarily portend a worse prognosis.\textsuperscript{42}

Extent of resection: the risk of recurrence is highest following subtotal resection. Gross total resection (GTR) (surgical) of primary intracranial tumor followed by craniospinal XRT as outlined above yields 41%-5-year survival.

Treatment failure: WHO Grade II tumors tend to recur initially at the site of origin.\textsuperscript{40} However, primary failure in 9–25% of patients is via drop mets.\textsuperscript{39,43}
38.4 Neuronal and mixed glial tumors

38.4.1 Desmoplastic infantile astrocytoma/ganglioglioma

The former entities “desmoplastic cerebral astrocytoma of infancy” and “desmoplastic infantile ganglioglioma” have been combined to “desmoplastic infantile astrocytoma and ganglioglioma” (DIG). A lesion with either astrocytic or dual glioneuronal differentiation. Prognosis is usually favorable.

38.4.2 Central neurocytoma

General information

Key concepts

- Rare, WHO Grade II neuronal tumor
- Primarily seen in young adults
- Gross total resection can be curative
- If MIB-1 labeling index > 2-4% there is an increased risk of recurrence after subtotal resection
- If MIB-1 labeling is elevated, radiation therapy after subtotal resection can reduce the risk of recurrence

Central neurocytoma is a WHO Grade II neuronal tumor that constitutes 0.1-0.5% of brain tumors. These are generally attached to the septum pellucidum within the lateral ventricles or they are within the third ventricle. Incidence peaks in the 3rd decade, but they can also present in children and the elderly. No gender predominates. The most common presentation is with increased intracranial pressure and ventriculomegaly.

Pathology

Central neurocytoma cells have small, round nuclei. Cells often have a “fried egg” appearance on H&E staining, which can mimic oligodendroglioma. There are two primary architectures: honeycomb (also mimicking oligodendroglioma) and fibrillary. Rosettes can also be seen. Immunohistochemistry is often positive for neuronal markers synaptophysin and Neu-N. When the diagnosis is not clear, electron microscopy is used to demonstrate neuronal features including: a prominent golgi apparatus, parallel microtubules, and dense core neurosecretory granules. 1p/19q deletion has not been reported in central neurocytoma, but it can be seen in extraventricular neurocytoma.

Variants

1. Extraventricular neurocytoma: a more rare subtype that may be located in the cerebral parenchyma, cerebellum, thalamus, brainstem, pineal region, and spinal cord. Tumor cells can be focally infiltrative into surrounding tissue. Pathology findings include vessel wall hyalinization and ganglionic differentiation. Immunohistochemistry is positive for synaptophysin in the cytoplasm and neuropil. Neu-N staining is often positive. Electron microscopy findings include round nuclei and neurosecretory granules, as in central neurocytoma. 1p and 19q deletions, in isolation or in combination, can be seen in extraventricular neurocytoma.

2. Liponeurocytoma: a lipid-laden neurocytoma that most often appears in the cerebellum. Rarely, similar tumors can also appear in the lateral ventricles. Some authors suggest the more inclusive name “Liponeurocytoma” should replace the separate WHO classification of “Cerebellar liponeurocytoma.” Others contend that the supratentorial exceptions are central neurocytomas which contain neurocytes that underwent lipidization, instead of having actual adipose metaplasia.

Imaging

CT scan: 25-50% of these tumors show calcifications. Tumors are usually iso- to hyperdense, with hypodense areas that represent cystic degeneration.

MRI: Tumors appear heterogeneously isointense on T1 and hyperintense on T2. MR spectroscopy often shows a high glycine peak. Moderate to strong contrast enhancement shows on both CT and MR images.
Treatment

1. Total resection is often curative. After gross total resection, radiation therapy is generally not necessary.\textsuperscript{45}
2. Subtotal resection can be followed by stereotactic radiosurgery, especially if MIB-1 labeling is >2-4\%.\textsuperscript{45,46,49,50}
3. Chemotherapy for recurrent and inoperable tumors has been reported with many agents, including: alkylating agents (carmustine, cyclophosphamide, ifosfamide, lomustine), platinum-based agents (carboplatin and cisplatin), etoposide, topotecan, and vincristine.\textsuperscript{49,50}
4. After treatment, patients should have long-term follow-up imaging as surveillance for tumor recurrence.\textsuperscript{46}

Prognosis

Total resection can be curative.\textsuperscript{45,49} Recurrence risk after subtotal resection varies with the MIB-1 labeling index. In a 2004 study of neurocytomas with MIB-1 labeling >2\% the 5-year local control rate after subtotal resection alone was 7\% but if subtotal resection was followed with radiation therapy it was 70\%.\textsuperscript{50} In a 2013 study, patients with MIB-1 labeling <4\% had no recurrence at 4 years after subtotal resection. If MIB-1 labeling was >4\% at subtotal resection, recurrence was found in 50\% of patients at 2 years and 75\% at 4 years.\textsuperscript{49} Most local recurrences occur within 3-6 years. Recurrence is more common in extraventricular neurocytoma.\textsuperscript{50}

38.4.3 Cerebellar liponeurocytoma

Née lipomatous medulloblastoma. Occurs exclusively in cerebellum of adults (mean age: 50 years). No gender preference.

Histology: clusters of neoplastic neurocytes with lipidization (resembling adipocytes) with background of small neoplastic cells with morphological features more suggestive of neurocytes. Synaptophysin (p.600) and MAP-2 immunostaining is consistent and diffuse, focal GFAP staining is common. Usually no mitotic figures. MIB-1 index 1–3\%.

38.4.4 Dysembryoplastic neuroepithelial tumors (DNT) or (DNET)

See references.\textsuperscript{51,52}

Epidemiology

Incidence: not accurately known because the diagnosis may be missed. Estimated range: 0.8–5\% of all primary brain tumors. Typically occurs in children and young adults.

Most common locations: temporal or frontal. Parietal and especially occipital lobe involvement is rare. DNTs have been reported in the cerebellum, pons & basal ganglia.

Pathology

A WHO Grade I glioma. Thought to arise embryologically from the secondary germinal layer (which includes subependymal layer, cerebellar external granular layer, hippocampal dentate fascia & subpial granular layer).

Multinodularity at low-power is a key feature, and the primary constituent cells are oligodendrocytes and to a lesser extent, astrocytes that are often pilocytic. Occasionally difficult to differentiate from oligodendroglioma.

Two distinct forms\textsuperscript{53} (do not appear to have different prognoses):

1. simple form: glioneural elements consisting of axon bundles perpendicular to the cortical surface, lined with oligodendrogial-like cells that are S-100 positive and GFAP negative. Normal appearing neurons floating in a pale eosinophilic matrix are scattered between these columns (no resemblance to ganglion cells, unlike gangliogliomas)
2. complex form: glioneural elements as described above in the simple form, with glial nodules scattered throughout. The glial component may mimic a low-grade fibrillary astrocytoma. Foci of cortical dysplasia occur

Clinical

Typically associated with longstanding medically intractable seizures, usually complex partial. Symptoms usually begin before age 20.
Imaging
Cortical lesions with no surrounding edema and no midline mass effect.
CT: hypodense with distinct margins. Deformity of overlying calvaria is common.
MRI: T1 WI: hypointense. T2 WI: hyperintense, septations may be seen. If there is enhancement, it is usually nodular.
PET scan: hypometabolic with [18F]-fluorodeoxyglucose. Negative [11C]-methionine uptake (unlike all other gliomas).

Outcome
Seizure control: usually improves after surgery. Degree of control seems to correlate with completeness of removal. Improvement in seizures correlates inversely with the duration of intractable seizures.
Recurrence/continued growth: recurrence after complete removal, or tumor growth after partial resection is rare. Adjuvant treatment (XRT, chemotherapy...) is of no benefit in these benign tumors. Mitoses or endothelial proliferation, seen on occasion, do not affect outcome. Malignant transformation is very rare.

38.4.5 Dysplastic gangliocytoma of cerebellum (Lhermitte-Duclos disease)

General information
AKA: ganglion enuroma of the cerebellum, purkinjoma, granular cell hypertrophy of the cerebellum, gangliocytoma dysplasticum, hamartoma of the cerebellum.
Rare (200 case reports) cerebellar lesion with features of both a malformation and a low grade (WHO I) neoplasm that has the propensity to progress (enlarge) and recur after surgery. May be focal or diffuse. Diffuse enlargement of cerebellar folia.

Pathology
Derangement of normal laminar cellular architecture of the cerebellum with:
1. thickening of the outer molecular cell layer
2. loss of middle Purkinje cell layer
3. infiltration of inner granular cell layer with dysplastic ganglion cells

Clinical
Typically a middle aged adult with signs and symptoms of a cerebellar mass. May also present with hydrocephalus or may be an incidental finding.

Imaging
CT: hypo- to iso-dense, nonenhancing lesion with mass effect.
NB: in a child with MRI findings of Lhermitte-Duclos disease (LDD) (even if classic), a medulloblastoma is statistically more likely (especially medulloblastoma with extensive nodularity (MBEN)).

Treatment
Controversial. A few cases with a benign course have been described. Shunting for hydrocephalus. Biopsy is recommended particularly for pediatric cases to rule-out medulloblastoma. Surgical excision may be considered when there is significant mass effect. Efficacy of XRT is unknown.
38.5 Choroid plexus tumors

38.5.1 General information

Most are histologically benign (choroid plexus papilloma (CPP), WHO I), although intermediate (atypical choroid plexus papilloma, WHO II) and malignant tumors (choroid plexus carcinoma (CPC), WHO III) may occur. Malignant degeneration from WHO I or II to grade III was seen in 2 out of 124 patients with 59 months mean follow-up. All may produce drop mets in the CSF, but WHO III do so more commonly. Although usually slow growing, they sometimes grow rapidly.

Atypical CPP have more mitotic figures than CPP without frank signs of malignancy seen in CPC, and up to 2 of the following 4 features may be observed: increased cellularity, nuclear pleomorphism, blurring of the papillary pattern, areas of necrosis.

38.5.2 Epidemiology

Prevalence: 0.4–1% of all intracranial tumors. 1.5–6% of tumors in pediatrics. Although they may occur at any age, 70% of patients are <2 yrs old. Some tumors occur in neonates, supporting the hypothesis that some of these are congenital.

Location: in adults these tumors are usually infratentorial, whereas in children they tend to occur supratentorial (a reverse from the situation for most other tumors) in the lateral ventricle with a predilection for the left side. See Intraventricular lesions (p. 1381) for differential diagnosis. They can be located anywhere there is choroid plexus, with the most frequent locations: the lateral or fourth ventricles, the CPA (from extension of choroid plexus through the foramen of Luschka).

38.5.3 Presentation

Most present with symptoms of increased ICP from hydrocephalus (H/A, N/V, craniomegaly), others may present with seizures, subarachnoid hemorrhage (with meningismus), or focal neurologic deficit (hemiparesis, sensory deficits, cerebellar signs, or cranial nerve palsies of III, IV and VI).

Hydrocephalus, which may result from: overproduction of CSF (although total removal of these tumors does not always cure the hydrocephalus – especially in patients with high CSF protein, hemorrhage from tumor or surgery, or ependymitis), obstruction of CSF outflow, or communicating hydrocephalus from CSF borne particulates.

38.5.4 Imaging

Brain MRI or CT without and with contrast usually demonstrates a densely enhancing multilobulated intraventricular mass classically with projecting “fronds.” Hydrocephalus is common.

38.5.5 Treatment

General information

There is no role for chemotherapy or radiation for WHO I lesions. For choroid plexus carcinoma, chemotherapy benefits a subset of patients.

Surgical treatment

Benign lesions may be cured surgically with total removal, and even the malignant tumors respond well to surgery. The operation may be difficult due to fragility of the tumor and bleeding from the choroidal arteries. However, persistence with a second and sometimes even third operation is recommended as 5-year survival rate of 84% can be achieved. Post-operative subdural collections after transcortical tumor excision may occur, and may result from a persistent ventriculospinal fistula, which may require subdural-peritoneal shunting.

38.5.6 Recurrence

12 recurrences (6% of WHO I and 29% of WHO II patients) requiring neurosurgical intervention occurred in 124 complete resections with 59 months mean follow-up.
38.6 Other neuroepithelial tumors

1. astroblastoma
2. chordoid glioma of the 3rd ventricle67: rare, benign tumor of adulthood. Solid, enhancing mass of the 3rd ventricle. Female: male ratio 3:1. Mitotic activity is absent in most tumors. GFAP immunostaining is common, S100 reactivity is variable. Histologically similar appearing to chordoid meningioma, which lacks GFAP staining. Attachment to wall of 3rd ventricle (hypothalamus) may prevent total removal

3. angiocentric glioma

39 Neuronal and Mixed Neuronal-Glial Tumors

39.1 Ganglioglioma

39.1.1 General information

Key concepts

- composed of two cell types: ganglion cells (neurons) and glial cells
- extremely rare (<2% of intracranial neoplasms)
- seen primarily in the first 3 decades of life
- characterized by slow growth and a tendency to calcify

The term “ganglioglioma” was introduced in 1930 by Courville. A tumor composed of two types of cells: ganglion cells (neurons) which may arise from primitive neuroblasts, and glial cells, usually astrocytic in any phase of differentiation.

39.1.2 Epidemiology

Incidence

Typically quoted as 0.3–0.6%. One series found gangliogliomas in 1.3% of all brain tumors (including mets), or 3% of primary brain tumors. Considering only children and young adults, incidence ranges from 1.2–7.6% of brain tumors.

Demographics

Occurs primarily in children and young adults (peak age of occurrence: 11 yrs).

39.1.3 Location

May occur in various parts of the nervous system (cerebral hemispheres, spinal cord, brainstem, cerebellum, pineal region, thalamus, intrasellar, optic nerve, and peripheral nerve have been reported). Most occur above the tentorium, primarily in or near the 3rd ventricle, in the hypothalamus or in the temporal or frontal lobes. Brainstem gangliogliomas (p. 633) occur rarely.

39.1.4 Pathology

Mixture of 2 types of neoplastic cells: neuronal (ganglion) and astrocytic (glial). Very slow growing.

Two major classifications: ganglioneuromas (less common, more benign; predominance of neuronal component) and gangliogliomas (preponderance of glial cells).

Grossly: white matter mass; well-circumscribed, firm, with occasional cystic areas and calcified regions. Most dissect easily from brain, but the solid portion may show an infiltrative tendency.

Microscopically: ganglion cells must demonstrate nerve cell differentiation, e.g. Nissl substance and axons or dendrites. Pitfall: differentiating neoplastic neurons from neurons entrapped by an invading astrocytoma may be difficult. Also, neoplastic astrocytes may resemble neurons on light microscopy. 2 of 10 patients had areas of oligodendroglia. One series found necrotic areas in 7 of 14 patients, minimal calcification, and Rosenthal bodies. Suggested criteria for diagnosis:

1. clusters of large cells potentially representing neurons (required for diagnosis)
2. no perineural clustering of glial cells around the suspected neoplastic neurons
3. fibrosis (desmoplasia)
4. calcification

Aggressive malignant changes in the glial component may dictate a poor outcome, although an “aggressive” background is not unusual and may not indicate malignancy.
39.1.5 Presentation
Most common presenting symptom was seizure, or a change in a pre-existing seizure pattern. Often, the seizures are difficult to control medically.

39.1.6 Radiologic Evaluation
Neuroradiologic findings are not specific for this tumor.
- Plain skull x-ray: calcification was noted in 2 of 6 patients.\(^3\)
- CT: all of 10 patients had a low density lesion on non-contrast CT; 8 enhanced slightly with contrast; 5 of the 10 had calcification on CT.\(^4\) 6 of the 10 were in temporal lobe (this predilection has been noted in many but not all series), and 4 were in frontal lobe. Frequently appears cystic on CT, but still may be found to be solid at operation. Mass effect rare (suggests slow growth).
- MRI: high signal on T1WI, low signal on T2WI. Calcifications appear as low signal on both.\(^3\)
- Angiography: shows either an avascular or a minimally vascular mass.

39.1.7 Treatment
Recommendation is wide radical excision when possible (may be more limited in spinal cord and brainstem tumors). Close follow-up is recommended, and re-resection should be considered for recurrence. The role of XRT is unknown, and due to the deleterious effects together with the good long-term prognosis, it is not recommended initially but may be considered for recurrence.\(^8\)

39.1.8 Prognosis
Russell and Rubinstein\(^9\) first proposed that the grade of the astrocytic component of the tumor determines the prognosis. This has been supported by some case reports, but clinical series have not been able to correlate histology with outcome.\(^8\) Thus, anaplasia is not significantly associated with a worse prognosis.\(^8\)
The majority of patients did well and were asymptomatic after resection. 1 patient in a series of 10 died 3 days post-op from cerebral edema.
In 58 patients, 5-year survival was 89\% and 10-year survival was 84\%. In 9 brainstem gangliogliomas, 5-year survival was 78\%.
The value of radiation therapy is not known. Consider radiation when growth is evident on follow-up CT, or when infiltration is felt to occur at time of surgery.
1 patient had degeneration to glioblastoma when a recurrence was discovered 5 years after removal (this patient received radiation therapy).
The prognosis with following subtotal resection of brainstem gangliogliomas is better than for brainstem gliomas as a group.\(^5\)

39.2 Paraganglioma
39.2.1 General information
AKA chemodectoma, AKA glomus tumors. Table 39.1 shows the designation of these tumors in various sites.

<table>

</tr>
<tr>
<td>adrenal medulla &amp; sympathetic chain</td>
<td>pheochromocytoma</td>
</tr>
</tbody>
</table>
These tumors arise from paraganglion cells (not chemoreceptor cells as previously thought, therefore the term chemodectoma is losing favor). Slow growing tumors (<2 cm in 5 years). Histologically benign (<10% associated with lymph node involvement or distant spread). Most contain secretory granules on EM (mostly epinephrine & nor-epinephrine, and these tumors may occasionally secrete these catecholamines with risk of life-threatening HTN and/or cardiac arrhythmias).

Glomus tumors may occur in 2 patterns:
1. familial: non multicentric. Up to 50%
2. nonfamilial. may be multicentric (metachronous) 5%

39.2.2 Pheochromocytoma

General information
Located in the adrenal gland. May be sporadic, or as part of familial syndrome (von Hippel-Lindau disease (p.703), MEN 2A & 2B, & neurofibromatosis). Consider genetic testing if age at diagnosis is < 50 years for mutations of VHL and other genetic abnormalities (RET, SDHS, SDHB, SDHC).

Laboratory studies
1. fractionated plasma metanephrines: 96% sensitivity, 85% specificity. More sensitive than serum catecholamines with sporadic elevations. Pheochromocytoma is ruled out if plasma normetanephrine (NMN)<112 pg/ml and metanephrine (MN)<61 pg/ml. Highly suspicious if NMN>400 pg/ml or MN>236 pg/ml
2. 24 hr urine collection for: total catecholamines (epinephrine and nor-epinephrine) and metanephrines (88% sensitivity, 99.7% specificity). Note: testing for vanillylmandelic acid (VMA) is no longer done as it does not measure fractionated metanephrines.
3. where elevation is found, a clonidine suppression test can be done. Normal response consists of a fall in plasma catecholamines to ≤50% of baseline and below 500 pg/ml (there will be a reduction in essential hypertension, but no change with pheochromocytoma or other tumor production)

Imaging
Indicated when laboratory tests confirm pheochromocytoma. MRI with contrast is preferred over CT. CT may be used when MRI is contraindicated, but is less sensitive, especially for lesions <1 cm diameter.

123I MIBG (iodine-123-meta-iodobenzylguanidine) scintigraphy detects extra-adrenal pheochromocytomas with 83–100% sensitivity, 95–100% specificity. If not available 131I MIBG may be used with 77–90% sensitivity, 95–100% specificity.

39.2.3 Carotid body tumors

General information
Possibly the most common paraganglioma (pheochromocytoma may be more common). Approximately 5% are bilateral; the incidence of bilaterality increases to 26% in familial cases (these are probably autosomal dominant).

Clinical
Usually present as painless, slow growing mass in upper neck. Large tumors may → cranial nerve involvement (especially vagus and hypoglossal). May also cause stenosis of ICA → TIs or stroke.

Evaluation
1. carotid angiogram: demonstrates predominant blood supply (usually external carotid, with possible contributions from vertebral and thyrocervical trunk). May also detect bilateral lesions. Characteristic finding: splaying of bifurcation
2. MRI (or CT): evaluates extent, and assesses for intracranial extension
Treatment
Resection reported to carry a high complication rate, including stroke (8–20%) and cranial nerve injury (33–44%). Mortality rate is 5–13%.

39.2.4 Glomus tumors

General information
Glomus tumors may be subdivided into glomus jugulare and glomus tympanicum tumors. Glomus jugulare tumors arise from the jugular bulb (in the jugular foramen at the junction of the sigmoid sinus and jugular vein). Glomus tympanicum tumors are centered higher than glomus jugulare. Glomus tumors are rare (0.6% of all head and neck tumors), yet the glomus tympanicum is the most common neoplasm of the middle ear. Glomus jugulare tumors (GJT) arise from glomus bodies, usually in the area of the jugular bulb, and track along vessels. May have finger-like extension into the jugular vein (which may embolize during resection). Most are slow growing, although rapidly growing tumors do occur.

Vascular supply: very vascular. Main feeders of GJT are from the external carotid (especially inferior tympanic branch of ascending pharyngeal artery, and branches of posterior auricular, occipital, and internal maxillary), with additional feeders from petrous portion of the ICA. Glomus tympanicum tumors feed from the auricular artery.

Epidemiology
Female: male ratio is 6:1. Bilateral occurrence is almost nonexistent.

Pathology

General information
Histologically indistinguishable from carotid body tumors. May invade locally, both through temporal bone destruction and especially along pre-existing pathways (along vessels, eustachian tube, jugular vein, carotid artery). Intradural extension is rare. Malignancy may occur, but is rare. These tumors rarely metastasize.

Secretory properties
These tumors usually possess secretory granules (even the functionally inactive tumors) and may actively secrete catecholamines (similar to pheochromocytomas, occurs in only 1–4% of GJT). Norepinephrine will be elevated in functionally active tumors since glomus tumors lack the methyltransferase needed to convert this to epinephrine. Alternatively, serotonin and kallikrein may be released, and may produce a carcinoid-like syndrome (bronchoconstriction, abdominal pain and explosive diarrhea, violent H/A, cutaneous flushing, hypertension, hepatomegaly and hyperglycemia). During surgical manipulation, these tumors may also release histamine and bradykinin, causing hypotension and bronchoconstriction.

Clinical

Symptoms
Patients commonly present with hearing loss and pulsatile tinnitus. Dizziness is the third most common symptoms. Ear pain may also occur.

Signs
Hearing loss may be conductive (e.g. due to obstruction of the ear canal) or sensorineural due to invasion of the labyrinth often with accompanying vertigo (the eighth nerve is the most common cranial nerve involved). Various combinations of palsies of cranial nerves IX, X, XI & XII occur – see Jugular foramen syndromes (p. 100) – with occasional VII palsy (usually from involvement within the temporal bone). Ataxia and/or hydrocephalus can occur with massive lesions that cause brainstem compression. Occasionally patients may present with symptoms due to secretory products (see below).

Otoscopic exam → pulsatile reddish-blue mass behind eardrum (occasionally, lamentably biopsied by ENT physician with possible ensuing massive blood loss).
Differential diagnosis

See Cerebellopontine angle (CPA) lesions (p. 1365). The major differential is neurilemmomas (vestibular schwannomas), both enhance on CT. A cystic component and extrinsic compression of the jugular bulb are characteristic of neurilemmomas. Angiography will differentiate difficult cases.

Evaluation

Neurophysiologic testing

Audiometric and vestibular testing should be performed.

Imaging

1. CT or MRI used to delineate location and extent of tumor; CT is better for assessing bony involvement of the skull base
2. Angiography: confirms diagnosis (helping to rule out vestibular schwannoma), and ascertains patency of contralateral jugular vein in event that jugular on side of tumor must be sacrificed; jugular bulb and/or vein are usually partially or completely occluded

Endocrine/laboratory studies

See also details (p. 653).

Classification

A number of classification schemes have been proposed. The modified Jackson classification is shown in Table 39.2.

Treatment

Surgical resection is usually simple and effective for small tumors confined to the middle ear. For larger tumors that invade and destroy bone, the relative role of surgery and/or radiation is not fully determined. With large tumors, surgery carries the risk of significant cranial nerve palsies.

Medical management

General information

For tumors that actively secrete catecholamines, medical therapy is useful for palliation or as adjunctive treatment before embolization or surgery. Alpha and beta blockers given before embolization or surgery blocks possibly lethal blood pressure lability and arrhythmias. Adequate blockade takes $\approx 2–3$ weeks of alpha blocker and at least 24 hours of beta blocker therapy; in emergency, 3 days of treatment may suffice.

Alpha blockers

Reduce BP by preventing peripheral vasoconstriction.

1. Phenoxybenzamine (Dibenzyline®): long acting; peak effect 1–2 hrs. Start with 10 mg PO BID and gradually increase to 40–100 mg per day divided BID

: 5 mg IV/IM (peds: 1 mg) 1–2 hrs pre-op, repeat PRN before and during surgery

Beta blockers
Reduces catecholamine induced tachycardia and arrhythmias (may also prevent hypotension that might occur if only alpha blockade is used). These drugs are not always needed, but when used 6 NB: these drugs must not be started before starting alpha-blockers (to prevent hypertensive crisis and myocardial ischemia).
1. propranolol (Inderal®): oral dose is 5–10 mg q 6 hrs. IV dose for use during surgery is 0.5–2 mg slow IVP
2. labetalol (Normodyne®) (p.126): may have some efficacy in blocking α selective and β non-selective (potency <propranolol)

Serotonin, bradykinin, histamine release blockers
These agents may provoke bronchoconstriction that does not respond to steroids, but may respond to inhaled β-agonists or inhaled anticholinergics. Somatostatin may be used to inhibit release of serotonin, bradykinin, or histamines. Since this drug has a short half-life, it is preferable to give octreotide (p.742) 100 mcg sub-Q q 8 hrs.

Radiation therapy
XRT may relieve symptoms and stop growth in spite of persistence of tumor mass. 40–45 Gy in fractions of 2 Gy has been recommended. Lower doses of ≈ 35 Gy in 15 fractions of 2.35 Gy appear as effective and have fewer side effects. Generally used as primary treatment only for large tumors or in patients too elderly or infirmed to undergo surgery. Some surgeons pretreat 4–6 mos pre-operatively with XRT to decrease vascularity (controversial).

Embolization
1. generally reserved for large tumors with favorable blood supply (i.e. vessels that can be selectively embolized with no danger of particles passing thru to normal brain)
2. post-embolization tumor swelling may compress brainstem or cerebellum
3. may be used preoperatively to reduce vascularity. Performed 24–48 hours pre-op (not used prior to that, because of post-embolization edema)
4. caution with actively secreting tumors which may release vasoactive substances (e.g. epinephrine) upon infarction from the embolization
5. may also be used as primary treatment (± radiation) in patients who are not surgical candidates.
   In this case, is only palliative, as tumor will develop new blood supply
6. absorbable (Gelfoam®) and non-absorbable (Ivalon®) materials have been used

Surgical treatment
General information
The tumor is primarily extradural, with extremely vascular surrounding dura.
Suboccipital approach may cause dangerous bleeding and usually results in incomplete resection. Team approach by a neurosurgeon in conjunction with a neuro-otologist and possibly head and neck surgeon has been advocated. This approach utilizes an approach to the skull base through the neck.
ECA feeders are ligated early, followed rapidly by draining veins (to prevent systemic release of catecholamines).
Sacrifice of the jugular vein (JV) is tolerated if the contralateral JV is patent (often, the ipsilateral JV will already be occluded).
Surgical complications and outcome
The most common complications are CSF fistula, facial nerve palsy, and varying degrees of dysphagia (from dysfunction of lower cranial nerves). Dysfunction of any of the cranial nerves VII thru XII can occur, and a tracheostomy should be performed if there is any doubt of lower nerve function, and a gastrostomy feeding tube may be needed temporarily or permanently. Lower cranial nerve dysfunction also predisposes to aspiration, the risk of which is also increased by impaired gastric emptying and ileus that may occur due to reduced cholecystokinin (CCK) levels post-op. Excessive blood loss can also occur.
Even after gross total tumor removal, recurrence rate may be as high as one third.
39.3 Neuroblastomas
39.3.1 General information
Tumors arising from sympathetic ganglion. May occur anywhere in the sympathetic nervous system, most commonly from adrenal gland (40%), followed by sympathetic ganglia of thoracic (15%), cervical (5%) and pelvic regions (5%). Neoplasms under this rubric include:
1. neuroblastomas: the most undifferentiated and aggressive in this group
2. ganglioneuroblastomas
3. ganglioneuromas

Note: Olfactory neuroblastomas are called esthesioneuroblastomas (p. 1388).

39.3.2 Presentation
May present with abdominal mass, local or radicular pain, or (with high thoracic or cervical tumors) Horner’s syndrome. Spinal cord compression may occur from invasion through the neural foramen, and scoliosis may occur. Catecholamine precursors (homovanillic acid (HVA), vanillylmandelic acid (VMA) and dopamine) may be excreted and cause HTN (can be assayed in urine). Periorbital tumor and scoliosis may occur. Catecholamine precursors (homovanillic acid (HVA), vanillylmandelic acid (VMA) and dopamine) may be excreted and cause HTN (can be assayed in urine). Periorbital tumor

40 Pineal Region and Embryonal Tumors

40.1 Pineal region tumors

40.1.1 General information

**Key concepts**

- wide variety of pathology: germ cell tumors (mostly germinomas, teratomas), astrocytomas, pineal tumors (mostly pineoblastomas) account for most tumors
- since tumors may be of mixed cell types, CSF tumor markers (β-hCG, AFP…) are not as useful for diagnosis as they are for following response to treatment
- traditionally a test dose of XRT was employed, but there is a growing trend to obtain tissue diagnosis in all cases if possible before instituting treatment

Pineal region: the area of the brain bounded dorsally by the splenium of the corpus callosum and the tela chooroidea, ventrally by the quadrigeminal plate and midbrain tectum, rostrally by the posterior aspect of the 3rd ventricle, and caudally by the cerebellar vermis.

A striking feature is the diversity of lesions (neoplastic and nonneoplastic) that may occur in this location due to the variety of tissues and conditions normally present, as shown in Table 40.1.

40.1.2 Pineal cysts (PCs)

General information

Usually an incidental finding (i.e. not symptomatic), seen on ≈ 4% of MRIs or on 25–40% of autopsies (many are microscopic). The most common ones are intra-pineal glial-lined cysts with diameter <1 cm. Etiology is obscure, PCs are nonneoplastic, and may be due to ischemic glial degeneration or due to sequestration of the pineal diverticulum. They have been regarded as benign, but

</tbody>
</table>
the natural history is not known with certainty. PCs may contain clear, slightly xanthochromic, or hemorrhagic fluid. Rarely, they may enlarge, and like other pineal region masses, may become symptomatic by causing hydrocephalus by aqueductal compression, gaze paresis including Parinaud’s syndrome, or hypothalamic symptoms. Positional H/As have been attributed to PCs, the theory is that the cyst could intermittently compress the vein of Galen and/or sylvian aqueduct. This remains unproven since asymptomatic compression of the vein of Galen and the quadrigeminal plate has been demonstrated on MRI.

**Imaging**

May escape detection on CT because the cyst fluid density is often similar to CSF. MRI T1WI shows round or ovoid abnormality in region of pineal recess, signal varies with protein content (isointense or slightly hyperintense). T2WI occasionally show increased intensity. Gadolinium occasionally enhances the cyst wall with a maximum thickness of 2 mm; irregularities of the wall with nodular enhancement suggests the lesion is not benign. Epidermoid-dermoid cysts may also occur in the pineal region, and are larger and have different signal characteristics on MRI.

**Management**

Asymptomatic PCs < 2 cm diameter with typical appearance should be followed clinically and with annual imaging studies. Surgery to relieve symptoms or to obtain a diagnosis is suggested for symptomatic lesions or for ones that show changes on MRI.

Surgery options for patients with hydrocephalus:
1. CSF shunt: may not relieve gaze disturbance (from pressure on tectal plate)
2. Cyst excision: relieves symptoms and establishes diagnosis. Low morbidity
3. Stereotactic or endoscopic aspiration: may not get enough tissue for diagnosis
4. Endoscopic third ventriculostomy (ETV) (p. 1517): useful only for typical PCs as it does not obtain tissue for pathology. A few cases of regression of PCs after ETV have been reported.

### 40.1.3 Pineal region neoplasms

**General information**

Tumors in this region are more common in children (3–8% of pediatric brain tumors) than in adults (≤1%). Over 17 tumor types occur in this region. Germoma is the most common tumor (21–44% in American/European population, 43–70% in Japan), followed by astrocytoma, teratoma and pineoblastoma. Many tumors are of mixed cell type.

Germ cell tumors (GCT), ependymomas and pineal cell tumors metastasize easily through the CSF ("drop metastases").

**Pineal gland tumors**

**Pineal cell tumors**

A pineocytoma (AKA pinealcytoma) is a well differentiated neoplasm arising from pineal epithelium. Pineoblastoma (AKA pineblastoma) is a malignant tumor that is considered a primitive neuroectodermal tumor (PNET) (p. 666). Both can metastasize through the CSF, and both are radiosensitive.

**Germ cell tumors (GCT)**

When they arise in the CNS, GCTs occur in the midline in the suprasellar and/or pineal region (simultaneous suprasellar and pineal region lesions is diagnostic of a GCT, so-called synchronous germ cell tumors, comprise 13% of GCTs, and are highly sensitive to XRT). In the pineal region, these tumors occur predominantly in males. In females, GCTs are more common in the suprasellar region. Aside from benign teratomas, all intracranial GCTs are malignant and may metastasize via CSF and systematically. Types of GCTs:
1. germinomas: malignant tumors of primitive germ cells that occur in the gonads (called testicular seminomas in males, dysgerminomas in females) or in the CNS. Survival with these is much better than with nongerminomatous tumors
2. non-germinomatous germ cell tumors (NGGCT) include:
   a) embryonal carcinoma
   b) choriocarcinoma
endodermal sinus tumor (EST) AKA yolk sac carcinoma: usually malignant
d) teratoma
  ● mature
  ● immature

Tumor markers
GCTs characteristically (but not always) give rise to tumor markers in the CSF; see Tumor markers used clinically (p.600). Elevated CSF beta-human chorionic gonadotropin (β-hCG) is classically associated with choriocarcinomas, but also occurs with up to 50% of germinomas (which are more common). Alpha-fetoprotein (AFP) is elevated with endodermal sinus tumors, embryonal carcinoma and occasionally with teratomas. Elevated placental alkaline phosphatase (PLAP) in serum or CSF occurs with intracranial germinomas. Table 40.2 summarizes these findings. When positive, tumor markers can be followed serially to assess treatment and to look for recurrence (they should be checked in serum and CSF). NB: tumor markers alone are not usually sufficient for making a definitive diagnosis of a pineal region tumor since many of these tumors are mixed cell type.

Pediatric
A breakdown of pediatric pineal region tumors in one series is shown in Table 40.3 (series A). In 36 patients <18 yrs age, 17 distinct histological tumor types were identified: 11 germinomas (the most common tumor), 7 astrocytomas, and the remaining 18 had 15 different tumors.

Adult
GCTs and pineal cell tumors occur primarily in childhood and young adults. Thus, over the age of 40, a pineal region tumor is more likely to be a meningioma or a glioma. Series B in Table 40.3 includes both adult and pediatric patients.

Clinical
Almost all patients have hydrocephalus by the time of presentation, causing typical signs and symptoms of headache, vomiting, lethargy, memory disturbance, abnormally increasing head circumference in infants, and seizures. Parinaud’s syndrome (p.99), or the syndrome of the sylvian aqueduct, may be present. Precocious puberty may occur only in boys with choriocarcinomas or germinomas with syncytiotrophoblastic cells, due to luteinizing hormone-like effects of β-hCG secreted in the CSF. Suprasellar GCT: triad of diabetes insipidus, visual deficit and panhypopituitarism.

Drop metastases from CSF seeding can produce radiculopathy and/or myelopathy.

Management
The optimal management strategy for pineal region tumors has yet to be determined.

abbreviations: β-hCG=beta human chorionic gonadotropin, AFP=alpha-fetoprotein, PLAP=placental alkaline phosphatase
elevated PLAP may also occur in serum
tumor enhanced uniformly and had the classic appearance of a germinoma on MRI, a test dose of 5 Gy was given, and if the tumor would shrink then the diagnosis of germinoma was virtually certain and XRT was continued without surgery. This may needlessly expose a patient with benign or radio-resistant tumors to XRT.

"Trial XRT" should be avoided in tumors suspected of being teratomas or epidermoid cyst on MRI, and the response may be misleading in the relatively common situation of tumors with mixed cell types.

Management suggestions
1. get MRI of cervical, thoracic and lumbar spine to assess for drop mets
2. send for GCT markers (β-hCG, AFP, PLAP) (p.660). Somewhat helpful, but not adequate for diagnosis: if negative for GCT markers, it may be a pineal cell tumor, or it may be a GCT without markers, see Tumor markers (p.660); if positive, it can still be a mixed cell-type tumor:
   a) serum
   b) CSF (if able to safely obtain; LP is contraindicated with large intracranial mass and/or obstructive hydrocephalus; CSF may be obtained from EVD if placed)

a 36 children ≤ 18 yrs
b 370 tumors in patients 3–73 yrs old
3. obtain histology in most cases. Most often this involves a biopsy, which should be generous (to avoid missing other histologies in mixed cell tumors)
   a) if hydrocephalus: transventricular biopsy
   b) if no hydrocephalus:
      • open biopsy or
      • stereotactic biopsy or
      •? by CACE (see below)
4. based on markers and histology:
   a) germinoma: XRT+chemo
   b) all other tumors: one option is resection followed by adjuvant therapy (usually not very helpful) – see Indications (p.662) for controversies

Hydrocephalus

Patients presenting acutely due to hydrocephalus may be best treated with external ventricular drainage (EVD). This permits control over the amount of CSF drained, prevents peritoneal seeding with tumor (a rare event19), and may avoid having a permanent shunt placed in the significant number of patients who will not need one after tumor removal (although ≈ 90% of patients with a pineal GCT require a shunt). Ventricular access, via EVD or Frazier burr hole (p.1450), in the post-op period is important in the event of acute hydrocephalus.

Stereotactic procedures

May be used to ascertain diagnosis (biopsy), or to treat symptomatic pineal region cysts.20,21 Caution is advised since the pineal region has numerous vessels (vein of Galen, basal veins of Rosenthal, internal cerebral veins, posterior medial choroidal artery)22 which may be displaced from their normal position. The complication rate of stereotactic biopsy is: ≈ 1.3% mortality, ≈ 7% morbidity, and 1 case of seeding in 370 patients, and the diagnostic rate is ≈ 94%.10 A shortcoming of stereotactic biopsy is that it may fail to disclose the histologic heterogeneity of some tumors.

Two main stereotactic trajectories: 1) anterolateral (low frontal) approach below the internal cerebral veins, and 2) posterolateral trans-parieto-occipital.11 One study found that the trajectory correlated with complications, and they recommended the anterolateral approach.23 However, the correlation of trajectory and complications was not born out in another study,10 and they found that the complication rate was higher in firm tumors (pineocytomas, teratomas, and astrocytomas) and they recommend an open approach when the tumor appears difficult to penetrate on the first attempt at biopsy.

Stereotactic radiosurgery may be appropriate for treatment of some lesions.

Computer-assisted cisternal endoscopic approach (CACE)

Employs a supracerebellar infratentorial approach that permits visualization of neurovascular structures and avoids traversing brain parenchyma.11

Radiation treatment

For controversies regarding “test dose” XRT, see Management (p.660). Germinomas are very sensitive to radiation (and chemotherapy), and are probably best treated with these modalities and followed.

XRT is also utilized post-op for other malignant tumors. For highly malignant tumors or if there is evidence of CSF seeding, craniospinal XRT with a boost to the tumor bed is appropriate.

If possible, XRT is best avoided in the young child. Chemotherapy may be used for age < 3 yrs until the child is older when XRT is better tolerated.14

Surgical treatment of the tumor

Indications

Controversial. Some authors feel that most tumors (except germinomas, which are best treated with XRT) are amenable to open resection.24 Others feel that resection should be limited to ≈ 25% of tumors which are10:

1. radioresistant (e.g. malignant nongerminoma GCTs): 35–50% of pineal region tumors (larger numbers occur in series not limited to pediatric patients)
2. benign (e.g. meningioma, teratomas…)
3. well encapsulated
4. NB: malignant germ cell tumors should be without evidence of metastases (those with metastases do not benefit from surgery on the primary tumor)
5. pineocytoma: recommendation is for surgical excision + SRS for any residual

Options

1. direct surgery: obtains generous tissue for biopsy. Curative for benign lesions. Not the optimum treatment for malignant tumors and germinomas without complications
2. biopsy followed by adjuvant therapy: the preferred management (p.660) for malignancies and germinomatous germ cell tumors

Surgical approaches
Choice is aided by the pre-op MRI and includes:

1. most common approach: midline infratentorial-supracerebellar approach of Horsley and Krause as refined by Stein. Cannot be used if the angle of the tentorium is too steep (best assessed on MRI). May be done in the sitting position – risk of air embolism (p.1445) – or in the Concorde position (p.1445)

2. occipital transtentorial: wide view. Risk of injury to occipital visual cortex or splenium of corpus callosum. Recommended for lesions centered at or superior to the tentorial edge or located above the vein of Galen or for rare cysts with superior extension. The occipital lobe is retracted laterally, and the tentorium is incised 1 cm lateral to the straight sinus

3. transventricular: indicated for large, eccentric lesions with ventricular dilatation. Usually via a cortical incision in the posterior portion of the superior temporal gyrus. Risks: visual defect, seizures, and on dominant side language dysfunction

4. lateral paramedian infratentorial

5. transcallosal: largely abandoned except for tumors extending into corpus callosum and third ventricle

6. paramedian infratentorial-supracerebellar approach may be used for cysts that do not extend superiorly or contralaterally: avoids midline venous structures

Important surgical considerations:
The base of the pineal gland is the posterior wall of the 3rd ventricle. The splenium of the corpus callosum lies above, and the thalamus surrounds both sides. The pineal projects posteriorly and inferiorly into the quadrigeminal cistern. The deep cerebral veins are a major obstacle to operations in this region. Venous drainage of the pineal region must be preserved.

Surgical outcome
Mortality rate: 5–10% Postoperative complications include: new visual field deficits, epidural fluid collection, infection, and cerebellar ataxia.

40.2 Embryonal tumors

40.2.1 General information

A few words about PNETs
Initially, the term primitive neuroectodermal tumor (PNET) encompassed a wide variety of previously individually named tumors which all seemed to share certain pathologic features suggesting origin from a common progenitor cell in the subependymal matrix (primitive neuroectodermal cells) (although the actual cell of origin is unknown). They are histologically indistinguishable but genetically distinct. Now, the recommendation is to call these “embryonal tumors”, but the term PNET is entrenched. These tumors include: retinoblastoma, pineoblastoma, neuroblastoma, esthesioneuroblastoma. Medulloblastoma (MB) is more than just a PNET of the posterior fossa (see below), as alterations involved in evolution of MBs such as beta-catenin and APC mutations are absent in pineoblastomas and supratentorial PNETs (sPNETs). At least some MBs originate from the external granular layer (EGL) of the cerebellum.

Embryonal tumors
Location: Embryonal tumors most commonly arise in the cerebellar vermis (medulloblastoma), but also occur in cerebrum, pineal, brainstem or spinal cord. Primary spinal cord PNETs are extremely rare (approximately 30 cases reported by 2007). sPNETs have a worse prognosis than MB (see below).

Dissemination: Embryonal tumors (ETs) may disseminate via the CSF spontaneously or iatrogenically (following surgery or shunting, the latter is a rare cause of tumor dissemination). Thus, all patients with ETs require spinal axis evaluation (gadolinium enhanced MRI is about as sensitive as water-soluble myelography) and cytologic examination of CSF. Prophylactic craniospinal XRT is indicated following surgical removal, but cranial XRT is avoided if at all possible before 3 years of age to avoid intellectual impairment and growth retardation; see Radiation injury and necrosis (p.1560). Extranodal metastases can also occur.
Collin’s law: AKA period of risk of recurrence (PRR) is often applied to children who have been treated for embryonal tumors (especially medulloblastoma) but may also be used with any tumor thought to arise from a gestational event. It states that PRR is equal to the age at diagnosis plus 9 months. Patients that remain free of recurrence beyond the PRR have a much lower risk of recurrence, however recurrence beyond this time has been reported in a small number (<1.4% of cases), and other tumors may occur e.g. as a result of induction by XRT used to treat the initial tumor.

40.2.2 Medulloblastoma (MB)

General information

Key concepts

- a small-cell embryonal tumor of the cerebellum found predominantly in children (peak: 1st decade). The most common pediatric brain malignancy
- usually arises in the cerebellar vermis in the region of the apex of the roof of the 4th ventricle (fastigium), often producing hydrocephalus
- brainstem invasion usually limits complete surgical excision
- all patients must be evaluated for “drop mets”

Epidemiology

In children: MBs comprise 15–20% of intracranial tumors, 30-55% of p-fossa tumors. MB is the most common malignant pediatric brain tumor. MBs comprise ≤1% of adult brain neoplasms. Peak incidence: during 1st decade. Median age at diagnosis: 5–7 years (75% are diagnosed by age 15). Male:female ratio is 2:1. Familial cancer syndromes that include MB: Gorlin syndrome, Turcot syndrome (p.610).

Pathology

All MB are WHO grade IV. Histologic subtypes:

1. classic (90%): small, densely packed undifferentiated cells with hyperchromatic nuclei, scant cytoplasm (and inconstant cell clusters in Homer-Wright rosettes) (sometimes called “blue tumor”) (monotonous appearance)
2. desmoplastic (6%): similar to classic type with “glomeruli” AKA pale islands (collagen bundles and scattered, less cellular areas). Marked tendency for neuronal differentiation. More common in adults. Prognosis controversial: may be the same or less aggressive than classic MB
3. large cell (4%): large, round, and/or pleomorphic nucleoli, higher mitotic activity. In the few case reports, all were male. More aggressive than classic. Reminisces atypical teratoid/rhabdoid tumors of cerebellum, but has different phenotype and cytogenetic features

Molecular biology

The molecular genetic alterations in MBs can be divided into 3 groups:

1. non-random chromosomal abnormalities: (e.g. consistent deletion of 17p markers) has been shown in 35–40% 
2. information from gene profiling:
   a) ZIC and NSCL1 were the genes most closely correlated with MBs 
   b) certain genes were associated with more favorable outcome (using 8 genes a pattern associated with 80%-year survival compared to 17% when the pattern was lacking)
3. abnormalities in signal transduction pathways: e.g. neurotrophin signaling pathway (important in cerebellar development) or Sonic hedgehog (Shh)

Seeding and metastases

≈ 10–35% have seeded the craniospinal axis at the time of diagnosis, and extraneural mets occur in 5% of patients, sometimes promoted by shunting (although this is uncommon).
Clinical
Clinical history is typically brief (6–12 weeks). MBs usually arise in the cerebellar vermis, at the apex of the roof of the 4th ventricle (fastigium in the region of the posterior medullary velum), which predisposes to early obstructive hydrocephalus. Usual presenting symptoms: H/A, N/V, and truncal & appendicular ataxia. Infants with hydrocephalus may present with irritability, lethargy, or progressive macrocrania. Spinal drop mets may produce back pain, urinary retention or leg weakness. Common signs: papilledema, ataxia, nystagmus, EOM palsies.

Evaluation
Usually appears as a solid, IV-contrast-enhancing lesion on CT or MRI (however, a rare diffuse variant in children <3 yrs, medulloblastoma with extensive nodularity (MBEN), has been described). Most are located in the midline in the region of the 4th ventricle (laterally situated tumors are more common in adults). Most have hydrocephalus. Ependymoma (p.1365) is the main entity to differentiate from on imaging.

CT: noncontrast → typically hyperdense (due to high cellularity), contrast → most enhance. 20% have calcifications.

MRI: T1WI → hypo- to isointense. T2WI → heterogeneous due to tumor cysts, vessels and calcifications. Most enhance (including MBEN)

Spinal imaging: MRI with IV gadolinium or CT/myelography with water-soluble contrast should be done to rule-out “drop mets.” Staging is done either pre-op or within 2–3 weeks of surgery.

Treatment
Stratification of patients into risk groups guides therapy (Table 40.4).

MB are highly radiosensitive and moderately chemosensitive.

Treatment of choice: surgical debulking of as much tumor as possible (without causing neurological injury) followed by craniospinal XRT (radiation is necessary because of propensity to recur and to seed). Invasion of or attachment to the floor of the fourth ventricle (brainstem in the region of the facial colliculus) often limits excision. It is better to leave a small residual on the brain-stem (these patients do fairly well) than it is to chase every last remnant into the brain-stem (neurologic deficit is more likely with this).

Surgical exposure of midline cerebellar medulloblastomas requires opening of the foramen magnum, usually removal of the posterior arch of C1, and occasionally the arch of C2. Tumor spread with arachnoidal thickening (“sugar coating”) may occur.

XRT: optimal irradiation dose: 35–40 Gy to whole craniospinal axis +10–15 Gy boost to tumor bed (usually posterior-fossa) and to any spinal mets seen, all fractionated over 6–7 wks. Reduce dosages by 20–25% for age <3 yrs, or use chemotherapy instead. Lower dose radiation (25 Gy) to the neuraxis may provide acceptable control when confirmed gross total excision is achieved.

Chemotherapy: there is no standardized chemotherapy regimen. Lomustine (CCNU), cisplatin and vincristine (VCR) are primarily used, but are usually reserved for recurrence, for poor risk patients (below), or for children <3 yrs age. Significant survival advantage was shown in poor-risk children with adjuvant chemotherapy (5-year actuarial disease-free survival rate=87%) compared to those without (33%). No difference was observed among standard-risk patients.

Shunts: 30–40% of children require permanent VP shunts following p-fossa resection. The risk of shunt-related seeding has been quoted as high as 10–20% but this is probably overestimated. In the past, tumor filters were frequently used. They are less commonly used today because of the high incidence of obstruction.

</tr>
<tr>
<td><strong>Intermediate risk patients</strong></td>
</tr>
<tr>
<td>An intermediate risk group probably exists, but has been poorly characterized</td>
</tr>
</tbody>
</table>
Prognosis
Poor prognosticators\(^\text{47}\)
- younger age (especially if < 3 yrs)
- disseminated (metastatic) disease
- inability to perform gross-total removal (especially if residual > 1.5 cm\(^2\) in patient with localized disease)
- histological differentiation along glial, ependymal, or neuronal lines

One stratification scheme is shown in Table 40.4.

The sex of the child is an important predictor for survival of MB; girls had a much better outcome.\(^\text{51}\) Gene expression profiling is highly predictive of response to therapy, predicting outcome with much greater accuracy than current staging criteria.\(^\text{26}\) The ability of multiple biological and clinical markers to predict outcomes for patients with MB is currently under investigation.\(^\text{52,53}\)

Long-term survivors of MB are at significant risk for permanent endocrinologic, cognitive, and psychological sequelae of treatments. Infants and very young children with MB remain a difficult therapeutic challenge because they have the most virulent form of the disease and are at highest risk for treatment-related sequelae.

Most common site of recurrence is p-fossa.

Collins' law (p. 664) has also been used to define the period of risk of recurrence (PRR) but exceptions to the law have been reported.\(^\text{51}\)

40.2.3 Supratentorial primitive neuroectodermal tumors

General information
Supratentorial primitive neuroectodermal tumor (sPNETs) are highly malignant lesions primarily affecting young children (65% occur in age < 5 years) and account for 2.5–6% of childhood brain tumors. Occur rarely in adults. No gender predilection. Histologically indistinguishable from medulloblastoma (MB), they have a distinct genetic profile, are more aggressive, and often respond poorly to MB-specific therapies (especially pineoblastomas). Overall survival rate for sPNETs is substantially lower than that for MBs, with an expected 3-year progression-free survival of approximately 50% for localized supratentorial PNETs.\(^\text{54,55}\)

Ependymoblastoma
A highly cellular embryonal form of ependymal tumor.\(^\text{56}\) Occurs most often in age < 5 yrs. Prognosis is poor, with median post-op survival ranging from 12–20 months, and almost 100% mortality rate at 3 yrs. As with other tumors in this category, there is a tendency for subarachnoid seeding.

40.2.4 Atypical teratoid/rhabdoid tumors (AT/RT)

A unique embryonal tumor of the CNS. Many of these tumors were probably previously misdiagnosed as MBs. Occurs primarily in infants and children (>90% are < 5 years of age, with most age < 2 years). A minority are associated with primary renal rhabdoid tumor. 50% of AT/RTs occur in posterior fossa with a predilection for the cerebellopontine angle (CPA).

33% have CSF spread at presentation. Most patients die within 1 year of diagnosis. Histopathology: some tumors are composed entirely of rhabdoid cells, others have a combination of rhabdoid and areas resembling PNET/MB. Other cell types include: malignant mesenchymal cells (usually spindle cells), malignant epithelial cells (glandular or squamous).

Molecular biology: AT/RT and the rhabdoid renal tumors have a deletion or monosomy of chromosome 22.

40.2.5 Esthesioneuroblastoma

General information
Esthesioneuroblastoma (ENB), originally described in 1924, AKA olfactory neuroblastoma, AKA olfactory esthesioneuroblastoma, AKA esthesioneurocytoma, AKA olfactory placode tumor.\(^\text{57}\) A rare nasal neoplasm with an incidence 0.4 per 1,000,000 people.\(^\text{58}\) Believed to arise from the olfactory neural crest cells in the upper nares, it is considered to be malignant. These tumors occur over a wide age range (3 to 90 years), with a bimodal peak between the second and third decade and a second peak in the sixth and seventh decades.
Imaging

MRI: isointense with brain on T1-weighted imaging and intermediate to high signal intensity on T2-weighted imaging and enhance heterogeneously with gadolinium. Signal characteristics may mimic meningioma. For higher stage lesions, the cribiform plate may be eroded, better seen on thin cut CT. The most important factor determining resectability is intracranial extension. Magnetic resonance aids in the distinction between extradural tumor, dural invasion, or parenchymal brain invasion. None of these are specific to this tumor.

Differential diagnosis

Includes SNUC, nasal melanoma, nasal squamous cell carcinoma, and meningioma.

Diagnosis

Endoscopic biopsy is typically performed in the otolaryngology office prior to surgery. A clinical oncology exam should be performed, and if there is suspicion for metastatic disease a PET scan should be ordered which is sensitive for metastatic disease.

Clinical classification systems

The modified Kadish system (which added category D to the original Kadish system) is shown in Table 40.5. This classification appears to correlate with survival. Alternative systems by Biller et al. and Dulguerov and Calcaterra (see Table 40.5) attempt to subdivide the Kadish C classification, however the more popular modified Kadish system is more frequently used.

Pathologic grading

Hyams grading, a system used to define all upper respiratory tract carcinomas is utilized which assess nuclear pleomorphism, mitotic activity, rosette presence, necrosis, and summates these to produce Hyams 1–4 classification. It has been shown in meta-analysis as well as large series that Hyams grade 1 and 2 predict benign disease course, as compared to Hyams 3 and 4 which predict poor disease course. It is recommended grading be performed in all cases.

Treatment

Primary Treatment is controversial. Some institutions believe in upfront combined radiation therapy and chemotherapy prior to craniofacial resection. However most practice upfront surgery, which classically consisted of endoscopic resection with negative margins for Kadish A and B lesions, and for Kadish C and D lesions craniofacial resection which was bifrontal craniotomy with associated lateral rhinotomy. However, with the advent of endoscopic techniques the lateral rhinotomy is often replaced with a purely endoscopic approach unless there is inferior lateral orbital or maxillary involvement, in which case the lateral rhinotomy is frequently used. Finally, some institutions are now managing Kadish stages purely endoscopically unless they are unable to get negative margins at the time of surgery, then conversion to an open approach is performed or SRS is performed, however this is controversial.

Outcome

Median overall survival is typically 7.2 ± 0.7 years.

<td>T4: Brain Involvement</td>
</tr>
</tbody>
</table>
Mean progression free survival is 4.8 ± 0.7 years. The 5 and 10 year survivals are 63% and 40%, respectively. Population based analysis of the Surveillance Epidemiology and End Results (SEER) database confirm that Kadish staging, lymph node involvement, and age at diagnosis have significant prognostic value. These findings have been confirmed in a large meta-analysis recently published by Kane et al., in 2010. Further, higher Hyams grading (grades 3 and 4) correlate with a poorer prognosis.

Salvage treatment: For patients with recurrent disease, this typically occurs in 2 patterns: that of intracranial recurrence or those with distant metastasis. Intracranial recurrence is typically treated with repeat transcranial resection, however stereotactic radiosurgery is a viable option. In patients with distant metastasis, those with cervical lymph node metastasis should undergo modified radical neck dissection to understand the extent of disease. This typically leads to chemotherapy, of which platinum based therapies remain the standard of therapy at this time.

41 Tumors of Cranial, Spinal and Peripheral Nerves

41.1 Vestibular schwannoma

41.1.1 General information

Key concepts

- Histologically benign tumor of cranial nerve VIII located in the cerebellopontine angle (CPA)
- Usually arises from inferior division (controversial) of the vestibular portion of the VIII nerve
- 3 most common early symptoms (clinical triad): hearing loss (insidious and progressive), tinnitus (high pitched) and dysequilibrium (true vertigo is uncommon)
- W/U: All patients: MRI (without & with contrast), audiometrics (pure tone audiogram and speech discrimination). In addition for small VSs (≤ 15 mm dia): ENG, VEMP, ABR
- Histology: comprised of Antoni A (narrow elongated bipolar cells) and Antoni B fibers (loose reticulated)
- Choice of management option (observation, surgery, XRT or chemotherapy (Avastin®)) depends heavily on tumor size, growth, hearing status, VII function and presence of NF2

Vestibular schwannoma (VS) is a histologically benign schwann-cell sheath tumor that usually arises from the inferior division of the vestibular nerve (not the cochlear portion). VSs arise as a result of the loss of a tumor-suppressor gene on the long arm of chromosome 22 (in sporadic cases this is a somatic mutation; in neurofibromatosis Type 2 (NF2) this is either inherited or represents a new mutation that may then be transmitted to offspring). Older terms included for reference, that should be avoided: acoustic neuroma, acoustic neurinomas (neurinoma being obsolete term for schwannoma), neurilemoma or neurilemmoma.

41.1.2 Epidemiology

One of the most common intracranial tumors, comprising 8–10% of tumors in most series. Annual incidence is probably about 1.5 cases per 100,000 population – over the past couple decades this estimate has increased and the typical size at diagnosis has decreased as a result of the proliferation of MRI scans. In the US, annual incidence has been found to vary between 1.1 and 1.3 per 100,000 population between 2004 and 2007. VSs typically become symptomatic after age 30. At least 95% are unilateral.

Neurofibromatosis Type 2

The incidence of vestibular schwannomas (VS) is increased in neurofibromatosis (NFT), with bilateral VS being pathognomonic of neurofibromatosis Type 2 (NFT2), see central NFT (p.605). Any patient <40 yrs old with unilateral VS should also be evaluated for NFT2. Cytologically, the VSs of NFT2 are identical to sporadic cases, however in NFT2 the tumors form grape-like clusters that may infiltrate the nerve fibers (unlike most sporadic VSs which displace the eighth nerve).

41.1.3 Pathology

Tumors are composed of Antoni A fibers (narrow elongated bipolar cells) and Antoni B fibers (loose reticulated). Verocay bodies are also seen, and consist of acellular eosinophilic areas surrounded by parallel arrangement of spindle shaped schwann cells (they are not a cell type).

41.1.4 Clinical

Symptoms

General information

Symptoms are shown in Table 41.1. The type of symptoms are closely correlated with tumor size. Most initially cause the triad of ipsilateral sensorineural hearing loss, tinnitus and balance difficulties. Larger tumors can cause facial numbness, weakness or twitching, and possibly brainstem symptoms. Rarely, large tumor may produce hydrocephalus. With current imaging modalities (CT and especially MRI), increasing numbers of smaller lesions are being detected.
Symptoms from 8th nerve compression
Unilateral sensorineural hearing loss, tinnitus and dysequilibrium are related to pressure on the eighth nerve complex in the IAC. These are the earliest symptoms, and by the time of diagnosis, virtually all tumors have caused otologic symptoms.

Hearing loss is insidious and progressive in most (c.f. the hearing loss in Meniere’s disease which fluctuates), however 10% report sudden hearing loss (see below). 70% have a high frequency loss pattern, and word discrimination is usually affected (especially noticeable in telephone conversation).

The tinnitus is usually high pitched.

Unsteadiness manifests primarily as difficulty with balance; true vertigo occurs in < 20%.

Sudden hearing loss: The differential diagnosis for sudden hearing loss (SHL) is extensive.6 Idiopathic SHL (i.e. no identified etiology: must rule out neoplasm, infection, autoimmune, vascular and toxic causes) occurs in an estimated 10 per 100,000 population.7 1% of patients with SHL will be found to have a VS, and SHL may be the presenting symptom in 1–14% of patients with VS.8 SHL with VS is presumably due to an infarction of the acoustic nerve, or acute occlusion of the cochlear artery.

Treatment options for SHL include:
1. steroids: e.g. prednisone 60 mg PO q d × 10 d then tapered8
2. famciclovir (Famvir®) 500 mg po T ID × 10 d
3. heparin has been shown not to be of help
4. conservative treatment: rest, restriction of salt, alcohol and tobacco9
5. experimental: consideration may be given to thrombolytic therapy (p.1286), e.g. rt-PA

Symptoms from 5th and 7th nerve compression
Otalgia, facial numbness and weakness, and taste changes occur as the tumor enlarges and compresses the fifth and seventh nerves. These symptoms usually do not occur until the tumor is > 2 cm. This highlights an interesting paradox: facial weakness is a rare or late occurrence, even though the 7th nerve is almost always distorted early; whereas facial numbness occurs sooner once trigeminal compression occurs (often in the presence of normal facial movement), despite the fact that the 5th nerve is farther away.10 This may be due to the resiliency of motor nerves relative to sensory nerves.

Symptoms from compression of brainstem and other cranial nerves
Larger tumors cause brainstem compression (with ataxia, H/A, N/V, diplopia, cerebellar signs, and if unchecked, coma, respiratory depression and death) and lower cranial nerve (IX, X, XII) palsies (hoarseness, dysphagia…). Obstruction of CSF circulation by larger tumors (usually > 4 cm) may produce hydrocephalus with increased ICP.

Rarely, 6th nerve involvement may cause diplopia.
Signs

Hearing loss due to VIII involvement is the earliest cranial nerve finding. 66% of patients have no abnormal physical finding except for hearing loss (for other findings, see Table 41.2).

Since hearing loss is sensorineural, Weber test (p.580) will lateralize to the uninvolved side, and if there is enough preserved hearing, Rinne test (p.580) will be positive (i.e. normal; air conduction >bone conduction) on both sides.

Facial nerve (VII) dysfunction is uncommon before treatment. When present, it is usually graded clinically on the House and Brackmann scale (see Table 41.3).

Vestibular involvement causes nystagmus (may be central or peripheral) and abnormal electroneystagmography (ENG) with caloric stimulation.

| Table 41.2 Signs in 131 vestibular schwannomas (excluding hearing loss) |
|-----------------------------|---------|
| Sign                        | %       |
| abnormal corneal reflex     | 33      |
| nystagmus                   | 26      |
| facial hypoesthesia         | 26      |
| facial weakness (palsy)     | 12      |
| abnormal eye movement       | 11      |
| papilledema                 | 10      |
| Babinski sign               | 5       |

| Table 41.3 Clinical grading of facial nerve function (House and Brackmann11) |
|-----------------------------|---------|
| Grade | Function | Description |
| 1     | normal   | normal facial function in all areas |
| 2     | mild dysfunction | 1. gross: slight weakness noticeable on close inspection; may have very slight synkinesis 2. at rest: normal symmetry and tone 3. motion: a) forehead: slight to moderate movement b) eye: complete closure with effort c) mouth: slight asymmetry |
| 3     | moderate dysfunction | 1. gross: obvious but not disfiguring asymmetry: noticeable but not severe synkinesis 2. motion: a) forehead: slight to moderate movement b) eye: complete closure with effort c) mouth: slightly weak with maximal effort |
| 4     | moderate to severe dysfunction | 1. gross: obvious weakness and/or disfiguring asymmetry 2. motion: a) forehead: none b) eye: incomplete closure c) mouth: asymmetry with maximum effort |
| 5     | severe dysfunction | 1. gross: only barely perceptible motion 2. at rest: asymmetry 3. motion: a) forehead: none b) eye: incomplete closure |
| 6     | total paralysis | no movement |
Differential diagnosis
See Cerebellopontine angle (CPA) lesions (p. 1365). The major differentials are: meningioma, or neuroma of an adjacent cranial nerve (e.g. trigeminal).

41.1.5 Evaluation

General information
1. Brain MRI without and with contrast. FIESTA MRI if available. If MRI is contraindicated, then a CT scan without and with contrast
2. Temporal bone CT for detailed bony anatomy if surgery is contemplated
3. Audiometric evaluation:
   a) pure tone audiogram (see below)
   b) speech discrimination evaluation (see below)
   c) patients with small VSs (≤ 15 mm dia) also get:
      • ENG: (p. 674) assesses superior vestibular nerve
      • VEMP: (p. 675) assesses inferior vestibular nerve
      • ABR: (p. 675) prognosticates chance of hearing preservation

Audiometric and audiological studies

General information
Baseline studies are helpful for management treatment decisions and for later comparison and to assess the contralateral ear.

Pure tone audiogram (PTA)
May be useful as first-step screening test. Air conduction assesses the entire system, bone conduction assesses from the cochlea and proximally. PTA assesses the functionality of hearing (to help in treatment decision making) and acts as a baseline for future comparison. The pure tone average (also abbreviated PTA) is a single numerical score that is an average of the thresholds for frequencies across the audio spectrum (at 500, 1000 & 2000 Hz). On a standard audiogram, X’s denote the left ear (AS) and O’s denote the right ear (AD).

Progressive unilateral or asymmetric sensorineural hearing loss of high tones occurs in >95% of VSs. High-frequency hearing loss also happens to be the most common type of hearing loss with age or with noise induced sensorineural hearing loss, but is usually symmetrical. Only ≈ 1 in 1000 patients with asymmetric hearing have a VS. Other causes of asymmetrical sensorineural hearing loss: other CPA lesions (e.g. meningioma), inner ear lesions, intraaxial lesions (including 9 infarctions), multiple sclerosis. On hearing screening tests, an unexplained PTA difference from one ear to the other >10–15 dB is suspicious and should be investigated further.

Speech discrimination evaluation
Speech discrimination is maintained in conductive hearing loss, moderately impaired in cochlear hearing loss, and worst with retrocochlear lesions. No longer used for diagnostic purposes; a score of 4% suggests a retrocochlear lesion, as does a score that is worse than would be predicted based on PTA testing (the speech recognition threshold should be similar to PTA thresholds below 4 kHz). Has found usefulness in determining serviceability of hearing and prognosticating for hearing preservation surgery. Open-set word recognition score (WRS Table 41.4) is a more sensitive measure of communication ability than PTA.

</tbody>
</table>
Definition of serviceable hearing

There are many definitions of what constitutes serviceable hearing. Also, even nonserviceable hearing can offer some benefit. If WRS is good (≥70%) but PTA is poor, a hearing aid may provide significant benefit.

Two commonly used scoring systems for hearing are shown here:

1. Modified Gardner-Robertson system for grading hearing: shown in Table 41.5. Class I patients may use a phone on that side, class II patients can localize sounds.
2. The American Academy of Otolaryngology – Head and Neck Surgery Foundation (AAO-HNS) hearing classification system: shown in Table 41.6.

Some definitions of serviceable hearing (see text that follows for details):

1. AAO-HNS class A or B
2. “50/50 rule”: Gardner-Robertson class I or II (pure tone audiogram threshold ≤50 dB and speech discrimination score ≥50%)
3. some prefer a 70/30 rule (70%WRS, 30 dB PTA)
4. in a patient with good hearing in the contralateral ear, a speech discrimination score (SDS) of <70% in the affected ear is not considered good hearing; whereas if the contralateral ear is totally deaf, a SDS of ≥50% can be useful

Additional tests that are helpful with small VSs (≤15 mm diameter)

The ENG and VEMP evaluate the superior and inferior division of the vestibular nerve (VN) respectively. The inferior VN is closer to the cochlear nerve than the superior VN (Fig. 1.7), and small tumors (≤4 mm) of the inferior VN tend to be deeper and closer to the cochlear nerve than similar sized tumors of the superior division which tend to be more superficial and more easily removed.

Electronystagmography (ENG): Only tests the horizontal semicircular canal assesses the superior vestibular nerve which innervates it. Normally, each ear contributes an equal portion of the response. The ENG is considered abnormal if there is ≥20% difference between the two sides. Response

*aaverage of pure tone hearing thresholds by air conduction at 0.5, 1, 2 & 3 kHz
*bspeech discrimination at 40 dB or maximum comfortable loudness
may be normal with a small tumor arising from the inferior division of vestibular nerve. NB: the vestibular nerve may continue to function until almost all of the nerve fibers are affected. Mnemonic for the directionality of the nystagmus (direction is classified based on the fast phase of the nystagmus). COWS (Cold Opposite, Warm Same). NB: this is different than caloric testing for brain death and is a source of confusion.

Vestibular evoked myogenic potential (VEMP): Assesses inferior vestibular nerve by imparting acoustic energy to the saccule. Independent of hearing (can be done even with deafness from profound sensorineural hearing loss). Electrodes are placed on sternocleidomastoid muscle (SCM).

Auditory brainstem responses (ABR): AKA BAER (p. 240). The most common findings are prolonged I-III and I-V interpeak latencies. No longer used for diagnostic purposes (sensitivity is only ≈ 88–90% (i.e. will miss 10–12% of VSs) and specificity is only 85% ABR is useful for prognostication – poor wave morphology correlates with lower chance of preserving hearing (even with good hearing).

Radiographic evaluation

MRI
Thin slice axial plane gadolinium enhanced MRI is the diagnostic procedure of choice with sensitivity close to 98% and almost 0% false positive rate. Characteristic findings: round or oval enhancing tumor centered on IAC. Large VSs (>3 cm dia) may show cystic appearing areas on CT or MRI; in actuality these areas are usually solid. Adjacent trapped CSF cisterns may also give cystic appearance. In a pilot study, hyperintensity on T2 has been associated with soft and suckable tumors at the time of surgery and a trend towards better VII function preservation.

FIESTA MRI (fast imaging employing steady state acquisition): uses CSF as the contrast agent (does not use gadolinium), may improve visualization of the tumor and nerves.

CT scan
CT with IV contrast is second choice for imaging modality. If MRI is contraindicated and clinical suspicion of VS is strong but the CT is negative, small lesions may be visualized by introducing 3-4 ml of subarachnoid air via lumbar puncture, and scanning the patient with the affected side up (to trap air in region of IAC), non-filling of the IAC is indicative of an intracanalicular mass. Even with air contrast, CT was normal in 6% in Mayo series. Many VSs enlarge the ostium of the IAC (called trumpeting). Normal diameter of the IAC: 5-8 mm. 3-5% of VSs do not enlarge the IAC on CT (percentage is likely higher in small VSs vs. large ones). Thin-cut temporal bone CT should be obtained for operative planning. Important features to identify:

- For middle fossa approach: bony coverage of Geniculate ganglion to identify dehiscence
- For translab approach:
  - Extent of pneumatization of the mastoid and position of sigmoid sinus. An anterior sinus with poorly pneumatized mastoids can indicate a tight space for this approach
  - Position of the jugular bulb. If high riding, can indicate a tight space in translab approach
- For retrosigmoid translabral approach: location and thickness of bone coverage over the posterior semicircular canal and vestibular aqueduct. The extent of peritubular air cells and retrofacial air cells needs to be assessed in planning the approach and preventing CSF leaks.

41.1.6 Management

Management options
Management options include:

1. expectant management: follow symptoms, hearing (audiometrics) and tumor growth on serial imaging (MRI or CT). Intervention is performed for progression. Growth patterns observed:
   a) little or no growth: applies to most (83%) VSs confined within the IAC and 30% extending into CPA (see natural history of growth below)
   b) slow growth ≈ 2 mm/yr
   c) rapid growth: ≥ 10 mm/yr
   d) a few actually shrink
2. radiation therapy (alone, or in conjunction with surgery)
   a) external beam radiation therapy (EBRT)
      - stereotactic radiation
      - stereotactic radiosurgery (SRS) (p. 1564): single dose
      - stereotactic radiotherapy (SRT) (p. 1564): fractionated
3. surgery: approaches include the following (see below for details)
   a) retrosigmoid (AKA suboccipital): may be able to spare hearing
   b) translabyrinthine (and its several variations): sacrifices hearing, may be slightly better for sparing VII
   c) middle fossa approach (extradural subtemporal): only for small lateral VSs

4. chemotherapy: some preliminary promise for progressive NF2-related vestibular schwannomas with bevacizumab (Avastin®), an anti-VEGF (vascular endothelial growth factor) monoclonal antibody (see below). Side effects: hemorrhage occurs in ≈ 7% due to vessel necrosis

Patient/tumor factors influencing management decisions

In addition to the usual factors involved in the decision process with brain tumors, e.g. the patient’s general medical condition, age, natural history, etc., elements unique to VSs include: chances of preserving VII & V nerve function and hearing (in those with serviceable hearing) (all of which are related to tumor size), and the presence of NF2.

Specifics:
1. natural history of growth
   a) usual quoted range: ≈ 1–10 mm/yr. However this can be quite variable
   b) strictly intracanalicular tumors: only 17% grew outside the meatus (in 552 VSs over 3.6 years mean follow-up (230 were intrameatal at time of diagnosis, 322 had extrameatal extension))
   c) extrameatal tumors (with extension into CP angle): 30% grew >2 mm (in 522 VSs over 3.6 years mean follow-up)
   d) VSs that did not grow in the 5 years after diagnosis did not grow after that
   e) 6% actually decrease in size

2. natural history of hearing function in untreated intracanalicular VSs in AAO-HNS Group A (Table 41.6) patients
   a) 50% deteriorated to a lower class over 4.6 years (loss of ≥ 10 dB PTA or ≥ 10% SDS)
   b) after 4.6 years of observation, the proportion of patients eligible for hearing preservation treatment (as determined by a word recognition score class I (70–100% SDS)) was reduced to 28% (a 44% reduction) and by AAO-HNS class A to 9% (a 53% reduction)
   c) the risk of losing hearing was not related to: age, gender, acoustic tumor size (all tumors were intracanalicular) or tumor sublocalization (fundus, central, porus)
   d) hearing loss was positively correlated to the absolute volumetric tumor growth rate (tumors that eventually expand out of the IAC have a faster rate and degree of hearing loss compared to tumors remaining in the IAC)
   e) the risk of losing hearing was significantly lower for patients with 100% word recognition score. Over 4.6 years observation, 89% remained in WRS class I (Table 41.4) compared to only 43% for patients with only a small (1–10%) loss of WRS at diagnosis

3. size: as tumors exceed 15 mm diameter, treatment complications increase
   a) significantly lower chance for hearing preservation
   b) increased incidence of VII injury

4. presence of cysts: cystic tumors may display sudden and dramatic growth

5. serviceable hearing: see Definition of serviceable hearing (p.674)

6. hearing in contralateral ear

Management algorithm

- Small tumors (<15 mm diameter) with perfect hearing (WRS 100%):
  - Observe both radiographically (CT or MRI scan) plus serial hearing tests:
    - Every 6 months × 2 years after diagnosis, then (if stable)
    - Annually until 5 years after diagnosis, then (if stable)
    - At years 7, 9 & 14 after diagnosis
  - Annual audiology evaluations
    - Hearing deterioration (WRS <100%) but no growth: see below
    - Rationale: in patients with small tumors and normal WRS, comparing the results of hearing preservation following surgery or SRS to the natural history, the conclusion is that established tumor growth should be the main determinant for treatment

- Small tumors with serviceable hearing: management is very controversial
  - In general, patients with serviceable hearing but WRS <100% have a 50% chance of preserving their serviceable hearing (50/50 rule or AAO-HNS class A or B) with either observation, SRS or microsurgical resection
Selection options for intervention

Once treatment is elected (see algorithm above), the type of treatment must be selected.

Comparison of microsurgery vs. radiosurgery (SRS)

1. hearing preservation
   a) for patients with testable pre-operative hearing
      - summary: radiosurgery or stereotactic radiation appears to be better at preserving hearing than microsurgery. The difference is minor for tumors <10 mm and very good pre-operative hearing (70% SDS, and 30 dB PTA). The advantage of radiation is more pronounced for larger tumors and greater pre-operative hearing loss. Details:
        - SRS: overall, at 3, 5, and 10 years, 81% 77% and 66% of the patients maintained their GR hearing class (Table 41.5). For patients receiving a tumor margin dose of 13 Gy or less, those same percentages were 93% 87% and 87%25. Hearing preservation appears to be related to the radiation dose to the cochlea rather than to the tumor itself.
        - microsurgery: hearing preservation is significantly related to the tumor size and to the experience of the surgical team. Hearing preservation in Samii’s series of 1000 VS23 improved from 24% in the first 200 cases to 49% in later cases. Hearing preservation in microsurgery has improved with the use of direct cochlear nerve monitoring27 compared to auditory brainstem responses monitoring only. Hearing preservation in patients with class A, small tumors and direct cochlear nerve monitoring (compound nerve action potential) was 91%25. With microsurgery, the durability of the hearing preservation is also excellent with only 15% of patients with class A hearing after surgery, and 33% of patients with class B hearing after surgery slipping one class at 5 years follow-up.

2. facial nerve preservation
   a) preservation has been excellent with both microsurgery and radiosurgery
   b) microsurgery: 98.5% overall20 and 100% in tumors not touching the brainstem. Staged resection has been advocated by some to improve facial nerve preservation in giant VS (>4–4.5 cm).
   c) radiosurgery: 98% of patients.25 The incidence of facial neuropathy has significantly decreased since the SRS dose was decreased to 12–13 Gy. Facial neuropathy in the recent series occurred in patients having received 18–20 Gy.

3. trigeminal neuropathy (TGN)
   a) a complication classically feared in large tumors especially following SRS
   b) SRS: 7% incidence of TGN (mainly in patients receiving higher doses, i.e. 18 Gy). No patients who received a dose <13 Gy developed TGN.
   c) microsurgery: post-op TGN is not reported in most series

4. tumor control (local control rates, LCR):
   a) tumor control has been a concern with radiosurgery and with the more recent decrease in dose from 18–20 Gy to 12–14 Gy, long term data are lacking
   b) microsurgery: tumor recurrence has been poorly studied. Quoted rates in the literature vary between 0.5% at 6 years to 9.2%
c) SRS: tumor recurrence requiring re-treatment at 5 years was 4%\(^2\) but 18\% of patients presented with transient increase in the size of the tumor ("pseudogrowth") at a mean of 8 months, with later regression in half and stabilization to the new size in the other half

Vertigo and dizziness

For patients with episodic vertigo or balance difficulties as the predominant symptom; also, see points under Selection options for intervention (p.677):
1. remember: patients with VS are susceptible to other causes of vertigo as well, and patients should undergo ENG and functional balance assessment
2. vertigo that is due to the VS is often self-limited, and improves in 6–8 weeks to a reasonably tolerable level with no treatment (patients may do better with so-called "vestibular rehab")
3. residual dizziness and balance disturbances are common whether stereotactic radiosurgery (SRS) or microsurgery (MS) is used, but are typically less after MS
4. a recent study based on patient’s reported vertigo intensity has shown that symptoms of vertigo are improved by any treatment versus observation (van Gompel et al\(^3\))
5. after SRS: a minimum of 5-6 mos, and sometimes up to eighteen months may be required to produce beneficial effects. Symptoms are improved more rapidly after MS than with SRS
6. following MS: The severity of dizziness after MS depends on the pre-operative vestibular function on the affected side. If the ipsilateral vestibular function is absent pre-operatively, then patients will not suffer from dizziness or nausea post-op. if ipsilateral vestibular function is intact pre-op, then patients may be very dizzy and nauseated in particular for the first 24 hrs
7. conclusion:
   • observation may be the best choice for ≈20\% of patients
   • when treatment is desired:
     ○ surgery is the best choice for most VSs producing vertigo
     ○ SRS may be the right choice for some, especially: elderly patients (>70 yrs) with other health problems, for recurrence of VS, and for individual preference

Hydrocephalus

When hydrocephalus is present, it may require separate treatment with a CSF shunt – see Surgical considerations (p.679) – and may possibly be done at the same time as surgery for the VS (if surgery for the VS is indicated).

41.1.7 Surgical treatment

Approaches

General information

Three basic surgical approaches:
1. those with possibility of hearing preservation
   a) middle fossa (MF): poor access to posterior fossa (see below)
   b) retrosigmoid (RS) (see below) AKA retrosigmoid-transmeatal approach
2. translabyrinthine (TL): non hearing preserving (see below)

Excellent results have been reported with each of these approaches. These guidelines assume that the surgical team is comfortable with all three approaches.

Decision algorithm for approach

The choice of approach is dictated by hearing salvageability and tumor size as follows:
1. salvageable hearing ( Table 41.7 for definition and guidelines)
   a) if tumor is intracanalicular (no extension beyond a few mm into the posterior fossa (CPA); note: differences of opinion exist regarding how much tumor in the CPA can be removed via MF); use the middle fossa approach. Note: some authors exclusively use the retrosigmoid approach for hearing preservation even for these tumors with excellent results
   b) if tumor extends >few mm into the posterior fossa: use the retrosigmoid approach (it is generally accepted that the cisternal part of the tumor is not well exposed by the middle fossa approach, especially regarding the ability to dissect tumor off the nerves)
2. non salvageable hearing (see Table 41.7 for definition and guidelines)
   a) Use translabyrinthine approach or retrosigmoid approach
b) Either can be used irrespective of tumor size. Surgical team preference is the main deciding factor. Some influencing aspects:

- a young patient with no cerebellar atrophy might favor a translab approach
- an anteriorly situated sigmoid sinus and/or a high riding jugular bulb restrict the working space in the translab approach, and might favor a retrosigmoid approach

Surgical considerations

General information

The first surgical removal of a vestibular schwannoma was performed over a century ago in 1894.34

The facial nerve is pushed forward by the tumor in ≈ 75% of cases (range: 50–80%), but may occasionally be pushed rostrally, less often inferiorly, and rarely posteriorly. It may even continue to function while it is flattened to a mere ribbon on the tumor capsule surface.

Anesthesia with minimal muscle relaxants allows intra-op seventh nerve monitoring. In only ≈ 10% of large tumors is the cochlear nerve a separate band on the tumor capsule, in the remainder it is incorporated into the tumor.

Although total excision of tumor is usually the goal of surgery, facial nerve preservation must take precedence over degree of resection. Near total resection (very small sliver of tumor left on the facial nerve) or subtotal resection are all excellent options if the tumor is tightly adherent to the facial nerve or the brainstem. Both have excellent long term tumor control rate with either observation or post-op radiation.

If hydrocephalus is present, it is used to be standard practice to place a CSF shunt and wait ≈ 2 weeks before the definitive operation.35 While still acceptable, this is less commonly done at present, and shunting or EVD is often performed under the same anesthesia.

Large tumors may be approached by a staged surgical approach to debulk tumor and preserve facial nerve, or a planned subtotal resection followed by radiation. For tumors >3 cm, such approach seems to lead to improved results of facial nerve function.36

The extra anesthesia time involved in translab approach may be detrimental in the elderly.

Middle fossa approach

- indications:
  a) hearing preservation
  b) laterally placed tumors
  c) small tumors (usually <2.5 cm)
- pros:
  a) allows drilling and exposure of the IAC all the way to the geniculate ganglion (good for laterally placed tumors)
  b) basically an extradural subtemporal operation
- cons:
  a) potential damage to temporal lobe with risk of seizures
  b) facial nerve is the most superficial nerve in this exposure and therefore the surgeon works “around” the facial nerve (possibility of injury)
- technique summary
  a) lumbar drain

b) usually straight incision, starting in front of the tragus, extending cephalad for 6 cm, held open with a self-retaining retractor

c) the temporalis muscle is incised vertically (along the muscle fibers) along the most posterior aspect of the exposure, as well and reflected anteriorly

d) craniotomy: 4 cm × 3 cm

e) elevate the middle fossa dura, section the middle meningeal artery. Identify and preserve the greater superficial petrosal nerve (GSPN), arcuate eminence, V3, and true edge of the petrous bone (the false edge is the groove occupied by the superior petrosal sinus)
f) drill and expose the internal auditory canal all the way to Bill’s bar (for tumors extending laterally)
g) localize the facial nerve with the nerve stimulator

h) open the IAC dura along the main axis of the IAC, avoiding VII

i) identify the vestibular, cochlear and facial nerves

j) dissect the tumor off the nerves

</tbody>
</table>

**Translabyrinthine approach**

Often preferred by neurotologists.

1. pros & cons: See Table 41.8

2. technique summary

   a) Position: supine head rotated to contralateral side, can be done either with pins or doughnut if it is anticipated that no retractors will be used

   b) Prep the abdomen for fat graft (almost always used)

   c) skin incision should be tailored to the location of the sigmoid sinus (observe location of the sigmoid sinus and pinna of the ear on the pre-op MRI). Usually smaller opening than retrosigmoid approach

      • does not require a craniotomy. For large tumors requiring an “extended translab”, 1–2 cm of retrosigmoid dura should be exposed during the mastoidectomy to allow for retraction of the sigmoid sinus

      • dural opening along the IAC after identification of VII with stimulator

      • for large tumor: section the superior petrosal sinus and section the tentorium to gain better intradural exposure

      • closure requires fat graft

### Booking the case: Translabyrinthine approach for vestibular schwannoma

Also see defaults & disclaimers (p. 27).

1. position: supine with shoulder roll

2. equipment:

   a) microscope

   b) high speed drill

   c) ultrasonic aspirator

3. some surgeons work with neurotologist to assist with the IAC and for follow-up

4. neuromonitoring: facial EMG (does not require EEG tech), SSEPs for tumors involving the brainstem (requires EEG tech)

5. post-op: ICU

6. consent (in lay terms for the patient – not all-inclusive):

   a) procedure: surgery through an incision behind the ear to remove a tumor growing inside the skull on the nerve to the ear. Possible need for post-op lumbar drain. Fat graft (≈ always used)
b) alternatives: nonsurgical management with follow-up MRIs, other surgical approaches, radiation (stereotactic radiosurgery)

c) complications: CSF leak with possible meningitis, loss of hearing in ipsilateral ear (if not already lost), paralysis of facial muscles on the side of surgery with possible need for surgical procedures to help correct (correction is often far from perfect), facial numbness, post-op balance difficulties/vertigo, brainstem injury with stroke

Retrosigmoid approach
AKA posterior fossa, AKA suboccipital approach

- pros:
  a) familiar to most neurosurgeons
  b) quick access to the tumor
  c) hearing preservation possible
  d) NOTE: this approach is very versatile. Samii resected all his acoustic tumors via a retrosigmoid approach; he achieved a significant amount of brain relaxation and improved exposure by using in the sitting position, which is generally not used in the USA because of associated complications (p.1445)

- cons:
  a) cerebellar retraction: not a problem for tumors <4 cm, provided the craniotomy is sufficiently lateral and the cisterna magna and the CP angle cistern has been opened
  b) headaches: it has been suggested that headaches are more common following retrosigmoid craniotomy than after translabyrinthine craniotomy. Postulated mechanisms: purely extradural drilling in translab with no bone dust in subarachnoid space. More anterior skin incision in translab and less disruption of the suboccipital musculature and greater occipital nerve

Booking the case: Retrosigmoid craniotomy for vestibular schwannoma

Also see defaults & disclaimers (p. 27).
1. position: lateral decubitus with tumor side up
2. equipment:
   a) microscope
   b) ultrasonic aspirator
   c) image guided navigation system (if used) (may be helpful for placing skin incision and craniotomy more than for tumor localization)
3. some surgeons work with neurotologist to assist with the IAC and for follow-up
4. neuromonitoring: facial EMG (does not require EEG tech), BAERs, near field monitoring (CNAP: compound nerve action potential)
5. post-op: ICU
6. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery through an incision behind the ear to remove a tumor growing inside the skull on the nerve to the ear. Possible need for post-op lumbar drain. Possible fat graft (optional)
   b) alternatives: nonsurgical management with follow-up MRIs, other surgical approaches, radiation (stereotactic radiosurgery)
   c) complications: CSF leak with possible meningitis, loss of hearing in ipsilateral ear (if not already lost), paralysis of facial muscles on the side of surgery with possible need for surgical procedures to help correct (correction is often far from perfect), facial numbness post-op balance difficulties/vertigo, brainstem injury with stroke. Facial numbness (infrequent)

Technique summary
1. position: lateral decubitus with tumor side up, head in pins rotated (might need shoulder roll), zygomatic arch horizontal. 30° elevation of the head is paramount; see Posterior fossa (suboccipital) craniectomy, Lateral oblique position (p.1446)
2. percutaneous lumbar drain (optional)
3. incision is shaped like the pinna of the ear, 3 finger breaths behind the external auditory canal
4. the craniotomy has to be lateral enough to expose part of the sigmoid and part of the transverse sinuses and to allow a straight line of sight to the lateral end of the IAC
5. to prevent CSF leak, seal all bone edges with bone wax
6. dural opening along the lines of the craniotomy
7. exposure is enhanced by opening the cerebello-pontine angle cistern and the cisterna magna under the microscope and draining CSF (20–40 ml of CSF can also be drained via a lumbar subarachnoid catheter)
8. the petrosal vein is often sacrificed at the beginning of the procedure to allow the cerebellum to relax and fall back and to avoid tearing off the transverse sinus. Be careful not to coagulate the SCA that often runs with the petrosal vein
9. using the facial nerve stimulator, the posterior aspect of the tumor is inspected to make sure the facial nerve has not been pushed posteriorly
10. the thin layer of arachnoid that covers most tumors is identified. Vessels within the arachnoid may contribute to cochlear function and may be preserved by keeping them with the arachnoid
11. the plane between tumor and cerebellum may be followed to the brainstem, and occasionally to the VII nerve (this plane is harder to follow once bleeding from tumor debulking occurs)
12. to help locate the origin of the VII nerve at the brainstem see Table 41.9 and CPA anatomy in Fig. 1.9
13. the posterolateral tumor capsule is opened, and internal decompression is performed. The tumor is collapsed inward and the capsule is kept intact and is rolled laterally of VII and is eventually removed. The most difficult area to separate VII from tumor is just proximal to the entrance to the porus acusticus. A general recommendation is to accept a subtotal or near total resection to preserve anatomic continuity of the facial nerve in cases where it is identified by stimulation but because it is so flattened it cannot be seen as a separate structure on the surface of the tumor.
14. after the extracanalicular portion of tumor is removed, the dura over the IAC is incised, and the IAC is drilled open and tumor is removed from this portion. To preserve hearing, the bony labyrinth must not be violated. The posterior semicircular canal (SCC) is the most vulnerable structure (Fig. 41.1). The vestibule of the SCCs is also at risk but is less likely to be entered. The maximal amount of temporal bone drilling that can be accomplished without entering the posterior SCC can be determined from the pre-op CT. The operculum of the temporal bone, is a small step-off palpable with a nerve hook posteriorly from the porus acusticus. It marks the location of the vestibular aqueduct and is a good landmark for the posterior extent of the drilling in the retrosigmoid exposure of the IAC. Measuring the distance from the IAC to the posterior semicircular canal on a pre-op CT and measuring the thickness of the bone overlying the posterior semicircular canal are recommended for safe exposure of the IAC, in particular for hearing preservation. However, opening the labyrinth cannot always be avoided; and any opening should be plugged with bone-wax or muscle. If the facial nerve is not intact and is not going to be grafted, then the IAC should be plugged, e.g. by bone wax covered with a small piece of hammered muscle (hammering makes the muscle sticky by activating extrinsic clotting factors) and Gelfoam®.

NB: large tumors: in some large tumors, the capsule may be adherent to the brainstem and so portions of tumor must be left; recurrence rate among these is ≈ 10–20%. Large tumors may also involve V superiorly (sometimes VII is pushed up against V), and inferiorly may involve IX, X, and XI. The lower cranial nerves can usually be spared by dissecting them off of the tumor capsule, and protecting them with cottonoids.
Post-op care and care for complications

Cranial nerve and brainstem dysfunction
Facial nerve (VII)
If eye closure is impaired due to VII dysfunction: natural tears 2 gts to affected eye q 2 hrs and PRN. Apply Lacrilube® to affected eye and tape it shut q hs. If there is complete VII palsy with little chance of early recovery, or if facial sensation (Vth nerve) is also impaired, tarsorrhaphy is performed within a few days.

Facial re-animation (e.g. hypoglossal-facial anastomosis) is performed after 1–2 months if VII was divided, or if no function returns after 1 year with an anatomically intact nerve.

Vestibular nerve (VIII)
Vestibular dysfunction is common post-op, nausea and vomiting due to this (and also intracranial air) is common. Balance difficulties due to this clear rapidly, however, ataxia from brainstem dysfunction may have a permanent component.

Lower cranial nerves
The combination of IX, X and XII dysfunction creates swallowing difficulties and creates a risk of aspiration.

Fig. 41.1 Structures of the left temporal bone. CT scan (left petrous bone, axial slice) provided courtesy of Chris Danner, M.D.
Brainstem dysfunction
Brainstem dysfunction may occur from dissection of tumor off of the brainstem. This may produce ataxia, contralateral paresthesias in the body. Although there may be improvement, once present, there is often some permanent residual.

CSF fistula
Also, see CSF fistula (cranial) (p.384) for general information. CSF fistula may develop through the skin incision, the ear (CSF otorrhea) through a ruptured tympanic membrane, or via the eustachian tube and then through the nose (rhinorrhea) or down the back of the throat.

Rhinorrhea may occur through any of the following routes (circled numbers in Fig. 41.2):
- via the apical cells to the tympanic cavity (TC) or eustachian tube (the most common path)
- entry into the bony labyrinth – in order to reach the middle ear would require rupture e.g. of the oval window by overpacking bone wax into the labyrinth
  - through the vestibule of the horizontal semicircular canal (SCC)
  - through the posterior SCC (the posterior SCC is the most common area that is entered by drilling)
- follows the perilymphatic cells and tracts to the mastoid antrum
- through the mastoid air cells surgically exposed at the craniotomy site

Most leaks are diagnosed within 1 week of surgery, although 1 presented 4 years post-op. They appear to be more common with more lateral unroofing of the IAC. Meningitis complicates a CSF leak in 5–25% of cases, and usually develops within days of the onset of leak. Hydrocephalus may promote the development of a CSF fistula.

Treatment: 25–35% of leaks stop spontaneously (one series reported 80%). Treatment options include:
1. non-surgical:
   a) elevate HOB
   b) a percutaneous lumbar subarachnoid drain may be tried, although some debate its efficacy, and there is a theoretical risk of drawing bacteria into the CNS
2. surgical treatment for persistent leaks: In general, post-operative CSF leak (including rhinorrhea) is best addressed with immediate surgical re-exploration
   a) in the case of a translabyrinthine approach with absent ipsilateral hearing: to treat rhinorrhea, pack and permanently close the Eustachian tube via a trans tympanic membrane approach. This is very effective and avoids re-opening the surgical incision and removing the previously placed fat graft.
   b) if hearing is preserved (which excludes translab), every effort should be made to preserve the Eustachian tube function to preserve middle ear function. Re-expose the surgical field, re-wax the air cells and place additional fat graft, fascia, pericranium or other sealant over the exposed air cells. This aggressive management is the most definitive and rapid treatment, and avoids prolonged bed rest required by placing a lumbar drain and trying to control the leak in a conservative way
3. a CSF leak may be an indication of altered CSF hydrodynamics. Most of these patients demonstrate frank ventriculomegaly (hydrocephalus). In some patients the leak may function as a
pressure relief valve and thereby ameliorate the ventriculomegaly (i.e., there would be hydrocephalus if there wasn’t a leak). Adjunctive CSF shunting is usually also necessary or the repair will be more likely to fail.

### Outcome and follow-up

Complete surgical removal was reported in 97–99% of cases.55

### Surgical morbidity and mortality

Also see Post-op considerations for p-ossa cranis (p. 1451). Estimated frequency of some complications:66; the most common complication is CSF leakage in 4–27%2 (see above), meningitis in 5.7% stroke in 0.7% subsequent requirement for CSF shunt (for hydrocephalus or to treat leak) in 6.5%

The mortality rate is ≈ 1% at specialized centers.23,45,47

#### Cranial nerve dysfunction

Table 41.10 shows statistics of VII and VIII cranial nerve preservation following suboccipital removal of VSs in several combined groups of patients. For more details, see below.

Post-radiation cranial neuropathies generally appear 6–18 months following stereotactic radiosurgery (SRS),49 and since more than half of these resolve within 3–6 months after the onset the recommendation is treat these with a course of corticosteroids.

**Facial nerve (VII)**

See Table 41.3 for the House and Brackmann grading scale. Grades 1–3 are associated with acceptable function. Facial nerve preservation is related to tumor size.

**Surgery:** With the use of modern facial nerve monitoring techniques, anatomical integrity of the facial nerve can be achieved in >90% even for very large tumors and in close to 99% in medium size tumors.50 In cases where the nerve is so flattened that tumor has to be left over the nerve to preserve its anatomical integrity, functional outcome of the facial nerve is nevertheless lower, especially with larger tumors. Excellent outcome (HB grade I–III) was only achieved in 75% of the patients with large tumors and 91% in medium size tumors.

**SRS for tumors ≤ 3 cm diameter:** With modern SRS dosimetry (12–13 Gy for patients with serviceable hearing and 13–14 Gy for patients with non serviceable hearing, the incidence of new facial nerve weakness was 4%51

**Vestibulo-acoustic nerve (VIII)**

Patients with unilateral VS and Class I or II hearing (Table 41.5) comprised 12% of cases in a large series.52 Preservation of hearing is critically dependent on tumor size, with little chance of preservation with tumors >1–1.5 cm diameter. Chances of preserving hearing may possibly be improved by intra-operative brainstem auditory evoked potential monitoring.53 In centers treating large numbers of VSs, hearing preservation rates of 35–71% can be achieved with tumors <1.5 cm52.54 (although a range of 14–48% may be more realistic55). Hearing may rarely be improved post-op.56

**SRS:** for tumors ≤ 3 cm diameter,57 hearing was preserved in 26% of 65 cases with pre-op pure tone threshold <90 dB. Hearing loss has been correlated with increase in tumor size.58 NB: there is a high rate of hearing loss at 1 year. SRT: useful hearing was preserved in 93%59

**Vestibular nerve function** is rarely normal post-op. Attempts at “vestibular” sparing surgery have shown no better results than surgery not specifically addressing this issue. Most patients with unilateral loss of vestibular nerve function will learn to compensate to a significant degree with input from the contralateral side, if normal. Patients with ataxia as a result of brainstem injury from the tumor or the surgery will have more difficulties post-op. Some patients will seem to do well initially post-op with respect to vestibular nerve function, only to undergo a delayed deterioration several

months post-op. These cases likely represent aberrant regeneration of the vestibular nerve fibers and may be extremely difficult to manage. Some experts advocate cutting the vestibular nerve, as for Meniere’s disease (p. 573).

Trigeminal nerve (V)
Postoperative trigeminal nerve symptoms occur transiently in 22% and permanently in 11% following microsurgery, similar to the results of SRS.60 New facial numbness occurred in 2% with SRT.59

Lower cranial nerves
Injuries to IX, X and XI occur infrequently following surgery on large tumors that distort the nerves and displace them inferiorly against the occipital bone.

Recurrence
Following microsurgery (MS)
Recurrence is highly dependent on extent of removal. However, recurrence can develop in tumors that were apparently totally removed, or when subtotal resection was performed. This can occur many years after treatment. Tumor progression rate following subtotal resection is ≈ 20%55 All patients should be followed with imaging (CT or MRI). In older series with up to 15 yrs follow-up, local control rate (LCR) after “total resection” is ≈ 94% More recent series with MRI follow-up indicate recurrence rates of 7–11% (3–16 yrs follow-up).55

Use of EBRT
EBRT may improve LCR in incompletely resected tumors as shown in Table 41.11 (note: with the long survival expected with benign tumors, post XRT complications may occur).

Microsurgery vs. SRS
The long-term results for SRS using the current recommended dose of 14 Gy are still not known34 (in spite of journal article titles suggesting otherwise62). In a non-randomized retrospective study60 of VSs < 3 cm dia, the short-term LCR (median 24 mos follow-up) was 97% for microsurgery vs. 94% for stereotactic radiosurgery (SRS). However, for benign tumors, long-term follow-up is critical (possibly 5–10 years49), and this study suggests that the long-term LCR will be better for MS than SRS. SRS studies with long-term follow-up63 are not directly comparable because in the cases with longest follow-up, higher radiation doses were used with a resultant higher incidence of radiation complications, and an anticipated better LCR.

Initially there may be temporary enlargement of the tumor accompanied by loss of central contrast enhancement following SRS in ≈ 5% of patients65 (with up to 2% of patients showing actual initial tumor growth), and so the need for further treatment after SRS should be postponed until there is evidence of sustained growth.65 Surgery should therefore be avoided during the interval from 6 to 18 months after SRS because this is time of maximum damage from the radiation.65

Although the numbers are small, there have been indications that the rate of VII nerve injury may be higher in patients undergoing microsurgery following SRS failure to achieve LCR compared to cases where microsurgery was the initial procedure,66,67 however, this has been disputed.65 Lastly, there is a potential for malignant transformation of VSs following SRS including triton tumors68,69 (malignant neoplasms with rhabdoid features) or the induction of skull base tumors (which has been reported with external beam radiation70), as well as the risk of late arterial occlusion (the AICA lies near the surface of VSs), any of which may occur many years later.

Treatment for recurrence following microsurgery
Repeat surgery for recurrent VS is an option. One series of 23 patients71 showed that 6 of 10 patients with moderate or normal VII function maintained at least moderate function after reoperation,

*a with doses < 45 Gy, LCR was 33% with > 45 Gy LCR was 94%
3 patients had increased ataxia, and 1 patient had a cerebellar hematoma. The use of SRS has been endorsed by some for recurrence of VS following one or more MS procedures.\(^5\) Using SRS for recurrent VSs resulted in worsening of facial nerve function in 23% of patients with Grade I-III function before SRS (median follow-up = 43 mos), and 14% developed new trigeminal symptoms.\(^5\) 6% of patients developed tumor progression after SRS.

Hydrocephalus

May occur following treatment (MS or SRS) for VS, and may even occur years later. The increased CSF pressure may also predispose to development of a CSF fistula.

### 41.2 Tumors of peripheral nerves: Perineurioma

An nerve sheath tumor. Variants:

1. intraneural perineurioma: usually solitary lesion of adolescence or young adulthood, affecting primarily peripheral nerves (cranial nerve involvement is rare). Pseudo–onion bulb formation with cylindrical enlargement of the nerve over 2–10 cm. Mitotic activity is rare, MIB-1 labeling index is low. Chromosome 22 loss is characteristic,\(^72\) no NFI association. Treatment: conservative sampling of lesion, not resection

2. soft tissue perineurioma: uncommon. Only rarely can an associated nerve be identified. Almost exclusively benign, but malignant variety does occur. Female: male ratio = 4:1. In males, hands are often affected. Discrete, but not encapsulated, diameter = 1.5–20 cm. Treatment: gross total excision is curative

### References

42 Meningiomas

42.1 General information

Key concepts

- slow growing, extra-axial tumor, usually benign, arise from arachnoid (not dura)
- imaging (MR or CT): classically broad based attachment on dura often with dural tail, typically enhance densely, may cause hyperostosis of adjacent bone
- MRI: isointense on T1 WI, hypodense on T2 WI
- 32% of incidentally discovered meningiomas do not grow over 3 years follow-up
- surgical indications: documented growth on serial imaging and/or symptoms referable to the lesion that are not satisfactorily controlled medically
- most (but not all) are cured if completely removed, which is not always possible
- most commonly located along falx, convexity, or sphenoid bone
- frequently calcified. Classic histological finding: psammoma bodies

Meningiomas are the most common primary intracranial tumors. They are usually slow growing, circumscribed (non-infiltrating), benign lesions. Histologically malignant (incidence: \( \approx 1.7\% \) of meningiomas\(^1\)) and/or rapidly growing varieties are also described; a rapidly growing lesion that looks like a meningioma may be a hemangiopericytoma (p.701). Actually arise from arachnoid cap cells (not dura). May be multiple in up to 8% of cases,\(^2\) this finding is more common in neurofibromatosis. Occasionally forms a diffuse sheet of tumor (meningioma en plaque). This section considers intracranial meningiomas.

May occur anywhere that arachnoid cells are found (between brain and skull, within ventricles, and along spinal cord). Ectopic meningiomas may arise within the bone of the skull (primary intraosseous meningiomas)\(^3\) and others occur in the subcutaneous tissue with no attachment to the skull. Most are asymptomatic (see below).

42.2 Epidemiology

As many as 3% of autopsies on patients >60 yrs age reveals a meningioma.\(^4\) Meningiomas account for 14.3–19% of primary intracranial neoplasms.\(^5\) Incidence peaks at 45 years age. Female: male ratio is 1.8:1.

1.5% occur in childhood and adolescence, usually between 10–20 years age.\(^6\) 19–24% of adolescent meningiomas occur in patients with neurofibromatosis type I (von Recklinghausen's).

42.3 Common locations

42.3.1 General information

Table 42.1 lists common locations. Other locations include: CP-angle, clivus, planum sphenoidale and foramen magnum. \( \approx 60–70\% \) occur along the falx (including parasagittal), along sphenoid bone (including tuberculum sellae), or over the convexity. Childhood meningiomas are rare, 28% are intraventricular, and the posterior fossa is also a common site.

42.3.2 Sphenoid wing (or ridge) meningiomas

Three basic categories\(^8\):
1. lateral sphenoid wing (or pterional): behavior and treatment are usually similar to convexity meningioma
2. middle third (or alar)
3. medial (clinoideal): tend to encase the ICA and the MCA as well as cranial nerves in the region of the superior orbital fissure and the optic nerve. May compress brainstem. Total removal is often not possible
42.3.3 Parasagittal and falx meningiomas

Up to 50% invade the superior sagittal sinus (SSS). Grouped based on location along AP direction of SSS as:
1. anterior (ethmoidal plate to coronal suture): 33% Most often present with H/A and mental status changes
2. middle (between coronal and lambdoidal sutures): 50% Most often present as Jacksonian seizure and progressive monoplegia
3. posterior (lambdoidal suture to torcular Herophili): 20% Most often present with H/A, visual symptoms, focal seizures, or mental status changes

Classification systems for the extent of SSS invasion include one by Bonnal and Brotchi,9 and a more recent one by Sindou et al.10 shown in Fig. 42.1.

Parasagittal meningiomas may originate at the level of the motor strip, and a common initial manifestation of these is a contralateral foot drop.11

| Table 42.1 Location of adult meningiomas (series of 336 cases) |
|-----------------------------------|-----|
| Location                          | %   |
| parasagittal                      | 20.8|
| convexity                         | 15.2|

| orbital                           | 1.2 |
| spinal                            | 1.2 |
| intrasylvian                      | 0.3 |
| extracalvarial                    | 0.3 |
| multiple                          | 0.9 |

42.3.4 Olfactory groove meningiomas

Presentation (usually asymptomatic until they are large) may include:
1. Foster Kennedy syndrome (p.99): anosmia (patient is usually unaware of this), ipsilateral optic atrophy, contralateral papilledema
2. mental status changes: often with frontal lobe findings (apathy, abulia…)
3. urinary incontinence
4. posteriorly located lesions may compress the optic apparatus causing visual impairment
5. large lesions may compress the fornix and cause short-term memory loss
6. seizure

The morbidity, mortality and difficulty in achieving total removal increase significantly for tumors >3 cm in size.12

Pre-op MRA, CTA or angiogram may be helpful to assess location of anterior cerebral arteries relative to the tumor. 70–80% of these get the majority of their blood supply from the anterior ethmoidal artery, which is usually not embolized due to risk to ophthalmic artery (and blindness). If there are substantial middle meningeal feeders, these may be embolized, but the benefit tends to be small.
42.3.5 Planum sphenoidale meningiomas

Arise from the flat part of the sphenoid bone (see Fig. 42.2) anterior to the chiasmatic sulcus in the posterior part of the anterior cranial fossa.

42.3.6 Tuberculum sellae meningiomas (TSM)

The site of origin of these tumors is only about 2 cm posterior to that of olfactory groove meningiomas. The tuberculum sellae is the bony elevation between the chiasmatic sulcus and the sella turcica (see Fig. 42.2). By definition, the anterior margin of the chiasmatic sulcus (the limbus sphenoidale) is the demarcation between the anterior and middle cranial fossa. Therefore these tumors originate in the middle fossa (unlike planum sphenoidale meningiomas which are in the anterior fossa).

TSMs are notorious for producing visual loss (chiasmal syndrome = primary optic atrophy + bitemporal hemianopsia). When a TSM grows posteriorly into the sella turcica it may be mistaken for a pituitary macroadenoma (see Fig. 89.3 for MRI and differentiating features).
42.3.7 Foramen magnum meningiomas

As with any foramen magnum (FM) lesion (p. 1367); the neurologic symptoms and signs can be very confusing and often do not initially suggest a tumor in this location.

In the French Cooperative Study, there were 106 FM meningiomas,13 31% arose from the anterior lip, 56% were lateral, and 13% arose from the posterior lip of the FM. Most are intradural, but they can be extradural or a combination (the latter 2 have a lateral origin and are often invasive, which makes total removal more difficult).14 They may be above, below, or on both sides of the vertebral artery.14

42.4 Pathology

Four critical histopathological variables:
1. grade see Table 42.2
2. histological subtype see Table 42.2
3. proliferation indices (p. 694)
4. brain invasion (p. 694)

There are a number of pathologic classification systems,15,16(p.465),17 and transitional forms between the major types exist. More than one histological pattern may be seen in a given tumor. The WHO 2000 classification is shown in Table 42.2.

1. meningiomas with low risk of both recurrence and/or aggressive growth (WHO grade III)
   a) meningothelial or meningotheliomatous, AKA syncytial: the most common. Sheets of polygonal cells. Some use the term angiomatous for meningotheliomatous variety with closely packed blood vessels
   b) fibrous or fibroblastic: cells separated by connective tissue stroma. Consistency is more rubbery than meningotheliomatous or transitional
   c) transitional: intermediate between meningotheliomatous and fibrous. Cells tend to be spindle shaped, but areas of typical meningotheliomatous cells occur. Whorls, some of which are calcified (psammoma bodies)
   d) psammomatous: calcified meningothelial whorls
   e) angiomatous
   f) microcystic: AKA “humid” or vacuolated meningioma. The characteristic dilated extracellular spaces are usually empty, but occasionally contain substance that stains positive for PAS (- glycoprotein) or contain fat.18 The cysts may coalesce and form grossly or radiologically visible cysts and may resemble astrocytomas
   g) secretory
   h) lymphoplasmacyte-rich

2. meningiomas with greater recurrence risk and/or aggressive growth include
   a) atypical meningioma: increased mitotic activity (1–2 mitotic figure/high-powered field), increased cellularity, focal areas of necrosis, giant cells. Cellular pleomorphism is not unusual

</tr>
</tbody>
</table>
but is not significant in and of itself. Increasing atypia appears to correlate with increasing aggressiveness

b) rhabdoid meningiomas: usually have malignant features and behave aggressively. Behavior in the absence of malignant features is undetermined\(^\text{19}\)
c) malignant meningiomas: AKA anaplastic, papillary or sarcomatous. Characterized by frequent mitotic figures, cortical invasion, rapid recurrence even after apparent total removal,\(^\text{20}\) and, rarely, metastases (see below). Frequent mitotic figures (≥4 mitoses per high-power field) or the presence of papillary features are strong predictors of malignancy. May be more common in younger patients

Obsolete terms (in the current WHO classification) presented for context in older literature: metaplastic, myxomatous, xanthomatous (abundant cytoplasmic lipids; appear vacuolated), lipomatous, granular, chondroblastic, osteoblastic, melanotic. Angioblastic or (meningeal) hemangiopericytomas; true hemangiopericytomas are sarcomas (p.701). (Others use the term “angioblastic” for tumors histologically similar to hemangioblastoma. Angioblastic meningiomas were felt to have more malignant clinical characteristics than other forms.\(^\text{16} (p\ 479-83)\))

Proliferation indices
Due to variation between institutions and observers, it is advised that proliferation indices (e.g. Ki-67 or MIB-1) not be used as the sole discriminant for grading. However, these indices do correlate with prognosis (see Table 42.3). Adding the phrase “with high proliferative activity” is suggested for tumors with a very high index.\(^\text{19}\)

42.4.1 Brain invasion
The presence of brain invasion increases the likelihood of recurrence to levels similar to atypical meningiomas (not anaplastic),\(^\text{22}\) but is not an indicator of malignant grade. Brain invasion in atypical meningiomas does not dictate malignant behavior. Adding the phrase “with brain invasion” is suggested to denote higher risk of recurrence.\(^\text{19}\)

42.4.2 Metastases
Very rarely a meningioma may metastasize outside the CNS. Most of these are angioblastic or malignant. Lung, liver, lymph nodes and heart are the most common sites.

42.4.3 Differential diagnosis/diagnostic considerations of meningioma
1. multiple meningiomas: suggests neurofibromatosis 2 (NF2)
2. pleomorphic xanthoastrocytoma (PXA) (p.635): may mimic meningiomas since they tend to be peripherally located and may have a dural tail
3. Rosai-Dorfman disease: especially if extracranial lesions are also identified. A connective tissue disorder with sinus histiocytosis and massive painless lymphadenopathy (most have cervical lymphadenopathy). Usually in young adults. Isolated intracranial involvement is rare. MRI: dural-based enhancing mass with signal characteristics similar to meningioma, may have dural tail. Most common intracranial locations: cerebral convexities, parasagittal, suprasellar, cavernous sinus. Pathology: dense fibrocollagenous connective tissue with spindle cells and lymphocytic infiltration, stains for CD68 & S-100. Histiocytic proliferation without malignancy. Foamy histiocytes are characteristic. Surgery and immunosuppressive therapy not effective. Low-dose XRT may be the best option

42.5 Presentation

Symptoms depend on the location of the tumor, and some specific locations are associated with well-described symptom complexes. Seizures may occur with supratentorial meningiomas as a result of irritation of the cerebral cortex.

Asymptomatic meningiomas

Meningiomas are the most common primary intracranial tumors, and most remain asymptomatic throughout the patient’s life. The routine use of CT & MRI for numerous indications inevitably results in the discovery of incidental (asymptomatic) meningiomas. In a population based study (the study population was middle class Caucasians and result may not be generalizable to other groups), incidental meningiomas were seen in 0.9% of MRIs. Another series, 32% of primary brain tumors seen on imaging studies were meningiomas, and 39% of these were asymptomatic. Of 63 cases followed for >1 year with nonsurgical management, 68% showed no increase in size over an average follow-up of 36.6 mos, whereas 32% increased in size over 28 mos average follow-up. Asymptomatic meningiomas with calcification seen on CT and/or hypointensity on T2WI MRI appeared to have a slower growth rate.

Data is lacking to make evidence-based management guidelines. A suggestion is to obtain a follow-up imaging study 3–4 months after the initial study to rule-out rapid progression, and then repeat annually for 2–3 years. The development of symptoms would prompt performing a study at that time.

Treatment is indicated for lesions that produce symptoms that cannot be satisfactorily controlled medically, or for those that demonstrate significant continued growth on serial imaging studies. When surgery was performed, the perioperative morbidity rate was statistically significantly higher in patients >70 years old (23%) than in those <70 (3.5%).

42.6 Evaluation

42.6.1 MRI

Occasionally may be isointense with brain on T1WI and T2WI, but most enhance with gadolinium. Brain edema may or may not be present. Calcifications appear as signal voids on MRI. Gives information regarding patency of dural venous sinuses (accuracy in predicting sinus involvement is ≈ 90%). “Dural tail” is a common finding.

42.6.2 CT

Appear as homogeneous, densely enhancing mass with broad base of attachment along dural border. Non-contrast Hounsfield numbers of 60–70 in a meningioma usually correlates with presence of psammomatous calcifications. There may be little cerebral edema, or it may be marked and may extend throughout the white matter of the entire hemisphere.

Intraventricular meningiomas: 50% produce extraventricular edema. On angio, these may falsely appear malignant.

Prostate cancer may mimic meningioma (prostate mets to brain are rare, but prostate frequently goes to bone, and may go to skull and can cause hyperostosis).

42.6.3 Angiography

Classic pattern: “comes early, stays late” (appears early in arterial phase, blush persists beyond venous phase). Meningiomas characteristically have external carotid artery feeders. Exceptions: low frontal median (e.g. olfactory groove) meningiomas which feed from the ICA (ethmoidal branches of the ophthalmic artery). Suprasellar meningiomas may also be fed by large branches of the ophthalmic arteries. Parasellar meningiomas tend to feed from the ICA. Secondary vascular supply may be derived from pial branches of the anterior, middle, and posterior cerebral arteries.

Artery of Bernasconi & Cassinari AKA artery of tentorium (a branch of the meningohypophyseal trunk) AKA the “Italian” artery: enlarged in lesions involving tentorium (e.g. tentorial meningiomas).

Angiography also gives information about occlusion of dural venous sinuses, especially for parasagittal/falx meningiomas. Oblique views are often best for evaluating patency of the superior sagittal sinus (SSS). Angiography can also help confirm diagnosis by the distinctive prolonged homogeneous tumor blush. Angiography also provides an opportunity for pre-op embolization (see below).
Pre-op embolization: Reduces the vascularity of these often bloody tumors, facilitating surgical removal. Timing of subsequent surgery is controversial. Some advocate waiting 7–10 days to permit tumor necrosis which simplifies resection. Complications include: hemorrhage (intratumoral and SAH), cranial nerve deficits (usually transient), stroke from embolization through ICA or VA anastomoses, scalp necrosis, retinal embolus, and potentially dangerous tumor swelling. Some meningiomas (e.g. olfactory groove) are less amenable to embolization.

42.6.4 Plain x-rays
May show: calcifications within the tumor (in ≈10%), hyperostosis or blistering of the skull (including floor of frontal fossa with olfactory groove meningiomas), enlargement of vascular grooves (especially middle meningeal artery).

42.7 Treatment
42.7.1 General information
Surgery is the treatment of choice for symptomatic meningiomas. Incidental meningiomas with no brain edema or those presenting only with seizures that are easily controlled medically may be managed expectantly with serial imaging as meningiomas tend to grow slowly, and some may “burn out” and cease growing (p.695).

Radiation therapy is considered for patients who are not surgical candidates, for some deep inaccessable tumors, for multiply recurrent meningiomas or for atypical or malignant meningiomas either after initial subtotal resection or after first recurrence.

42.7.2 Surgical technique
General information
These tumors are often very bloody. Preoperative embolization and autologous blood donation may be helpful for specific tumors. General principles of meningioma surgery:
1. early interruption of the blood supply to the tumor
2. internal decompression (using ultrasonic aspirator, cautery loops…)
3. dissection of the tumor capsule from the brain by cutting and coagulating vascular and arachnoid attachments while infolding the tumor into the area of decompression with minimal retraction on adjacent brain
4. removal of attached bone and dura when possible

Position
As usual, the head should be elevated ≈ 30° above the right atrium.
- For meningiomas involving the superior sagittal sinus (SSS):
  • for tumors involving the anterior third of the SSS: supine semi-sitting position
  • for tumors of the middle third of the SSS: lateral position with the side of the tumor down, the neck tilted 45° toward the upward shoulder
  • for tumors of the posterior third of the SSS: prone position

Sinus involvement

Greenberg IMHO

Attempting to occlude or bypass the middle third of the superior sagittal sinus involved with meningioma is treacherous. Even in expert hands, there is significant risk of venous infarction/sinus occlusion with 8% morbidity and 3% mortality, and complete removal is still not assured. Venous drainage may occur through the dura adjacent to the sinus, in the skin, bone of the skull and even the tumor itself may participate. It is almost always preferable to leave residual tumor and consider treating it with radiation therapy than to cause a venous infarction.
Alternatives for treatment of dural sinus involvement include:

Superior sagittal sinus (SSS). If the tumor occludes the SSS, it has been suggested that the sinus can be resected carefully preserving veins draining into the patent portions of the sinus. However, this should be undertaken with great trepidation since patients still not infrequently develop venous infarcts, probably as a result of loss of minimal sinus flow and venous channels in the dura. Before ligating the sinus, the lumen should be inspected for a tail of tumor within partial occlusion of superior sagittal sinus:

1. anterior to the coronal suture, the sinus may usually be divided safely
2. posterior to the coronal suture (or, perhaps more accurately – posterior to the vein of Trolard), it must not be divided or else severe venous infarction will occur
   a) with superficial involvement (Type I, Fig. 42.1), tumor may be dissected off the sinus with care to preserve patency
   b) with extensive involvement:
      • sinus reconstruction: hazardous. Thrombosis rate using venous graft approaches 50% and is close to 100% with artificial grafts (e.g. Gore-Tex) which should not be used
      • it may be best to leave residual tumor, and follow with CT or MRI. If the residual tumor grows, or if the Ki-67 score is high (p.694), SRS may be used; SRS may also be used as initial treatment for tumors that are <2.3–3 cm (p.1564).

Transverse sinus (TS). A patent dominant TS must not be suddenly occluded

Sphenoid wing, parasagittal or falx meningiomas (general principles)

Once tumor is exposed a partial internal debulking is performed. Then the point of attachment (to the falx or sphenoid bone) is peeled away using bipolar cautery to divide feeding vessels. Then the main portion of the tumor may be separated from brain, with the tumor being avascular once the vascular pedicle has been transected.

Parasagittal and falx meningiomas

The inferior portion of the tumor may adhere to branches of the anterior cerebral artery. Middle or posterior third tumors are exposed using a horseshoe incision based in the direction of the major scalp feeding vessels. The patient may be placed in a lateral position, or the sitting position may be used with doppler monitoring for air embolism (p.1445). Anterior third tumors are approached using a bicoronal skin incision with the patient supine. For tumors that cross the midline, burr holes are placed to straddle the SSS. For managing superior sagittal sinus involvement, see above.

Since these tumors are often debulked from the inside, removal tends to be bloodier than meningiomas that can be removed in 1 piece. The ability to embolize these tumors pre-op is somewhat limited, but may be an adjunct. Technique: Cut through tumor leaving a thin layer on dura. Then remove the now relatively avascular part that impresses the brain. Then make an incision through the dura near the tumor; it tends to be bloody, but once you have control of both sides of the dura you can begin to excise the dura around the tumor (you may need to leave a cuff on SSS if it is involved).

Sphenoid wing meningiomas

A pterional craniotomy (p.1453) is utilized. The neck is extended to allow gravity to retract the brain off of the floor of the skull.

Lateral sphenoid wing meningiomas: The approach to these tumors is often similar to convexity meningiomas. The height of the skin incision and bone opening should be high enough to encompass the tumor.

Medial sphenoid wing meningiomas: A lumbar drain is used. The head is turned 30° off the vertical. Aggressive extradural removal of sphenoid wing is performed. An FTOZ approach may provide additional exposure. The sylvian fissure is split widely. The ICA and MCA are often encased by tumor (look for the appearance of “grooves” on the surface of the tumor on MRI, which indicates vessels, e.g. MCA). To locate the ICA, identify MCA branches and follow them proximally into the tumor. The optic nerve is best identified at the optic canal. Avoid excessive retraction of the optic apparatus. The deep portion of the tumor often has numerous small parasitic vessels from the ICA (which makes this part very bloody), and may also invade the lateral wall of the cavernous sinus (which creates risk of cranial nerve deficits with attempted removal). Therefore, the recommendation is to leave some tumor behind and use radiosurgery to deal with it.
**Olfactory groove meningiomas**

Approached via a bifrontal craniotomy (preserving the periosteum to cover the frontal air sinus and floor of frontal fossa at the end of the case). Small tumors may be approached via unilateral craniotomy on the side with the most tumor. For large tumors, a lumbar CSF drain will help with brain relaxation. The head is rotated 20° to one side to facilitate dissection of the anterior cerebral arteries and optic nerve while preventing visualization of both sides of the tumor involvement. The neck is slightly extended. The dura is opened low, and the superior sagittal sinus is ligated and divided at this location. Amputation of the frontal pole should be done if necessary to avoid excessive retraction. Vascular feeding arteries come through the floor of the frontal fossa in the midline. Initially, the anterior tumor capsule is opened and the tumor debulked from within heading towards the floor of the frontal fossa to interrupt the blood supply. The posterior capsule of the tumor is dissected carefully as this portion of the tumor may encase branches of the anterior cerebral artery, and/or optic nerves and chiasm. A large tumor with suprasellar extension usually displaces the optic nerve and chiasm inferiorly. If necessary, the frontopolar branch and other small branches may be sacrificed without problem. Post-op risks include CSF leak through the ethmoid sinuses.

**Tuberculum sellae meningiomas**

These tumors typically displace both optic nerves posteriorly and laterally. Occasionally, the nerves are completely engulfed by tumor.

**Cerebellopontine angle meningiomas**

Usually arise from the meninges covering the petrous bone. May be divided into those that occur anterior to, and those that occur posterior to the IAC.

**Foramen magnum meningiomas**

Tumors arising from the posterior or posterolateral lip of the foramen magnum (FM) are removed relatively easily. Anterior and lateral FM tumors may be operated by the posterolateral approach, and for anterior tumors, a transcandylar approach may alternatively be used.

With meningiomas below the vertebral artery (VA), the lower cranial nerves are displaced superiority with the VA. However, when the tumor is above the VA, the position of the lower cranial nerves cannot be predicted. Large tumors may adhere to or encase neurovascular structures, and these should be internally debulked and then dissected free.

Posterior suboccipital approach: Used for meningiomas arising from the posterior lip of the FM or slightly posterolateral.

The patient is positioned prone or three-quarter prone. Neck flexion should be kept to a minimum to avoid brainstem compression by the tumor. The surgeon must remain vigilant for the PICA and vertebral arteries, which may be encased.

42.7.3 Radiation therapy (XRT)

Generally regarded as ineffective as primary modality of treatment. Many prefer not to use XRT for “benign” lesions. Efficacy of XRT in preventing recurrence is controversial (see below under Recurrence); some surgeons reserve XRT for malignant (invasive), vascular, rapidly recurring (“aggressive”), or non-resectable meningiomas.

For recurrent atypical or anaplastic meningioma with residual disease post-op, XRT with 55–60 Gy is recommended.

42.8 Outcome

5 year survival for patients with meningioma: 91.3% 

Recurrence

The extent of surgical tumor removal is the most important factor in the prevention of recurrence. The Simpson grading system for the extent of meningioma removal is shown in Table 42.4. An often overlooked aspect of the Simpson grading system is that it refers exclusively to removal of intradural tumor, and thus leaving tumor e.g. in the sagittal sinus could still be compatible with complete removal. Recurrence after gross total tumor removal occurred in 11–15% of cases, but was 29% when removal is incomplete (length of follow-up not specified); 5-year recurrence rates of 37%
after partial resection are also quoted. The overall recurrence rate at 20 years was 19% in one series, and 50% in another. Malignant meningiomas have a higher recurrence rate than benign ones.

Value of XRT

A retrospective series of 135 non-malignant meningiomas followed 5–15 years post-op at UCSF revealed a recurrence rate of 4% with total resection, 60% for partial resection without XRT, and 32% for partial resection with XRT. Mean time to recurrence was longer in the XRT group (125 mos) than in the non-XRT group (66 mos). These results suggest that XRT may be beneficial in partially resected meningiomas. Alternatively, one can follow these patients with CT or MRI and use XRT for documented progression.

In addition to the usual side effects of XRT – see Radiation injury and necrosis (p.1560) – there is also a case report of a malignant astrocytoma developing after XRT was used to treat a meningioma.

43 Other Tumors Related to the Meninges

43.1 Mesenchymal, non-meningothelial tumors

43.1.1 Hemangiopericytoma

A sarcoma arising from pericytes (surrounding blood vessels). May metastasize (usually to bone, lung or liver). Occur anywhere (soft tissues, muscles, thoracic aorta, kidney, omentum...). May mimic meningioma on CT or MRI (MRS may help distinguish). Recurrence is common, sometimes late. Neurosurgically relevant sites:
1. intracranial: includes intraventricular
2. spinal

Treatment: Surgery is primary treatment. XRT may reduce recurrence rate. Chemotherapy is used for metastases or for tumors failing local control measures.

43.1.2 Primary cerebral sarcoma

Rare. May result from sarcomatous change in preexisting tumor such as meningioma, glioblastoma, or oligodendroglioma.

43.2 Primary melanocytic lesions

Primary CNS melanoma

Probably arises from melanocytes in the leptomeninges. May spread through CSF pathways. May occasionally metastasize outside the CNS to produce systemic metastases. The peak age for this tumor is in the 4th decade (compared to the 7th decade for primary cutaneous melanoma).

43.3 Hemangioblastoma

43.3.1 General information

Key concepts

- highly vascular well-circumscribed solid or cystic neoplasm of CNS or retina
- the most common primary intra-axial tumor in the adult posterior fossa
- may occur sporadically or as part of von Hippel-Lindau disease
- on imaging, may be solid, or cystic with enhancing mural nodule
- CBC: may be associated with erythrocytosis (polycythemia)

Hemangioblastomas\(^4\) (HGB) are histologically benign tumors. Intracranially, they occur almost exclusively in the p-fossa (hemangioblastomas are the most common primary intra-axial p-fossa tumor in adults). May occur in cerebellar hemisphere, vermis or brainstem. Less than 100 supratentorial cases have been reported. May also occur in spinal cord (p.789) (1.5–2.5% of spinal cord tumors). Relationship and/or identity with angioblastic meningiomas is controversial. Also difficult to distinguish histologically from a renal cell carcinoma.

HGB may occur sporadically, but 20% occur as part of von Hippel-Lindau (VHL) disease (see below). Retinal HGB and/or angiomas occur in 6% of patients with cerebellar HGBs.

43.3.2 Hemangioblastomas (in general)

Epidemiology

HGB represent 1–2.5% of intracranial tumors. They comprise 7–12% of primary p-fossa tumors.\(^5\) 5–30% of cases of cerebellar HGB and 80% of spinal HGB are associated with VHL (see above).

Sporadic cases tend to present in the 4th decade, whereas VHL cases present earlier (peak in 3rd decade). In sporadic cases, the HGB are solitary and originate in the cerebellum (83–95%), spinal cord (3–13%), medulla oblongata (2%) or cerebrum (1.5%).\(^6\) 5–30% of patients with cerebellar HGB have VHL.\(^7\)
Presentation
S/S of cerebellar HGB are usually those of any p-fossa mass – H/A, N/V, cerebellar findings...; see Posterior fossa (infratentorial) tumors (p.592) – and obstructive hydrocephalus may occur. HGB is rarely documented as a cause of apoplexy due to intracerebral hemorrhage (ICH) (lobar or cerebel-
lar), however, some studies indicate that if cases of ICH are carefully examined, abnormal vessels consistent with HGB (and occasionally misidentified as AVM) may be found with surprising fre-
quency (in spite of negative CT and/or angiography).6
Retinal HGBs tend to be located peripherally, and may hemorrhage and cause retinal detachment. Erythrocytosis may be due to erythropoietin liberated by the tumor.

Pathology
No report of malignant change. May spread thru CSF after surgery, but remain benign. No true caps-
ule, but usually well circumscribed (narrow zone of infiltration). May be solid, or cystic with a
mural nodule (70%of cerebellar lesions are cystic; nodules are very vascular, appear red, are often
located near pial surface, and may be as small as 2 mm; cyst fluid is clear yellow with high protein).
In cystic lesions, the cyst wall is lined with non-neoplastic compressed cerebellum. The cyst develops
because the vessel walls are so thin that they leak water, proteins don’t cross as readily.
Cardinal feature: numerous capillary channels, lined by a single layer of endothelium, surrounded
by reticulin fibers (stains positive with reticulin stain). Macrophages stain PAS positive.
Three types of cells:
1. endothelial
2. pericytes: surrounded by basement membrane
3. stromal: polygonal. Foamy clear cytoplasm, often lipid laden. Origin controversial

Three types of HGB recognized9:
1. juvenile: thin walled capillaries & dilated vessels tightly packed
2. transitional: thin walled capillaries & dilated vessels intermingled with stromal cells, some of
which are lipid laden (sudanophilic)
3. clear cell: neoplasm made up almost entirely of sheets of xanthoma cells with a rich vascular
stroma

Cyst patterns10:
1. no associated cysts: 28%
2. peritumoral cyst alone: 51%
3. intratumoral cyst: 17%
4. peritumoral AND intratumoral cysts: 4%

Evaluation
Patients with a p-fossa HGB (radiologically suspected or histologically proven) should undergo MRI
of entire neuraxis because of possibility of spinal HGBs (may be distant from p-fossa lesion; may
suggest possibility of VHL).
CT: solid lesions are usually isodense with intense contrast enhancement. Cystic HGBs remain
low density with contrast, with the nodule enhancing.
MRI: preferable to CT due to the tumor’s predilection for the p-fossa. May show serpentine vascu-
lar signal voids, especially in the periphery of the lesion. Also, peripheral hemosiderin deposits may
occur from previous hemorrhages.5
Vertebral angiography: usually demonstrates intense vascularity (most other tumors of the p-foss-
a are relatively avascular). May be required in HGBs where nodule is too small to be imaged on CT/
MRI. 4 patterns: 1) vascular mural nodule on side of avascular cyst, 2) vascular lesion surrounding
intratumoral cyst, 3) solid vascular mass, & 4) multiple, separate vascular nodules.
Labs: often discloses polycythemia (no hematopoietic foci within tumor). In cases with suggestive
history, labwork to rule-out catecholamine production from pheochromocytoma may be indicated;
see Endocrine/laboratory studies (p.655).

Treatment
Surgery
Surgical treatment may be curative in cases of sporadic HGB, not in VHL.
Pre-operative embolization may help reduce the vascularity.
Cystic HGBs require removal of mural nodule (otherwise, cyst will recur). The cyst wall is not removed unless there is evidence of tumor within the cyst wall on MRI (typically thick-walled cysts) or visually at the time of surgery. 10 5-ALA fluorescence may aid in visual localization of small hemangioblastomas within the cyst wall. 11

Solid HGBs tend to be more difficult to remove. They are treated like AVMs (avoid piecemeal removal), working along margin and devascularizing blood supply. A helpful technique is to shrink the tumor by laying a length of bipolar forceps along tumor surface and coagulating. HGBs with attachment to floor of 4th ventricle may be hazardous to remove (cardio-respiratory complications).

Multiple lesions: if ≥ 0.8–1 cm diameter: may treat as in solitary lesion. Smaller and deeper lesions may be difficult to locate at time of surgery.

Cystic brainstem HGB: the solid nodule of the tumor is removed under the microscope by bipolarizing and cutting the gliotic adhesions to the parenchyma. Removal of the cyst wall is not necessary. There is often a cleavage between the tumor and the floor of the fourth ventricle which facilitates tumor removal. To reduce bleeding, avoid piecemeal removal. Preserve large draining veins until the arterial feeders to the mural nodule have been isolated and resected. 12

Radiation treatment
Effectiveness is dubious. May be useful to reduce tumor size or to retard growth, e.g. in patients who are not surgical candidates, for multiple small deep lesions, or for inoperable brainstem HGB. Does not prevent regrowth following subtotal excision.

43.3.3 von Hippel-Lindau disease (VHL)
General information

Key concepts
- disorder with hemangioblastomas (HGB) 1° of cerebellum, retina, brainstem & spinal cord, as well as renal cysts/tumors, pheochromocytomas (among others)
- autosomal dominant, due to inactivation of tumor suppressor gene on 3p25
- expression and age of onset are variable, but ≈ always manifests by age 60
- mean age of developing HGBs is at least 10 years younger than sporadic HGBs

A multisystem neoplastic disorder characterized by a tendency to develop hemangioblastomas (HGB) of the retina, brain and spinal cord, renal clear cell carcinoma (RCC), pheochromocytomas, endolymphatic sac tumors, and others. 6,13 (retinal location is 2nd most common after cerebellar, Table 43.1). The variability of von Hippel-Lindau disease (VHL) has lead some to suggest the use of the term hemangioblastomatosis.

Epidemiology
Incidence: 1 in 31,000 to 36,000 live births. ≈ 30% of patients with cerebellar HGB have VHL. 7

Genetics
Autosomal dominant inheritance with ≈ 95% penetrance at age 60 yrs. 5,16 4% of VHL are asymptomatic carriers. The VHL gene is a tumor suppressor gene on chromosome 3p25, and biallelic inactivation is required for tumor development. 7 Most patients inherit a VHL gene (allele) with the germline mutation from the affected parent and a normal somatic (wild-type) VHL gene from the unaffected parent.

Subtypes of VHL
See reference. 17

Type I. May have any manifestation of VHL except pheochromocytoma
Type II. Pheochromocytoma is characteristic
Type IIA. Have low risk of renal cell Ca and neuroendocrine pancreatic tumor
Type IIB. Higher risk of renal cell Ca and neuroendocrine pancreatic tumor

Type IIC. Risk of pheochromocytoma only (without risk of HGB or RCC)

### Diagnostic criteria

Suggested diagnostic criteria for VHL:

1. in 80% of patients with VHL, there is a multigenerational family history, and only 1 manifestation (CNS HGB or visceral lesion) is necessary to make the diagnosis in these patients

2. if no family history (20% of VHL, many of these represent a de novo mutation): 2 manifestations including 1 CNS or retinal HGB are required

3. genetic testing in uncertain cases (see below)

### Tumors associated with VHL

1. cerebellar hemangioblastomas (HGB):
   a) prevalence: 44–72% of VHL patients
   b) mean age of diagnosis in VHL patients with cerebellar hemangioblastomas is at least 10 years younger than sporadic cerebellar hemangioblastomas
   c) cysts are commonly associated with cerebellar, brainstem and spinal HGBs
   d) cysts grow at a faster rate than the HGBs, symptoms related to mass effect are frequently secondary to the cysts
   e) cerebellar HGBs were located in the superficial, posterior and superior half of the cerebellar hemispheres
   f) 93% of the cerebellar HGBs were located in the cerebellar hemispheres and 7% in the vermis
   g) the HGBs are also more frequently found in the superficial posterior half of the brainstem and the spinal cord
   h) the HGBs have multiple sequential growth and quiescent phases

2. spinal cord hemangioblastomas
   a) occur in 13–44% of VHL patients
   b) 90% are located rostrally within the cervical and thoracic cord. Almost all (96%) of the tumors are located in the posterior half of the spinal cord, 4% are located in the ventral half of the spinal cord. 1–3% are found in the lumbosacral nerve roots

*see references 6, 14, 15 for more
c) by way of comparison, 80% of spinal cord HGB are associated with VHL, whereas only 5–31% of cerebellar HGB are associated with VHL
d) 95% of symptom-producing spinal HGBs are associated with syringomyelia
3. brainstem hemangioblastomas
   a) usually located in the posterior medulla oblongata usually around the obex and the region within the area postrema
4. pheochromocytomas (PCC): 20% of PCC are associated with VHL. PCC occur in 7–20% of families with VHL
5. endolymphatic sac tumors (ELST):
   a) locally invasive benign tumors that occur in 10–15% of VHL patients (30% of these will develop bilateral ELSTs – VHL is the only disease with bilateral ELSTs). Rarely metastasize
   b) presents with hearing loss in 95% (may be acute (86%) or insidious (14%), tinnitus (90%), vertigo or imbalance (66%), andural fullness (30%), and facial paresthesias (8%)
   c) mean age of onset of hearing loss: 22 years (range: 12–50)
6. retinal hemangioblastomas
   a) occur in >50% of VHL patients. Mean age a presentation: 25 years
   b) frequently bilateral, multifocal and recurrent
   c) often asymptomatic. Visual symptoms occur with progressive growth, edema, retinal detachments and hard exudates
   d) typically located in the periphery and near or on the optic disc
   e) microangiomas measuring a few hundred microns without dilated feeding vessels may be located in the periphery
   f) retrobulbar HGB are rare (5.3% in NIH cohort)
   g) severity of optic disease correlates with CNS and renal involvement
   h) early diagnosis and treatment with laser photocoagulation, and cryotherapy can prevent visual loss. Low dose external XRT may be an option for refractory cases
7. renal-cell carcinoma (RCC)
   a) the most common malignant tumor in VHL. Usually a clear cell carcinoma
   b) lifetime risk for RCC in VHL: ≈ 70%
   c) the growth rate of RCC is high variable
   d) RCC is the cause of death in 15–50% of patients
   e) metastases respond poorly to chemotherapy and radiation
   f) bilateral and multiple lesions are common
   g) partial nephrectomy or tumor enucleation is preferred to avoid/delay dialysis and transplantation
   h) nephron- or renal-sparing surgery recommended for tumors less <3 cm
   i) promising techniques: cryo- and radiofrequency ablation of tumors <3 cm
8. renal cysts
   a) 50–70% of VHL patients have bilateral and multiple renal cysts
   b) rarely cause profound renal impairment
   c) chronic renal failure or renal hypertension not as common as with polycystic kidney disease
9. epididymal cystadenomas
   a) benign lesions that arise from the epididymal duct
   b) found in 10–60% of male VHL patients
   c) typically appear in the teenage years
   d) may cause infertility if bilateral
   e) may be multiple
10. broad ligament cystadenomas
    a) arise from the embryonic mesonephric duct
    b) true incidence unknown
    c) rarely reported and usually not recognized in women with VHL
11. pancreatic neuroendocrine tumors and cysts
    a) 35 to 70% of patients with VHL develop an endocrine tumor or cyst
    b) pancreatic cysts are generally asymptomatic and often multiple
    c) pancreatic neuroendocrine tumors are usually non-functional and 8% of them are malignant
    d) differential diagnosis: pancreatic islet cell tumors, MEN2

**Treatment**

Resection of individual CNS tumors is usually reserved until symptomatic to decrease the number of operations over a lifetime since the tumors in VHL are usually multiple, tend to recur, and the growth pattern is saltatory. Surgery is the treatment of choice for accessible cystic HGBs. For details, see Treatment, under Hemangioblastoma (p.702).
Stereotactic radiosurgery (SRS): May provide local control rates of >50% over 5 years. SRS has been recommended for asymptomatic HBG >5 mm diameter if they are cystic or progressing in size during surveillance. Cranial treatment plan: using a median dose of 22 Gy (range: 12–40 Gy) prescribed to the median 82% isodose line in 1–4 sessions. In cystic lesions, treatment is confined to the contrast enhancing mural nodule (the cyst wall is not treated). Spinal treatment plan: median dose of 21 Gy (range 20–25 Gy) prescribed to the median 77% isodose line in 1–3 sessions. Radiosurgery is usually contraindicated in hemangioblastomas with a cyst.

Surveillance

Because of the lifetime risk of developing tumors, regular surveillance is needed. Various protocols have been proposed, including those by the NIH and the Danish clinical recommendations. The algorithm recommended by the VHL Family Alliance for patients with VHL and at-risk relatives is shown in Table 43.2. (Screening at-risk relatives can be stopped at age 60 years if no abnormalities have been detected.) Individuals who do not carry the altered gene on DNA testing do not require surveillance.

</tbody>
</table>

<sup>a</sup>adapted<sup>32</sup>  
<sup>b</sup>indirect ophthalmoscope exam by retinologist familiar with VHL  
<sup>c</sup>abbreviations: PE=physical exam by physician familiar with VHL, ELST=endolymphatic sac tumor
Prognosis

The lifespan of patients with VHL is decreased. 30–50% die of renal cell Ca (RCC). Metastases from RCC and neurologic complications from cerebellar HGB are the primary causes of death. Metastases respond poorly to chemotherapy and XRT.

Resources

Genetic screening for VHL can be done at a few centers. Information for patients and families can be found at www.vhl.org/.

44.1 CNS lymphoma

44.1.1 General information

Key concepts

- may be primary or secondary (pathologically identical)
- suspected with homogeneously enhancing lesion(s) in the central gray matter or corpus callosum (on MRI or CT) especially in AIDS patients
- may present with multiple cranial-nerve palsies
- diagnosis highly likely if tumor seen in conjunction with uveitis
- very responsive initially to steroids → short-lived disappearance (may produce “ghost tumors”)
- treatment: usually XRT ± chemotherapy. Role of neurosurgery usually limited to biopsy and/or placement of ventricular access reservoir for chemotherapy
- risk factors: immunosuppression (AIDS, transplants), Epstein-Barr virus, collagen vascular diseases

CNS involvement with lymphoma may occur secondarily from a “systemic” lymphoma, or may arise primarily in the CNS. It is controversial whether most intracranial malignant lymphomas are primary\(^1\) or secondary.\(^2\)

44.1.2 Primary vs. secondary lymphoma

Secondary CNS lymphoma

Non CNS lymphoma is the fifth most common cause of cancer deaths in the U.S., 63% of new cases are non-Hodgkin’s. Secondary CNS involvement usually occurs late in the course. Metastatic spread of systemic lymphoma to the cerebral parenchyma occurs in 1–7% of cases at autopsy.\(^3\)

Primary CNS lymphoma

Older names include: reticulum cell sarcoma and microglioma\(^4\) since they were thought to possibly arise from microglia which were considered part of the reticuloendothelial system.

A rare, malignant primary CNS neoplasm comprising 0.85–2% of all primary brain tumors and 0.2–2% of malignant lymphomas.\(^5\) May occasionally metastasize outside the CNS.

44.1.3 Epidemiology

The incidence of primary CNS lymphoma (PCNSL) is rising relative to other brain lesions, and will likely exceed that of low-grade astrocytomas and approach meningiomas. This is in part due to the occurrence of PCNSL in AIDS and transplant patients, but the incidence has also increased in the general population over the past 20 years.\(^6\)

- Male:female ratio = 1.5:1 (based on literature review\(^7\)).
- Median age at diagnosis: 52 yrs\(^7\) (younger among immunocompromised patients: \(\approx 34\) yrs).
- Most common supratentorial locations: frontal lobes, then deep nuclei; periventricular also common. Infratentorially: cerebellum is the most common location.

44.1.4 Conditions with increased risk of primary CNS lymphomas (PCNSL)

1. collagen vascular disease
   a) systemic lupus erythematosus
   b) Sjögren’s syndrome: an autoimmune connective tissue disorder
   c) rheumatoid arthritis
2. immunosuppression
   a) organ transplant recipients: related to chronic immunosuppression. Falls under category of post transplant lymphoproliferative disease (PTLD)\(^8\)
b) severe congenital immunodeficiency syndrome ("SCIDS")

c) AIDS\textsuperscript{9,10}: CNS lymphoma occurs in \(\approx 10\%\) of AIDS patients, and is the first presentation in 0.6%
d) possibly increased incidence in the elderly due to reduced competency of immune system

3. Epstein-Barr virus\textsuperscript{11} is associated with a broad spectrum of lymphoproliferative disorders, and is detectable in \(\approx 30–50\%\) of systemic lymphomas, however, it has been associated with almost 100\% of PCNSL,\textsuperscript{12} especially AIDS-related cases\textsuperscript{13}(p 317)

### 44.1.5 Pathology

Characteristic sites: corpus callosum, basal ganglia, periventricular.

The neoplastic cells are identical to those of systemic lymphomas. Most are bulky tumors that are contiguous with the ventricles or meninges.

Histologic distinguishing features: tumor cells form cuffs around blood vessels which demonstrate multiplication of basement membranes (best demonstrated with silver reticulum stain).

Frozen section distorts the cells and may lead to a misdiagnosis of malignant glioma.\textsuperscript{13}(p 320)

Immunohistochemical stains differentiates B-cell lymphomas from T-cell lymphomas (B-cell types are more common, especially in PCNSL and in AIDS).

EM shows absence of junctional complexes (desmosomes) that are usually present in epithelial derived tumors.

Intravascular lymphomatosis\textsuperscript{14}: Formerly: (malignant) angioendotheliomatosis. A rare lymphoma with no solid mass in which malignant lymphoid cells are found in the lumen of small blood vessels in affected organs. CNS involvement is reported in most cases. Presentation is non specific: patients are often febrile, and may present with progressive multifocal cerebrovascular events (including stroke or hemorrhage), spinal cord or nerve root symptoms including cauda equina syndrome (p. 1050), encephalopathy or peripheral or cranial neuropathies.\textsuperscript{15} Initial transient cerebral symptoms may mimic TIAs or seizures. The ESR is often elevated prior to initiation of steroids. Lymphoma cells may be seen in the CSF.

Painful skin nodules or plaques occur in \(\approx 10\%\) of cases, generally involving the abdomen or lower extremities, and these cases may be diagnosed with skin biopsy (differential diagnosis here includes angioendotheliomatosis, a benign capillary and endothelial cell disorder). Otherwise, diagnosis often requires brain biopsy (open or stereotactic), in which involved areas on imaging studies are targeted. Pathology: malignant lymphoid cells distend and occlude small arteries, veins and capillaries with little or no parenchymal extension.\textsuperscript{13}(p 324) Treatment with combination chemotherapy can result in long-term remission in some patients, but early diagnosis before permanent damage occurs is critical (diagnosis is rarely made pre-mortem).

### 44.1.6 Presentation

**General information**

Presentation is similar with primary or secondary CNS lymphoma: the two most common manifestations are those due to epidural spinal cord compression and those of carcinomatous meningitis (multiple cranial nerve deficits) (p. 811). Seizures occur in up to 30\% of patients.\textsuperscript{3}

**Symptoms**

1. presents with non-focal non-specific symptoms in over 50\% of patients; at time of presentation most commonly includes:
   a) mental status changes in one–third
   b) symptoms of increased ICP (H/A, N/V)
   c) generalized seizures in 9\%
2. focal symptoms in 30–42\% of cases:
   a) hemimotor or hemisensory symptoms
   b) partial seizures
   c) multiple cranial-nerve palsies (due to carcinomatous meningitis)
3. combination of focal and non-focal symptoms

**Signs**

1. non-focal in 16\%
   a) papilledema
   b) encephalopathy
   c) dementia
2. focal findings in 45% of cases:
   a) hemimotor or hemisensory deficits
   b) aphasia
   c) visual field deficits
3. combination of focal and non-focal signs

Uncommon but characteristic syndromes
1. uveocyclitis, coincident with (in 6% of cases) or preceding the diagnosis of (in 11% of cases) lymphoma
2. subacute encephalitis with subependymal infiltration
3. MS-like illness with steroid-induced remission

44.1.7 Evaluation
All patients should be assessed (history, physical, and if appropriate, laboratory tests) for any of the conditions associated with lymphoma (p.710). Since primary CNS lymphoma is less common than secondary involvement, any patient with CNS lymphoma should have work-up for occult systemic lymphoma including:
1. careful physical exam of all lymph nodes (LN)
2. evaluation of perihilar and pelvic LN (CXR, CT of chest & abdomen)
3. routine blood and urine testing
4. bone marrow biopsy
5. MRI of the entire spine
6. testicular ultrasound in males
7. ophthalmologic examination (including slit-lamp evaluation of both eyes) in all
   a) for possible uveitis
   b) ≈28% of patients with PCNSL will also have intraocular lymphoma. Often resistant to methotrexate, but responds to low dose ocular XRT (7–8 Gy)

44.1.8 Diagnostic tests
General information
On imaging (CT or MRI) 50–60% occur in one or more cerebral lobes (in grey or white matter). 25% occur in deep midline structures (septum pellucidum, basal ganglion, corpus callosum). 25% are infratentorial. 10–30% of patients have multiple lesions at the time of presentation. In contrast, systemic lymphomas that spread to the CNS tend to present with leptomeningeal involvement instead of parenchymal tumors.¹⁰

CT
Non-AIDS-related cases tend to enhance homogeneously, whereas AIDS-related cases often have a necrotic center and appear as multifocal ring-enhancing lesions¹⁷ (the wall is thicker than with an abscess).

Non-AIDS related cases: CNS lymphomas should be suspected with homogeneously enhancing lesion(s) in the central gray or corpus callosum. 75% are in contact with ependymal or meningeal surfaces (this together with dense enhancement may produce a “pseudomeningioma pattern”, however lymphomas lack calcifications and tend to be multiple). 60% are hyperdense to brain, only 10% are hypodense. Characteristically, >90% of these tumors enhance; this is densely homogeneous in over 70% As a result, when rare non-enhancing cases occur it often leads to a delay in diagnosis.¹⁸ The appearance of enhanced PCNSL on CT has been likened to “fluffy cotton balls.” There may be surrounding edema¹⁹ and there is usually mass effect.

There is an almost diagnostic tendency of rapid partial to complete resolution on CT (and even at the time of surgery) following the administration of steroids, earning the nickname of “ghost-cell tumor”²⁰,²¹ or disappearing tumor.

MRI
No pathognomonic feature. May be difficult to discern if tumor is located subependymally (signal characteristics similar to CSF); proton-weighted image may avoid this pitfall. Nenhancing lymphoma (on MRI or CT) is rare²² (some of these may enhance after XRT) but may be underreported. Bright on DWI (restricted diffusion), isointense to hypointense on ADC map.
CSF
Should only be obtained if no mass effect. Usually abnormal, but non-specific. Most common abnormalities are elevated protein (in >80%), and increased cell count (in 40%). Cytology is positive for lymphoma cells (pre-operatively) in only 10% (sensitivity may be higher with leptomeningeal involvement as in non-AIDS patients than with parenchymal involvement commonly seen in AIDS). Repeating up to 3 LPs may increase yield. Although the diagnosis of lymphoma can be made from CSF, cells obtained in this manner are not adequate for detailed tissue typing which is possible with solid tissue from biopsy.

Angiography
Rarely helpful. 60% of cases show only an avascular mass. 30–40% show diffuse homogeneous staining or blush.

44.1.9 Treatment
Surgery
Surgical decompression with partial or gross total removal does not alter patient’s prognosis. The main indications for surgery:
- Biopsy: obtain solid tissue to ascertain that the tumor is a lymphoma, and to determine the type of lymphoma. Stereotactic techniques are often well-suited for these often deep tumors.

Radiation therapy
The standard treatment after tissue biopsy is whole-brain radiation therapy. Doses used tend to be lower than for other primary brain tumors. ≈ 40–50 Gy total are usually given in 1.8–3 Gy daily fractions.

Chemotherapy
General information
In non-AIDS cases, chemotherapy combined with XRT prolongs survival compared to XRT alone.

Methotrexate (MTX)
The addition of intraventricular MTX (rather than just intrathecal via LP) delivered through a ventricular access device (6 doses of 12 mg twice a week, with IV leucovorin rescue) may result in even better survival. In the event of an intrathecal MTX overdose (OD), interventions recommended: ODs of up to 85 mg can be well tolerated with little sequelae; immediate LP with drainage of CSF can remove a substantial portion of the drug (removing 15 ml of CSF can eliminate ≈ 20–30% of the MTX within 2 hrs of OD). This can be followed by ventriculolumbar perfusion over several hours using 240 ml of warmed isotonic preservative-free saline entering through the ventricular reservoir and exiting through a lumbar subarachnoid catheter. For major OD of >500 mg, add intrathecal administration of 2,000 U of carboxypeptidase G2 (an enzyme that inactivates MTX). In cases of MTX OD, systemic toxicity should be prevented by treating with IV dexamethasone and IV (not IT) leucovorin.

Rituximab
Available since 1997 for treatment of refractory systemic B-cell non-Hodgkins lymphoma. Intrathecally, may be more effective for CD33+ lymphomas.

44.1.10 Prognosis
With no treatment, median survival is 1.8–3.3 months following diagnosis.
- With radiation therapy, median survival is 10 months, with 47% 1-year median survival, and 16% 2-year median survival. 3-year survival is 8% and 5-year survival is 3–4%. With intraventricular MTX, median time to recurrence was 41 mos. Occasionally, prolonged survival may be seen.
- About 78% of cases recur, usually ≈ 15 months after treatment (late recurrences also are seen). Of these recurrences, 93% are confined to the CNS (often at another site if the original site responded well), and 7% are elsewhere.
In AIDS-related cases, the prognosis appears worse. Although complete remission occurs in 20–50% following XRT, the median survival is only 3–5 months, usually related to AIDS-related opportunistic infection. However, neurologic function and quality of life improve in ≈ 75%.

Although there are individual studies that show trends, there are no prognostic features that consistently correlate with survival.

44.2 Multiple myeloma

44.2.1 General information

Multiple myeloma (MM) (sometimes referred to simply as myeloma) is a neoplasm of a single clone of plasma cells characterized by proliferation of plasma cells in bone marrow, infiltration of adjacent tissues with mature and immature plasma cells, and the production of an immunoglobulin, usually monoclonal IgG or IgA (referred to collectively as M-protein). Circulating pre-myeloma cells lodge in appropriate microenvironments (e.g. in bone marrow) where they differentiate and expand. Although MM is often referred to in the context of “metastatic lesions” to bone, it is also sometimes considered a primary bone tumor. If only a single lesion is identified, then it is referred to as a plasmacytoma (see below).

44.2.2 Epidemiology

In the U.S., incidence is ≈ 1–2 per 100,000 in caucasians, and is ≈ twice that in blacks. MM accounts for 1% of malignancies, and 10% of hematologic cancers. The peak age of occurrence is 60–70 yrs of age, with <2% of patients being <40 yrs old. Slightly more common in males. Monoclonal gammopathy without MM occurs in ≈ 0.15% of the population, and in long-term follow-up 16% of these develop MM with an annual rate of 0.18%.

44.2.3 Presentation

General information

MM presents as a result of the following (underscored items are characteristic for MM):

1. proliferation of plasma cells: interferes with normal immune system function → increased susceptibility to infection
2. bone involvement
   a) bone marrow involvement → destruction of hematopoietic capacity → normocytic normochromic anemia, leukopenia, thrombocytopenia
   b) bone resorption
      • weakening of the bone → pathologic fractures (see below)
      • → hypercalcemia (present initially in 25% of MM patients, see below)
   c) swelling or local tenderness of bone
   d) bone pain: characteristically induced by movement, and absent at rest
   e) spinal involvement
      • invasion of spinal canal in ≈ 10% of cases → spinal cord compression → myelopathy
      • nerve root compression (radiculopathy)
3. overproduction of certain proteins by plasma cells. May lead to:
   a) hyperviscosity syndrome
   b) cryoglobulinemia
   c) amyloidosis
   d) renal failure: multifactorial, but monoclonal light chains play a role

Skeletal disease

MM involvement is by definition multiple, and is usually restricted to sites of red marrow: ribs, sternum, spine, clavicles, skull, or proximal extremities. Lesions of the spine and/or skull are the usual reasons for presentation to the neurosurgeon.

Bone resorption in MM is not due simply to mechanical erosion by plasma cells. Increased osteoclastic activity has been observed.

Plasma cell tumors of the skull involving the cranial vault usually do not produce neurologic symptoms. Cranial nerve palsies can arise from skull base involvement. Orbital involvement may produce proptosis (exophthalmos).
Neurologic involvement

Neurologic manifestations can occur as a result of:

1. tumor involvement of bone causing compression (see above)
   a) tumor in spine with compression of spinal cord or nerve roots
   b) tumor in skull with compression of brain or cranial nerves
2. deposition of amyloid within the flexor retinaculum of the wrist — carpal tunnel syndrome; the median nerve itself does not contain amyloid, and therefore responds well to surgical division of the transverse carpal ligament (p.524)
3. diffuse progressive sensorimotor polyneuropathy: occurs in 3–5% of patients with MM
   a) about half are due to amyloidosis (p.549)
   b) polyneuropathy can also occur without amyloidosis, especially in the rare osteosclerotic variant of MM
4. multifocal leukoencephalopathy has been described in MM
5. hypercalcemia: may produce a dramatic encephalopathy with confusion, delirium or coma. Neurologic symptoms of hypercalcemia associated with MM are more common than in hypercalcemia of other etiologies
6. very rare: intraparenchymal metastases

44.2.4 Evaluation

The diagnostic criteria for MM is shown in Table 44.1. Tests that may be used in evaluating patients with MM or suspected MM include:

1. 24 hour urine for kappa Bence-Jones protein present in 75% (Note: Small proteins (comprised of light chains of immunoglobulins) found in the urine of ≈ 80% of patients with MM (may also occur in other conditions). Monoclonal proteins cannot be detected in the urine or serum of ≈ 1% of MM patients; two or more monoclonal bands are produced in ≈ 0.5–2.5% of patients with MM)
2. bloodwork: serum protein electrophoresis (SPEP) and immune electrophoresis (IEP) (looking for IgG kappa band)
3. skeletal radiologic survey. Characteristic x-ray finding: multiple, round, “punched-out” (sharply demarcated) lytic lesions in the bones typically involved (see above). Osteosclerotic lesions are seen in <3% of patients with MM. Diffuse osteoporosis may also be seen
4. CBC: anemia eventually develops in most patients with MM. It is usually of moderate severity (Hgb ≈ 7–10 gm%) with a low reticulocyte count
5. technetium-99 m nuclear bone scan is usually negative in untreated MM (due to rarity of spontaneous new bone formation) and is less sensitive than conventional radiographs. Therefore it is not usually helpful except perhaps to implicate etiologies other than MM to explain the observed findings. After treatment, bone scan may become positive as osteoblastic activity ensues (“flare” response)
6. serum creatinine: for prognostication
7. bone marrow biopsy: virtually all MM patients have “myeloma cells” (although sensitive, this is not specific and other diagnostic criteria should be sought)

44.2.5 Treatment

Many aspects of treatment fall into the purvey of the oncologist (see review). Some aspects pertinent to neurosurgical care include:

1. XRT (p.808): MM is very radiosensitive. Focal XRT for pain due to readily identifiable bone lesions, may allow pathologic fractures to heal and is effective in spinal cord compression

<table>
<thead>
<tr>
<th>Table 44.1 Criteria for diagnosis of MM</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Cytologic criteria</td>
</tr>
<tr>
<td>a) marrow morphology: plasma cells and/or myeloma cells ≥ 10% of 1000 or more cells</td>
</tr>
<tr>
<td>b) biopsy proven plasmacytoma</td>
</tr>
<tr>
<td>2. Clinical and laboratory criteria</td>
</tr>
<tr>
<td>a) myeloma protein (M-component) in serum (usually &gt; 3 gm/dl) or urine IEP</td>
</tr>
<tr>
<td>b) osteolytic lesions on x-ray (generalized osteoporosis qualifies if marrow contains &gt; 30% plasma or myeloma cells)</td>
</tr>
<tr>
<td>c) myeloma cells in ≥ 2 peripheral blood smears</td>
</tr>
</tbody>
</table>

*diagnosis requires 35: 1A & 1B, or 1A or 1B and 2A, 2B, or 2C
2. mobilization: immobilization due to pain and fear of pathologic compression fractures leads to further detrimental increases in serum calcium and weakness
3. pain control: mild pain often responds well to salicylates (contraindicated in thrombocytopenia). Local XRT is also effective (see below)
4. percutaneous kyphoplasty (p.1011) may be used for some spine lesions (preferred over vertebroplasty because of reduced potential of spreading neoplasm)
5. therapy for hypercalcemia usually improves symptoms related to that derangement
6. bisphosphonates (p.1122) inhibit bone resorption and rapidly reduces hypercalcemia. Pamidronate is currently preferred over older agents
7. bortezomib (Velcade®): the first proteasome inhibitor, indicated for treatment of refractory MM

44.2.6 Prognosis
Untreated MM has a 6 month median survival. Solitary plasmacytoma has a 50%–10-year survival. If there is an solitary site of involvement but M-protein is present (i.e. essentially a plasmacytoma except for the M-protein), elimination of the M-protein following XRT indicates a 50–60% chance of remaining free of MM, if the M-protein doesn’t resolve, there is a high chance of developing MM.

44.3 Plasmacytoma
44.3.1 General information
A neoplasm of a single clone of plasma cells similar to multiple myeloma (see above) but meeting the following criteria:
1. there must be no other lesions on complete skeletal survey (not bone scan)
2. bone marrow aspirate must show no evidence of myeloma
3. and serum and urine electrophoresis should show no M-protein

MM will develop in 55–60% of patients with a solitary plasmacytoma in 5 years, and in 70–80% by 10 yrs.

44.3.2 Treatment
1. local XRT provides good local control rates
2. percutaneous kyphoplasty (p.1011): preferred over vertebroplasty because of reduced potential of spreading neoplastic cells

45 Pituitary Tumors – General Information and Classification

45.1 General information

Key concepts

- most are benign adenomas arising from the anterior pituitary (adenohypophysis)
- presentation (see below): most commonly present due to hormonal effects (includes: hyperprolactinemia, Cushing’s syndrome, acromegaly...), mass effect (most commonly: bitemporal hemianopsia from compression of optic chiasm), as an incidental finding, or infrequently with pituitary apoplexy (p. 720)
- work-up for a newly diagnosed intrasellar lesion: see Table 46.1
- prolactinoma is the only type for which medical therapy (DA agonists) may be the primary treatment in certain cases (p. 737). For other tumor types, options primarily consist of surgery (transsphenoidal or transcranial), or XRT
- post-op concerns include: diabetes insipidus, adrenal insufficiency, CSF leak

See also review of pituitary embryology & neuroendocrinology (p. 149).

45.2 General tumor types

45.2.1 Pituitary adenomas

Most primary pituitary tumors are benign adenomas which arise from the anterior pituitary gland (adenohypophysis). Adenomas may be classified by a number of schemes, including: by endocrine function (aided by immunostaining), by light microscopy (p. 727) with routine histological staining and by electron microscopic appearance.

Microadenoma: A pituitary tumor < 1 cm diameter. Currently, 50% of pituitary tumors are < 5 mm at time of diagnosis. These may be difficult to find at the time of surgery.

Macroadenomas: Tumors > 1 cm diameter.

45.2.2 Pituitary carcinoma

See reference.¹

Rare (<140 reports). Usually invasive and secretory (most common hormones: ACTH, PRL). Can metastasize, at which point prognosis is poor (66%-1-year mortality). Little improvement with further surgery, XRT, or chemotherapy.

45.2.3 Neurohypophyseal tumors

Neurohypophyseal tumors (tumors of the neurohypophysis i.e. the posterior pituitary) are rare; see Pituicytoma (p. 728).

45.3 Epidemiology

Pituitary tumors represent ≈10% of intracranial tumors (incidence is higher in autopsy series). They are most common in the 3rd and 4th decades of life, and affect both sexes equally. The incidence is increased in multiple endocrine adenomatosis or neoplasia (MEA or MEN) (especially type I: autosomal dominant inheritance with high penetrance, also involves pancreatic islet cell tumors (which may produce gastrin and hence Zollinger-Ellison syndrome) and parathyroids (hyperparathyroidism), and in which the pituitary tumors are usually nonsecretory).

45.4 Differential diagnosis of pituitary tumors

See differential diagnosis (p. 1371), which also includes non-neoplastic etiologies.
45.5 Clinical presentation of pituitary tumors

45.5.1 General information

Classically, pituitary tumors are divided into functional (or secreting), and non-functional (AKA endocrine-inactive, which are either nonsecretory, or else secrete products such as gonadotropin that do not cause endocrinologic symptoms).

In general, secreting tumors tend to present earlier as a result of symptoms caused by physiologic effects of excess hormones that they secrete\(^2\) (this applies less e.g. to prolactinomas in males since the symptoms may be mild or unrecognized). Nonsecreting tumors usually do not present until they are sufficiently large enough to cause neurologic deficits by mass effect.

45.5.2 Presentation

General information

Presentation may be the result of: endocrine syndromes, mass effect, incidental finding (essentially only with macroadenomas), pituitary apoplexy.

Endocrinologic disturbance

Hormone oversecretion (secretory tumor)

\(\approx 65\%\) of adenomas secrete an active hormone (48% prolactin, 10% GH, 6% ACTH, 1% TSH)\(^3\):

1. prolactin (PRL) (p.722): can cause amenorrhea-galactorrhea syndrome in females), impotence in males:Etiologies:
   a) prolactinoma (p.722): neoplasia of pituitary lactotrophs
   b) stalk effect (p.732): pressure on the pituitary stalk may reduce the inhibitory control over PRL secretion
2. growth hormone (GH): elevated GH is due to a pituitary adenoma >95% of the time
   a) in adults: causes acromegaly (p.725)
   b) in prepubertal children (before epiphyseal plate closure): produces pituitary gigantism (very rare)
3. corticotropin AKA adrenocorticotropic hormone (ACTH):
   a) Cushing’s disease (endogenous hypercortisolism): see below
   b) Nelson syndrome (p.724): can develop only in patients who have had an adrenalectomy
4. thyrotropin (TSH) (p.726): secondary (central) hyperthyroidism
5. gonadotropins (luteinizing hormone (LH) and/or follicle stimulating hormone (FSH)): usually does not produce a clinical syndrome

Underproduction of pituitary hormones

May be caused by compression of the normal pituitary by large tumors. More common with non-secretory tumors than with secretory tumors. In order of sensitivity to compression (i.e. the order in which pituitary hormones become depressed from mass effect): GH, gonadotropins (LH & FSH), TSH, ACTH (mnemonic: Go Look For The Adenoma). Chronic deficiency of all pituitary hormones (panhypopituitarism) may produce pituitary cachexia (AKA Simmonds’ cachexia).

NB: selective reduction of a single pituitary hormone is very atypical with pituitary adenomas. May occur with autoimmune hypophysitis (p.1373), which most commonly involves ACTH or ADH (causing DI\(^4\) – see below)

1. Deficiency of specific hormones

   2. growth hormone deficiency (note: growth hormone stimulation test (p.736) is more sensitive and specific for GH deficiency than measuring basal GH levels):
      a) in children: produces growth delay
      b) in adults: produces vague symptoms with metabolic syndrome (decreased lean body mass, centripetal obesity, reduced exercise tolerance, impaired sense of well-being)
      c) hypogonadism: amenorrhea (women), loss of libido, infertility
3. hypothyroidism: cold intolerance, myxedema, entrapment neuropathies (e.g. carpal tunnel syndrome), weight gain, memory disturbance, integumentary changes (dry skin, coarse hair, brittle nails), constipation, increased sleep demand
4. hypoadrenalism: orthostatic hypotension, easy fatigability
5. diabetes insipidus: almost never seen pre-operatively with pituitary tumors (except possibly with pituitary apoplexy, see below). If DI is present, other etiologies should be sought, including:
   a) autoimmune hypophysitis (p.1373)
   b) hypothalamic glioma
   c) suprasellar germ cell tumor
6. gonadotropin deficiency (hypogonadotrophic hypogonadism) with anosmia is part of Kallmann syndrome.

**Mass effect (other than compression of the pituitary)**

Because they tend to get to a larger size before detection, this is more common with nonfunctioning tumors. Of functional tumors, prolactinoma is the most likely to become large enough to cause mass effect (especially in males or non-menstruating females); ACTH tumor is least likely. Non-specific symptoms include headaches. Seizures are rarely attributable to pituitary adenomas and other etiologies should be sought. Mass effect may occur suddenly as a result of expansion with pituitary apoplexy (see below).

Structures commonly compressed and their manifestations include:
1. optic chiasm: classically produces bitemporal hemianopsia (non-congruous). May also cause decreasing visual acuity
2. involvement of third ventricle may produce obstructive hydrocephalus
3. cavernous sinus
   a) pressure on cranial nerves contained within (III, IV, VI): ptosis, facial pain, diplopia (below)
   b) occlusion of the cavernous sinus: proptosis, chemosis
   c) encasement of the carotid artery by tumor: may cause slight narrowing, but complete occlusion is rare
4. invasive adenomas (p.721) infrequently present with CSF rhinorrhea with invasive prolactinomas this may be precipitated by shrinkage resulting from medical treatment
5. macroadenomas may produce H/A possibly via increased intrasellar pressure

**Pituitary apoplexy**

**General information**

**Key concepts**

- due to expansion of a pituitary adenoma from hemorrhage or necrosis
- typical presentation: paroxysmal H/A with endocrinologic and/or neurologic deficit (usually ophthalmoplegia or visual loss)
- management: immediate administration of glucocorticoids, and transsphenoidal decompression within 7 days in most cases

**Definition**

Neurologic and/or endocrinologic deterioration due to sudden expansion of a mass within the sella turcica.

**Etiology**

Sudden intrasellar expansion may occur as a result of hemorrhage, necrosis and/or infarction within a pituitary tumor and adjacent pituitary gland. Occasionally, hemorrhage occurs into a normal pituitary gland or Rathke’s cleft cyst.

**Epidemiology**

In Wilson’s series, 3% of his patients with macroadenomas had an episode of pituitary apoplexy. In another series of 560 pituitary tumors, a high incidence of 17% was found (major attack in 7%, minor in 2%, asymptomatic in 8%). It is common for apoplexy to be the initial presentation of a pituitary tumor.

**Clinical features of pituitary apoplexy**

Patients often present with abrupt onset of H/A, visual disturbance, and loss of consciousness. Neurologic involvement includes:

1. visual disturbances: one of the most common findings. Includes:
   a) ophthalmoplegia (unilateral or bilateral): opposite the situation with a pituitary tumor, ophthalmoplegia occurs more often (78%) than visual pathway deficits (52–64%)
   b) one of the typical field cuts (p.730) seen in pituitary tumors
2. reduced mental status: due to ↑ ICP or hypothalamic involvement
3. cavernous sinus compression can cause venous stasis and/or pressure on any of the structures within the cavernous sinus
   a) trigeminal nerve symptoms
   b) proptosis
   c) ophthalmoplegia (Cr. N. III palsy is more common than VI)
   d) ptosis may be an early symptom \(^{13,24}\)
   e) pressure on carotid artery
   f) compression of sympathetics within the cavernous sinus may produce a form of Horner’s syndrome with unilateral ptosis, miosis, & anhidrosis limited to the forehead
   g) carotid artery compression may cause stroke or vasospasm
4. when hemorrhage breaks through the tumor capsule and the arachnoid membrane into the chiasmatic cistern, signs and symptoms of SAH may be seen
   a) N/V
   b) meningismus
   c) photophobia
5. increased ICP may produce lethargy, stupor or coma
6. hypothalamic involvement may produce
   a) hypotension
   b) thermal dysautoregulation
   c) cardiac dysrhythmias
   d) respiratory pattern disturbances
   e) diabetes insipidus
   f) altered mental status: lethargy, stupor or coma
7. suprasellar expansion can produce acute hydrocephalus

Evaluation
CT or MRI shows hemorrhagic mass in sella turcica and/or suprasellar region, often distorting the anterior third ventricle.
Cerebral angiography should be considered in cases where differentiating pituitary apoplexy from aneurysmal SAH is difficult.

Management of pituitary apoplexy
Pituitary function is consistently compromised, necessitating rapid administration of corticosteroids and endocrine evaluation.
In the absence of visual deficits, prolactinomas may be treated with bromocriptine.
Rapid decompression is required for: sudden constriction of visual fields, severe and/or rapid deterioration of acuity, or neurologic deterioration due to hydrocephalus. Surgery in ≤7 days of pituitary apoplexy resulted in better improvement in ophthalmoplegia (100%), visual acuity (88%), and field cuts (95%) than surgery after 7 days, based on a retrospective study of 37 patients.\(^ {15}\) Decompression is usually via a transsphenoidal route (transcranial approach may be advantageous in some cases). Goals of surgery:
1. to decompress the following structures if under pressure: optic apparatus, pituitary gland, cavernous sinus, third ventricle (relieving hydrocephalus)
2. obtain tissue for pathology
3. complete removal of tumor is usually not necessary
4. for hydrocephalus: ventricular drainage is generally required

45.6 Specific types of pituitary tumors
45.6.1 Invasive pituitary adenomas
About 5% of pituitary adenomas become locally invasive. The genetic make-up of these tumors may differ from more benign adenomas,\(^ {16}\) even though the histology is similar. Numerous classifications systems have been devised for invasive adenomas, Wilson’s system\(^ {27} \) (modified from Hardy\(^ {18,19} \)) is shown in Table 45.1.
The clinical course is variable, with some tumors being more aggressive than others. Occasionally, these tumors grow to gigantic sizes (>4 cm dia), and these are often very aggressive and follow a malignant course.\(^ {20}\) At times, an adenoma may push the medial wall of the cavernous sinus ahead of it without actually perforating this dural structure (i.e. not actually invading the sinus).\(^ {21}\) This is difficult to
reliably identify on MRI, and the most definitive sign of cavernous sinus invasion is carotid artery encasement.22

**Presentation**

1. **visual system**
   a) most present due to compression of the optic apparatus, usually producing gradual visual deficit (however, sudden blindness is not unheard of)
   b) extraocular muscle deficits may occur with cavernous sinus invasion, and usually develop after visual loss
   c) exophthalmos may occur with orbital invasion due to compromise of orbital venous drainage
2. **hydrocephalus**: suprasellar extension may obstruct one or both foramen of Monro
3. invasion of the skull base may lead to nasal obstruction. CSF rhinorrhea may occasionally be precipitated by tumor shrinkage in response to dopamine agonists (e.g. bromocriptine) as a result of uncovering areas of bone erosion. This carries the risk of ascending meningitis.23
4. tumors that secrete prolactin (p.719) often present with findings of hyperprolactinemia and with these, the prolactin levels are usually >1000 ng/ml (caution: giant invasive adenomas with very high PRL production may have a falsely low PRL level due to “hook effect” (p.733)

### 45.6.2 Hormonally active pituitary tumors

**Prolactinomas**

The most common secretory adenoma. Arise from neoplastic transformation of anterior pituitary lactotrophs. See Table 46.4 for DDs of hyperprolactinemia.

**Manifestations of prolonged hyperprolactinemia:**

1. **females**: amenorrhea-galactorrhea syndrome (AKA Forbes-Albright syndrome, AKA Ahumada-del Castillo syndrome). Variants: oligomenorrhea, irregular menstrual cycles. 5% of women with primary amenorrhea will be found to have a PRL-secreting pituitary tumor.24 Remember: pregnancy is the most common cause of secondary amenorrhea in females of reproductive potential. The galactorrhea may be spontaneous or expressive (only on squeezing the nipples)
2. **males**: impotence, decreased libido. Galactorrhea is rare (estrogen is also usually required). Gynecomastia is rare. Prepubertal prolactinomas may result in small testicles and feminine body habitus
3. either sex:
   a) infertility is common
   b) bone loss (osteoporosis in women, and both cortical and trabecular osteopenia in men) due to a relative estrogen deficiency, not due to the elevated prolactin itself

</tbody>
</table>

*a specify: 1) anterior, 2) middle, or 3) posterior fossa*
At the time of diagnosis, 90% of prolactinomas in women are microadenomas, vs. 60% for males (probably due to gender specific differences in symptoms resulting in earlier presentation in females). Some tumors secrete both PRL and GH.

**Cushing’s disease**

**General information and Cushing’s syndrome**

Cushing’s syndrome (CS) is a constellation of findings caused by hypercortisolism. Cushing’s disease (p.723) – endogenous hypercortisolism due to hypersecretion of ACTH by an ACTH secreting pituitary adenoma – is just one cause of CS. The most common cause of CS is iatrogenic (administration of exogenous steroids). Possible etiologies of endogenous hypercortisolism are shown in Table 45.2. To determine the etiology of CS, see Dexamethasone suppression test (p.734).

Conversion factors for ACTH and cortisol between U.S. units and SI units are shown in Eq (45.1) and (45.2).

\[ \text{ACTH: } 1 \text{pg} = \frac{1}{4} \text{ng/liter} \]  
\[ \text{Cortisol: } 1 \mu g = \frac{27.59}{l \text{iter}} \text{nmol/liter} \]

**Ectopic ACTH secretion**

Hypercortisolism may also be due to ectopic secretion of ACTH usually by tumors, most commonly small-cell carcinoma of the lung, thymoma, carcinoid tumors, pheochromocytomas, and medullary thyroid carcinoma. In addition to findings of Cushing’s syndrome, patients are typically cachectic due to the malignancy which is usually rapidly fatal.

**Prevalence of Cushing’s disease**

40 cases/million population. ACTH-producing adenomas comprise 10–12% of pituitary adenomas. Cushing’s disease is 9 times more common in women, whereas ectopic ACTH production is 10 times more common in males. Non-iatrogenic CS is 25% as common as acromegaly.

At the time of presentation, over 50% of patients with Cushing’s disease have pituitary tumors <5 mm in diameter, which are very difficult to image with CT or MRI. Most are basophilic, some (especially the larger ones) may be chromophobic. Only ≈ 10% are large enough to produce some mass effect, which may cause enlargement of the sella turcica, visual field deficit, cranial nerve involvement and/or hypopituitarism.

**Clinical findings in Cushing’s disease**

Findings are those of Cushing’s syndrome (hypercortisolism from any cause) include:

1. weight gain  
   a) generalized in 50% of cases

<table>

</tbody>
</table>

[^a]: ACTH may be normal or slightly elevated; normal ACTH levels in the presence of hypercortisolism are considered inappropriately elevated
b) centripetal fat deposition in 50%: trunk, upper thoracic spine (“buffalo hump”), supraclavicular fat pad, neck, “dewlap tumor” (episternal fat), with round plethoric face (“moon faces”) and slender extremities

2. hypertension
3. ecchymoses and purple striae, especially on flanks, breasts and lower abdomen
4. amenorrhea in women, impotence in men, reduced libido in both
5. hyperpigmentation of skin and mucous membranes: due to MSH cross-reactivity of ACTH. Occurs only with elevated ACTH, i.e. Cushing’s disease (not Cushing’s syndrome) or ectopic ACTH production (also below)
6. atrophic, tissue-paper thin skin with easy bruising and poor wound healing
7. psychiatric: depression, emotional lability, dementia
8. osteoporosis
9. generalized muscle wasting with complaints of easy fatigability
10. elevation of other adrenal hormones: androgens may produce hirsutism and acne
11. sepsis: associated with advanced Cushing’s syndrome

Laboratory findings in Cushing’s disease
1. hyperglycemia: diabetes or glucose intolerance
2. hypokalemic alkalosis
3. loss of diurnal variation in cortisol levels
4. normal or elevated ACTH levels
5. failure to suppress cortisol with low-dose (1 mg) dexamethasone test (p. 734)
6. elevated 24-hour urine free-cortisol
7. CRH levels will be low (not commonly measured)

Nelson’s syndrome (or Nelson syndrome) (NS)

General information

Key concepts
- A rare condition that follows 10–30% of total bilateral adrenalectomies (TBA) performed for Cushing’s disease; see indications for TBA (p. 743).
- Classic triad: hyperpigmentation (skin & mucous membranes), abnormal ↑ ACTH, and progression of pituitary tumor (the last criteria is now controversial).
- Treatment options: surgery (transsphenoidal or transcranial), XRT, medication

A rare condition that follows 10–30% of total bilateral adrenalectomies (TBA) performed for Cushing’s disease; see indications for TBA (p. 743). NS is due to continued growth of corticotroph (ACTH-secreting) adenoma cells. Usually occurs 1–4 years after TBA (range: 2 mos-24 years). Theoretical explanation (unproven): following TBA, hypercortisolism resolves, and CRH levels increase back to normal from the (reduced) suppressed state; corticotroph adenomas in patients with NS have an increased & prolonged response to CRH resulting in increased growth. Also, corticotrophs in NS and CD show reduced inhibition by glucocorticoids. It is controversial if some cases may be related to insufficient glucocorticoid replacement after TBA.

Manifestations
See reference.
1. hyperpigmentation (due to melanin stimulating hormone (MSH) cross reactivity of ACTH and actual increased levels of MSH due to increased proopiomelanocortin production). Often the earliest sign that Nelson’s syndrome is developing. Look for linea nigra (midline pigmentation from pubis to umbilicus) and hyperpigmentation of scars, gingivae, and areolae. DDx of hyperpigmentation includes: primary adrenal insufficiency (high levels of ACTH), ectopic ACTH secretion, hemochromatosis (more bronze color), jaundice (yellowish)
2. tumor growth → increased mass effect (p. 720) or invasion: the most serious consequence. These corticotroph tumors are among the most aggressive of pituitary tumors. May produce any of the problems associated with macroadenomas (optic nerve compression, cavernous sinus invasion, pituitary insufficiency, H/A, bony invasion...) as well as necrosis with precipitous intracranial hypertension; see pituitary apoplexy (p. 720)
3. malignant transformation of the corticotroph tumor (very rare)
4. hypertrophy of adrenal tissue rests: may be located in the testes → painful testicular enlargement and oligospermia. Rarely the rests can secrete enough cortisol to normalize cortisol levels or even cause a recurrence of Cushing’s disease despite the adrenalectomy

Evaluation
1. Laboratories
   a) ACTH > 200 ng/L (usually thousands of ng/L) (normal: usually < 54 ng/L)
   b) exaggerated ACTH response to CRH (not required for diagnosis)
   c) other pituitary hormones may be affected as with any macroadenoma causing mass effect (p. 720) and endocrine screening (p. 731) should be done
2. Formal visual field testing (p. 730): should be done in patients with suprasellar extension or in those being considered for surgery (as a baseline for comparison)

Treatment
See treatment (p. 739).

Acromegaly

General information

**Key concepts**

- abnormally high levels of growth hormone in an adult. > 95% of cases are due to a benign pituitary somatotroph adenoma, > 75% are > 10 mm at time of diagnosis
- effects include soft tissue and skeletal changes, cardiomyopathy, colon Ca
- work-up: endocrine tests (p. 730), cardiology consult, colonoscopy
- treatment (p. 741): surgery for most, and then if necessary, medical therapy (p. 741) and/or XRT (p. 745)
- suggested criteria for biochemical cure (p. 753): normal IGF-1, growth hormone level < 5 ng/ml, AND GH nadir of < 1 ng/ml after OGST (p. 736)

Incidence: 3 cases/1-million persons/year. > 95% of cases of excess GH result from a pituitary somatotroph adenoma. Growth hormone carcinoma is extremely rare. Ectopic GH secretion may occur uncommonly with: carcinoid tumor, lymphoma, pancreatic islet-cell tumor. By the time of diagnosis, > 75% of pituitary GH tumors are macroadenomas (> 10 mm dia) with cavernous sinus invasion and/or suprasellar extension.

25% of acromegalics have thyromegaly with normal thyroid studies. 25% of GH adenomas also secrete prolactin. Acromegaly occurs rarely as part of a genetic syndrome, including: multiple endocrine neoplasia type 1 (MEN 1), McCune-Albright syndrome, familial acromegaly, and Carney complex.

Clinical

Elevated levels of GH in children before closure of the epiphyseal plates in the long bones produces gigantism. Usually presents in the teen years.

In adults, elevated GH levels produce acromegaly (age: usually > 50 yrs) with findings that may include [31,32] (also see Table 45.3):

1. skeletal overgrowth deformities
   a) increasing hand and foot size
   b) thickened heel pad
   c) frontal bossing
   d) prognathism
2. cardiovascular
   a) cardiac findings (structural and functional): arrhythmias, valvular disease, concentric myocardial hypertrophy
   b) hypertension (30%)
3. soft tissue swelling (includes macroglossia)
4. glucose intolerance
5. peripheral nerve entrapment syndromes (including carpal tunnel syndrome)

\*reversibility with normalization of GH levels

6. debilitating headache
7. excessive perspiration (especially palmar hyperhidrosis)
8. oily skin
9. joint pain
10. sleep apnea
11. fatigue
12. colon cancer: risk is \( 2 \times \) risk of general population\textsuperscript{33}

Patients with elevated levels of GH (including partially treated cases) have 2–3 times the expected mortality rate\textsuperscript{34} primarily due to hypertension, diabetes, pulmonary infections, cancer, and cardiovascular disease (Table 45.3). Soft-tissue swelling and nerve entrapment may be reversible with normalization of GH levels, however many disfiguring changes and health risks are permanent (Table 45.3 for specifics).

**Thyrotropin (TSH)-secreting adenomas**

**General information**

Rare: comprise \( \approx 0.5–1\% \) of pituitary tumors\textsuperscript{3,35} Produces central (secondary) hyperthyroidism (note: central hyperthyroidism may also occur with pituitary resistance to thyroid hormones\textsuperscript{36}): elevated circulating T3 and T4 levels, with elevated or inappropriately normal TSH\textsuperscript{36} (TSH should be
undetectable in primary hyperthyroidism). Up to 33% of tumors positive for TSH immunostaining are nonsecretory. Many of these tumors are plurihormonal, but the secondary hormone is usually clinically silent. Most of these tumors are aggressive and invasive and are large enough at presentation to also produce mass effect (especially if prior thyroid ablative procedures have been done, which occurs in up to 60% of cases due to lack of recognition of pituitary abnormality).

Clinical
Symptoms of hyperthyroidism: anxiety, palpitations (due to a-fib), heat intolerance, hyperhidrosis, and weight loss despite normal or increased intake. Signs: hyperactivity, lid lag, tachycardia, irregular rhythm when a-fib is present, hyperreflexia, tremor. Exophthalmos and infiltrative dermopathy (e.g. pretibial myxedema) are present only in Grave’s disease.

45.6.3 Pathological classification of pituitary tumors

Light microscopic appearance of adenomas
Older classification system. Of limited usefulness. With newer techniques (EM, immunohistochemistry, radio-immuno assay…) many tumors previously considered nonsecretory have been found to have all the components necessary to secrete hormones.

In order of decreasing frequency:
1. chromophobe: most common (ratio of chromophobe to acidophil is 4-20:1). Originally considered “non-secretory”, in actuality may produce prolactin, GH, or TSH
2. acidophil (eosinophilic): produce prolactin, TSH, or usually GH
3. basophil → gonadotropins, β-lipotropin, or usually ACTH → Cushing’s disease

Classification of adenomas based on secretory products

1. endocrine-active tumors: ≈70% of pituitary tumors produce 1 or 2 hormones that are measurable in the serum and cause defined clinical syndromes, these are classified based on their secretory product(s)
2. endocrine-inactive (nonfunctional) tumors (note: a and b constitute the bulk of endocrine-inactive adenomas):
   a) null-cell adenoma
   b) oncocytoma
   c) gonadotropin-secreting adenoma
   d) silent corticotropin-secreting adenoma
   e) glycoprotein-secreting adenoma

Tumors of the neurohypophysis and infundibulum

General information
The most common tumors encountered in the posterior pituitary are metastases (owing to the rich blood supply).

Granular cell tumors
AKA (infundibular) granular cell tumor (GCT). WHO grade I. Obsolete terms: choristoma, granular cell myoblastoma, pituicytoma (this term is now reserved for a circumscribed glial neoplasm – see below). Tumors with nests of large cells having granular, eosinophilic cytoplasm.

While rare, GCTs are the most common primary tumor of the neurohypophysis and pituitary stalk/infundibulum with a predilection for the stalk (these result in suprasellar extension). GCTs have been identified in the gastrointestinal tract, genitourinary tract, orbital region as well as in other locations of the central nervous system with no connection to the pituitary gland or hypothalamus (e.g. spinal meninges). Female:male ratio ≥2:1. Asymptomatic microscopic clusters of granular cells (tumorettes) are more common, with an incidence up to 17%.

The most common presentation is with visual field deficits due to optic chiasm compression. However, any symptom typical of a hormonally inactive sellar mass may occur.

Imaging: may appear radiographically identical to adenomas. Rarely considered in the differential diagnosis pre-op. Isodense on CT and isointense on T1W1 MRI, dense homogeneous enhancement on CT & MRI.

Treatment: if GTC is suspected pre-op, a transcranial approach is preferred over transphenoidal because of the vascularity which has prevented total resection in 60–70% of reported cases. XRT may be considered for subtotal resection.
Pituicytoma
Less favored alternate terms include posterior pituitary astrocytoma. Rare (mostly case reports). Circumscribed tumor with spindle cells, arising from the neurohypophysis or infundibulum. WHO grade I. Reported only in adults.

Treatment: surgical excision. Subtotal removal may be followed by recurrence over several years.

References

46 Pituitary Adenomas – Evaluation and Nonsurgical Management

46.1 Evaluation

46.1.1 History and physical

Directed to look for signs and symptoms of:

1. endocrine hyperfunction (see Functional pituitary tumors above), including:
   a) prolactin: amenorrhea (women), nipple discharge (primarily in women since estrogen is also required), impotence (males)
   b) thyroid: heat intolerance
   c) growth hormone: change in ring size or shoe size or coarsening of facial features, gigantism (children)
   d) cortisol: hyperpigmentation, Cushingoid features

2. endocrine deficits due to mass effect (p. 720) on pituitary

3. visual field deficit: bedside confrontational testing to rule-out visual field deficit (classically bitemporal hemianopsia, see below)

4. deficits of cranial nerves within cavernous sinus
   a) III, IV, VI: disorder of pupil and extraocular muscles
   b) V1, V2: reduced sensation in forehead, nose, upper lip and cheek

46.1.2 Diagnostic tests

Overview

Initial (screening) tests to work-up a patient presenting with a known or suspected pituitary mass are shown in Table 46.1. Further testing is indicated for abnormal results or for strong suspicion of specific syndromes (see indicated page for details).

Visual fields

Formal visual field testing: by perimetry with a tangent screen (using the small red stimulus since desaturation of color is an early sign of chiasmal compression) or by Goldman or automated Humphrey perimeter (the latter requires good cooperation from the patient to be valid).

Visual field deficit patterns

Depends in part on location of chiasm with respect to sella turcica: the chiasm is located above the sella in 79%, posterior to the sella turcica (postfixed chiasm) in 4%, in front of the sella (pre-fixed) in 5%.

1. compression of the optic chiasm:
   a) bitemporal hemianopsia (p. 560) that obeys the vertical meridian: classic visual field deficit associated with a pituitary tumor. Due to impingement on crossing nasal fibers in the chiasm
   b) other reported patterns that occur rarely: monocular temporal hemianopsia

2. optic nerve compression: more likely in patients with a postfixed chiasm
   a) loss of vision in the ipsilateral eye. If carefully sought, there is usually a superior outer (temporal) quadrantanopsia in the contralateral eye (so-called junctional scotoma AKA “pie in the sky” defect) from compression of the anterior knee of Wilbrand (p. 1214); may also be an early finding even without a post-fixed chiasm
   b) may produce central scotoma or monocular reduction in visual acuity

3. compression of the optic tract: may occur with a pre-fixed chiasm. Produces homonymous hemianopsia

Initial endocrinologic evaluation (screening) modified

See reference. Also, see Table 46.1. May give indication of tumor type, determines whether any hormones need to be replaced, and serves as a baseline for comparison following treatment. Includes clinical assessment for signs and symptoms, as well as laboratory tests. Screening tests should be checked in
all patients with pituitary tumors. Note: selective loss of a single pituitary hormone together with thickening of the pituitary stalk is strongly suggestive of autoimmune hypophysitis (p.1373).

1. adrenal axis screening; see tests to assess cortisol reserve (p.735)
   a) cortisol levels normally peak between 7-8 AM. AM cortisol may normally be elevated slightly above the reference range. 8 AM cortisol level: better for detecting hypocortisolism.
   Normal:
   Normal: 6-18 mcg/100 ml.
   Interpretation:
   • 8 AM cortisol<6 mcg/100 ml: suggestive of adrenal insufficiency
   • 8 AM cortisol 6-14 mcg/100 ml: nondiagnostic
   • 8 AM cortisol>14 mcg/100 ml: adrenal insufficiency is unlikely
   b) in questionable cases, including to distinguish pseudo-Cushing states from Cushing’s syndrome (p.734)
   c) 24-hour urine free cortisol: more accurate for hypercortisolism (e.g. to look for Cushing’s syndrome)
   Normal:
   Normal: 6-25 mcg/24 hrs.
   Interpretation:
   • <6 mcg/24 hrs: typical of pseudocushing state
   • 6-15 mcg/24 hrs: possible cushing disease
   • >15 mcg/24 hrs: definite cushing disease

2. thyroid axis: the basis for thyroid screening is shown in Table 46.2
   a) screening: T4 level (total or free), thyroid-stimulating hormone (TSH) (AKA thyrotropin). Normal values: free T4 index is 0.8–1.5, TSH 0.4–5.5 mU/ml, total T4 4–12 mcg/100 ml (NB: be sure to check both T4 AND TSH)
   b) further testing: thyrotropin-releasing hormone (TRH) stimulation test (indicated if T4 is low or borderline): check baseline TSH, give 500 mcg TRH IV, check TSH at 30 & 60 mins. Normal response: peak TSH twice baseline value at 30 mins. Impaired response with a low T4 indicates pituitary deficiency. Exaggerated response suggests primary hypothyroidism
3. gonadal axis

a) screening:
- serum gonadotropins: FSH & LH
- sex steroids: estradiol in women, testosterone in men (measure total testosterone)

b) further testing: none dependable in differentiating pituitary from hypothalamic disorders

4. prolactin levels (PRL): for prolactin neurophysiology (p.151)

a) interpretation is shown in Table 46.3. See Table 46.4 for differential diagnosis of hyperprolactinemia. Prolactin level correlates with size of prolactinomas: if PRL is <200 ng/ml, ≈ 80% of tumors are microadenomas, and 76% of these will have normal PRL after surgery; if PRL >200, only ≈ 20% are microadenomas

b) blood samples should be obtained midmorning (i.e. not soon after awakening) and not after stress, breast stimulation, or physical examination, which may increase PRL levels

c) be aware of the following when interpreting PRL levels:
- because of variations in secretion (daily fluctuations can be as high as 30%) and intrinsic inaccuracies of radioimmunoassay, PRL levels should be rechecked if there is a reason to question a specific result
- heterophilic antibodies (seen in individuals routinely exposed to animal serum products) can cause anomalous results
- stalk effect: PRL is the only pituitary hormone primarily under inhibitory regulation (p.151). Injury to or compression of the hypothalamus or pituitary stalk from surgery or compression by any type of tumor can cause modest elevation of PRL due to decrease in prolactin inhibitory factor (PRIF). Rule of thumb: the percent chance of an elevated PRL being due to a prolactinoma is equal to one half the PRL level. Persistent post-op PRL elevation may occur even with total tumor removal as a result of injury to stalk (usually ≤90 ng/ml; stalk effect doubtful if PRL >150). For stalk effect, follow these patients, do not use bromocriptine

* Caution: replacing thyroid hormone with inadequate cortisol reserves (as may occur in panhypopituitarism) can precipitate adrenal crisis; see management (p.738)
"prolactin level >200 ng/ml": if the lab reports the prolactin level as ">200" (or some other high value) instead of an actual number, it usually indicates a very high prolactin level that exceeds the upper limits of the assay. Call the lab and ask them to determine the actual value. This usually requires the lab to run serial dilutions until the PRL is in a range that their assay can quantify (they may be able to do it with the specimen they have, or else the patient will need to have another blood draw). The reasons this is important: (1) treatment decisions: PRL>500 usually indicates that surgery alone will not be able to normalize the PRL (p.739); (2) to assess response to treatment: it is essential to know what value you are starting with to determine response to medication, surgery, XRT…

hook effect: extremely high PRL levels may overwhelm the assay (the large numbers of PRL molecules prevent the formation of the necessary PRL-antibody-signal complexes for

bnormal values vary, use your lab’s reference range  
csome authors recommend 200 ng/ml as the cutoff for probable prolactinomas  
dfor DDx of hyperprolactinemia see Table 46.4

Table 46.4 Differential diagnosis of elevated prolactin (PRL) level (hyperprolactinemia)

1. pregnancy-related
   a) during pregnancyb: 10–400 ng/ml  
   b) postpartum: PRL decreases ≥ 50%(to ≤ 100 ng/ml) in the first week postpartum, and is usually back to normal in 3 weeks  
   c) in the lactating female: suckling increases PRL, which is critical for lactogenesis (once initiated, nonpregnant PRL levels can maintain lactation). First 2–3 months postpartum: basal PRL=40–50 ng/ml, suckling → increases × 10–20. 3–6 months postpartum: basal PRL levels become normal or slightly elevated, and double with suckling. PRL should normalize by 6 months after weaning

2. pituitary adenoma
   a) prolactinoma: larger prolactin microadenomas and macroadenomas usually produce PRL>100 ng/ml  
   b) stalk effect (p. 732): rule of thumb, the percent chance of an elevated PRL being due to a prolactinoma is equal to one half the PRL level  
   c) some tumors secrete both PRL and GH

3. drugs: dopamine receptor antagonists (e.g. phenothiazines, metoclopramide), oral contraceptives (estrogens), tricyclic antidepressants, verapamil, H2 antagonists (e.g. ranitidine), some SSRIs in particular paroxetine (Paxil®)...

4. primary hypothyroidism: TRH, a prolactin releasing factor (PRF), (p.151) will be elevated

5. empty sella syndrome (p.766)

6. post-ictal (p. 467): PRL usually normalizes within 1–2 hrs after a seizure

7. breast or chest-wall trauma/surgery; usually ≤ 50 ng/ml

8. excessive exercise: usually ≤ 50 ng/ml

9. stress: in some cases the stress of having the blood test is enough to elevate PRL, anorexia nervosa

10. ectopic secretion; reported in renal cell or hepatocellular tumors, uterine fibroids, lymphomas

11. infiltrating hypothalamic tumors

12. renal failure

13. carcinoma

14. macroprolactinemia: see text

*hyperprolactinemia from causes other than prolactinomas rarely exceeds 200 ng/ml  
badways R/O pregnancy as a cause of amenorrhea & hyperprolactinemia in a female with reproductive potential
radioimmunoassay) and produce falsely low results. Therefore, for large adenomas with a normal PRL level, have the lab perform several dilutions of the serum sample and re-run the PRL, especially in patients with clinical hyperprolactinemia

- macroprolactinemia: a situation where prolactin molecules polymerize and bind to immunoglobulins. Prolactin in this form has reduced biologically activity but produces a laboratory finding of hyperprolactinemia. Clinical significance is controversial, asymptomatic patients usually do not require treatment

5. growth hormone:
   a) IGF-1 (somatomedin-C) level (p.736) is the recommended initial test (testing for elevated IGF-1 is extremely sensitive for acromegaly)
   b) checking a single random GH level may not be a reliable indicator (p.736) and is therefore not recommended

6. neurohypophysis (posterior pituitary): deficits are rare with pituitary tumors
   a) screening: check adequacy of ADH by demonstrating concentration of urine with water deprivation
   b) further testing: measurement of serum ADH in response to infusion of hypertonic saline

Specialized endocrinologic tests

Cushing’s syndrome

Tests for hypercortisolism

These tests are used to determine if hypercortisolism (Cushing’s syndrome, CS) is present or not, regardless of etiology. Usually only needed if the screening 24-hr urine free cortisol (p.731) is equivocal (the basis of these tests is shown in Table 46.5).

1. overnight low-dose dexamethasone (DMZ) suppression tests:
   a) overnight low dose test: give DMZ 1 mg PO @ 11 P.M. and draw serum cortisol the next day at 8 A.M. Results:
      - cortisol < 1.8 mcg/dl (note: this is the currently accepted normal value; previously it was 5 mcg/dl): Cushing’s syndrome is ruled out (except for a few patients with CS who suppress at low DMZ doses, possibly due to low DMZ clearance)
      - cortisol 1.8 - 10 mcg/dl: indeterminate, retesting is necessary
      - cortisol > 10 mcg/dl: CS is probably present. False positives can occur in the so-called pseudo-Cushing’s state where ectopic CRH secretion produces hyperplasia of pituitary corticotrophs that is clinically indistinguishable from pituitary ACTH producing tumors (requires further testing). Seen in: 15% of obese patients, in 25% of hospitalized and chronically ill patients, in high estrogen states, in uremia, and in depression. The combined DMZ-CRH test can be used to identify this (see reference). False positives also may occur in alcoholics or patients on phenobarbital or phenytoin due increased metabolism of DMZ caused by induced hepatic microsomal degradation
   b) 2 day low dose test (used when overnight test is equivocal): give DMZ 0.5 mg PO q 6 hrs for 2 days starting at 6 A.M.; 24 hr urine collections are obtained prior to test and on the 2nd day of DMZ administration. Normal patients suppress urinary 17-hydroxycorticosteroids (OHCS) to less than 4 mg/24 hrs, whereas ≈ 95% of patients with CS have abnormal response (higher amounts in urine)

2. 11 PM salivary cortisol: this is the time of the usual cortisol nadir. Test must be run at NIH approved lab. Accuracy is as good as low-dose DMZ suppression test

Distinguishing Cushing’s disease from ectopic ACTH secretion

These tests are used to distinguish primary Cushing’s disease (CD) (pituitary ACTH hypersecretion) from ectopic ACTH production and adrenal tumors (may be required since 40% of CD patients have a normal MRI)

<table>

</tr>
<tr>
<td>DMZ does not interfere with measurement of urinary and plasma cortisol and 17-hydroxycorticosteroids</td>
</tr>
</tbody>
</table>
1. random serum ACTH: if < 5 ng/L indicates ACTH independent CS (e.g. adrenal tumor). Not sensitive or specific due to variability of ACTH levels
2. abdominal CT: usually shows unilateral adrenal mass with adrenal tumors, or normal or bilateral adrenal enlargement in ACTH-dependent cases
3. high-dose dexamethasone (DMZ) suppression test: (NB: up to 20% of patients with CD do not suppress with high-dose DMZ. Phenytoin may also interfere with high-dose DMZ suppression^15) a) overnight high-dose test: obtain a baseline 8 A.M. plasma cortisol level b) then give DMZ 8 mg PO @ 11 P.M. and measure plasma cortisol level the next morning at 8 A.M. c) in 95% of CD cases plasma cortisol levels are reduced to < 50% of baseline, whereas in ectopic ACTH or adrenal tumors it will usually be unchanged
4. metyrapone (Metopiron®) test: performed on an inpatient basis. Give 750 mg metyrapone (suppresses cortisol synthesis) PO q 4 hrs for 6 doses. Most patients with CD will have a rise in 17-OHCS in urine of 70% above baseline, or an increase in serum 11-deoxycortisol 400-fold above baseline
5. corticotropin-releasing hormone (CRH) stimulation test: CD responds to exogenous CRH 0.1 mcg/kg IV bolus with even further increased plasma ACTH and cortisol levels; ectopic ACTH and adrenal tumors do not^16
6. inferior petrosal sinus (IPS) sampling (or, cavernous sinus sampling is preferred by some): done by interventional neuroradiologist. Uses a microcatheter to measure ACTH levels on each side at baseline, and then at 2, 5 & 10 minutes after stimulation with IV CRH (with simultaneous peripheral ACTH levels at each interval). General information:
   a) IPS sampling is not needed when the following criteria of CD are met^17:
      • ACTH-dependent Cushing’s disease
      • visible pituitary adenoma on MRI
   b) may also determine likely side of a microadenoma within the pituitary (thus may be able to avoid bilateral adrenalectomy which requires lifelong gluco- and mineralo-corticoid replacement and risks Nelson’s syndrome (p.724) in 10–30% of the time this test falsely lateralizes the tumor due to the communication through the circular sinus
   c) a baseline IPS ACTH to peripheral ACTH ratio > 1.4:1 is consistent with primary Cushing’s disease
   d) a post CRH ratio > 3 is also consistent with primary Cushing’s disease
   e) complication rate: 1–2% includes puncture of the sinus wall

Assessing cortisol reserve
1. cosyntropin stimulation test^18:
   a) draw a baseline cortisol level (fasting is not required; test can be performed at any time of day)
   b) give cosyntropin (Cortrosyn®) (a potent ACTH analogue) 1 ampoule (250 mcg) IM or IV
   c) then check cortisol levels at 30 mins (optional) and at 60 mins
   d) normal response: peak cortisol level > 18 mcg/dl AND an increment > 7 mcg/dl, or a peak > 20 mcg/dl regardless of the increment
   e) subnormal response: indicates adrenal insufficiency. In primary adrenal insufficiency, pituitary ACTH secretion will be elevated. In secondary adrenal insufficiency, chronically reduced ACTH causes adrenal atrophy and unresponsiveness to acute stimulation with this exogenous ACTH analogue
   f) normal response: rules out primary and overt secondary adrenal insufficiency, but may be normal in mild cases of reduced pituitary ACTH or early after pituitary surgery where adrenal atrophy has not occurred. In these cases further testing may be positive: see metyrapone test (p.753) or ITT (see below)
2. insulin tolerance test (ITT): “gold standard” for assessing integrity of the hypothalamic-pituitary-adrenal axis. Cumbersome to do. Abnormal in 80% of CS. Assesses ACTH, cortisol & GH reserve
   a) rationale: an appropriate cortisol increment in response to insulin-induced hypoglycemia suggests patient will also be able to respond to other stresses (acute illness, surgery…)
   b) contraindications: seizure disorder, ischemic cardiac disease, untreated hypothyroidism
   c) pre-test preparation: D/C estrogen replacement for 6 weeks prior to test. Have 50 ml of D50 and 100 mg IV hydrocortisone available during test
   d) protocol: give regular insulin 0.1 U/kg IV push, and draw blood for glucose, cortisol and GH at 0, 10, 20, 30, 45, 60, 90 and 120 mins (monitor blood sugar by fingerstick during test, and give IV glucose if patient becomes symptomatic). If fingerstick blood sugar is not < 50 mg/dl by 30 minutes and patient is asymptomatic, give additional regular insulin 5 U IV. There must be 2 specimens after adequate hypoglycemia
Acromegaly
For suspected acromegaly, the most useful test is an IGF-1 level.
1. insulin-like growth factor-1 (IGF-1) (formerly somatomedin-C) level: an excellent integrative marker of average GH secretion. Normal levels depend on age (peaking during puberty), gender, pubertal stage and lab. Typical fasting levels by age are shown in Table 46.6. Estrogen may suppress IGF-1 levels
2. growth hormone (GH): normal basal fasting level is <5 ng/ml. In patients with acromegaly, GH is usually >10 ng/ml but can be normal. Normal basal levels do not reliably distinguish normal patient from GH deficiency. Furthermore, due to pulsatile secretion of GH, normal patients may have sporadic peaks up to 50 ng/ml. Occasionally acromegaly may be present even with GH levels as low as 37 pg/ml. random GH levels are not generally useful for diagnosing acromegaly (see above for IGF-1)
3. other tests used uncommonly
   a) oral glucose suppression test (OGST): less precise and more expensive than measuring IGF-1, however may be more useful than IGF-1 for monitoring initial response to therapy. GH levels are measured at 0, 30, 60, 90 & 120 minutes after a 75 gm oral glucose load. If the GH nadir is not <1 ng/ml, the patient is acromegalic.
   b) growth-hormone releasing hormone (GHRH) levels: may help diagnose ectopic GH secretion in a patient with proven acromegaly with no evidence of pituitary tumor on imaging. If an extrapituitary source is suspected, chest and abdominal CT and/or MRI should also be obtained.
   c) GHRH stimulation test: results may be discordant in up to 50% of patients with acromegaly and is thus rarely used (as of this writing, pharmaceutical production of GHRF has been discontinued)
4. octreotide scan: SPECT imaging 4 and 24 hours after injection with 6.5 mCi of indium-111 OctreoScan, a somatostatin receptor imaging agent

Radiographic evaluation
General information
≈ 50% of pituitary tumors causing Cushing’s syndrome are too small to be imaged on CT or MRI (therefore endocrinologic testing is required to prove the pituitary origin). See differential diagnosis of intrasellar lesions (p.1371); some are indistinguishable radiographically.

Normal AP diameter of pituitary gland: female of childbearing age (±13–35 yrs): ≤11 mm, for all others normal is ≤9 mm. (Note: pituitary glands in adolescent girls may be physiologically enlarged (mean height: 8.2 ± 1.4 mm) as a result of hormonal stimulation of puberty.25)

Skull x-ray
A lateral skull x-ray may help define the bony anatomy of the sphenoid sinus in cases where transsphenoidal surgery is contemplated (currently, CT scan is usually employed).

MRI
Imaging test of choice for pituitary tumors.
Ordering MRI:
• typical order on initial workup: brain MRI and pituitary MRI without and with contrast (pituitary protocol includes thin coronal cuts through sella showing cavernous sinus and optic chiasm) with image navigation protocol (e.g. BrainLab™, or Stealth™…)
• if you are hunting for a microadenoma, then a dynamic MRI increases the chances that you might catch the tumor at a time when it enhances differentially from the gland.
• for follow-up of macroadenomas: routine coronal & sagittal pituitary MRI without & with contrast

Findings: Information about invasion of cavernous sinus, and about location and/or involvement of para-sellar carotids. MRI may fail to demonstrate tumor in 25–45% of cases of Cushing’s disease.26
3 T vs. 1.5 T MRI: based on 5 cases of Cushing’s disease, a 3 T MRI showed the adenoma more clearly in 2 cases, in 1 case it showed the tumor on the correct side opposite to where the 1.5 T MRI showed it, and in 2 cases neither 1.5 T nor 3 T MRI could show the microadenoma).27

Microadenoma: 75% are low signal on T1WI, and high signal on T2WI (but 25% can behave in any way, including completely opposite to above). Enhancement is very time-dependent. Imaging must be done with 5 minutes of contrast administration to see a discrete microadenoma. Initially, gadolinium enhances the normal pituitary (no blood brain barrier) but not the pituitary tumor. After ≈30 minutes, the tumor enhances about the same. Dynamic MRI scans have been used to increase the sensitivity (contrast is injected while the MRI scanner is running).

Neurohypophysis: normally is high signal on T1WI (possibly due to phospholipids). Absence of this “bright spot” often correlates with diabetes insipidus as may occur with autoimmune hypophysitis (p.1373), however, failure to image the bright spot is not uniformly abnormal.

Deviation of the pituitary stalk may also indicate the presence of a microadenoma. Normal thickness of the pituitary stalk is approximately equal to basilar artery diameter. Thickening of stalk is usually NOT adenoma, differential diagnosis for a thickened stalk: lymphoma, autoimmune hypophysitis (p.1373), granulomatous disease, hypothalamic glioma.

CT
Generally superseded by MRI. May be appropriate when MRI is contraindicated (e.g. pacemaker). When done, should include direct coronal imaging, or coronal reconstructions from thin-cut axial CT. If MRI cannot be done, consider also cerebral angiography to demonstrate parasellar carotid arteries and to R/O aneurysm as a possibility.

Calcium in pituitary usually signifies hemorrhage or infarction within tumor.

Angiography
Sometimes used in cases considered for transsphenoidal surgery (e.g. as a complement to CT) to localize the parasellar carotids (note: MRI provides this information, and evaluates invasion of cavernous sinuses, usually obviating the need for angiography).

46.2 Management/treatment recommendations
46.2.1 General information
See treatment of pituitary apoplexy (p.720). For large invasive adenomas, see below.

Note: Prolactinoma is the only pituitary tumor for which medical therapy (dopamine agonist) is the primary treatment modality (in certain cases).
Hormone replacement therapy (HRT)

HRT may be required for patients with documented endocrine deficits pre-op or post-op in cases where pituitary function is not normal. Critical issues:

1. corticosteroids
   a) indications: inadequate cortisol reserve as demonstrated by failing a cosyntropin stimulation test; failure to achieve a peak cortisol level > 18 mcg/dl in response to cosyntropin (p.735)
   b) may start cortisol immediately after bloodwork for cosyntropin test is drawn (do not need to wait for test results) – then, when test results available, continue or stop therapy based on test results
   c) physiologic replacement dose: cortisol 20 mg po q AM and 10 mg po q 4 PM. Stress doses may be needed (p.146) in some situations

2. thyroid hormone replacement
   a) thyroid replacement can precipitate adrenal crisis if started before cortisol in a patient with adrenal insufficiency (as may occur in panhypopituitarism)
      • do a cosyntropin stimulation test (p.735) and start cortisol
      • thyroid replacement may be initiated after 1 full day of cortisol.
         : start with synthroid 125 mcg/d
   b) although there are warnings not to do surgery on a hypothyroid patient, the reality is that it takes 3–4 weeks for adequate replacement and hypothyroid patients frequently undergo surgery before then with no untoward effect

3. testosterone replacement: may increase intratumoral levels of estradiol which may promote tumor growth. wait for stabilization of tumor before starting

46.2.2 Management of large, invasive adenomas

See reference 29

1. prolactinomas
   a) dopamine agonists (DA) (p.739) unless there is unstable deficit
   b) for unstable deficit, or if the tumor does not respond to DAs: debulk the tumor transsphenoidally and then rechallenge with DA therapy

2. tumors secreting growth hormone or ACTH: an aggressive surgical approach is indicated with these tumors since the secretion product is harmful and effective medical adjuvants are lacking
   a) pre-treat invasive GH-secreting tumors with somatostatin analogue therapy before surgery to reduce surgical risks (general and cardiac)
   b) elderly patients or tumors > 4 cm diameter: debulk tumor transsphenoidally and/or adjuvant therapy (XRT and/or medications)
   c) young age and size < 4 cm: radical surgery (may utilize a cranio-orbito-zygomatic skull base approach; may be curative)

3. nonfunctional adenomas
   a) elderly patient: expectant management is an option, with intervention for signs of progression (radiographic or neurologic)
   b) central tumor or elderly patient with progression: transsphenoidal tumor debulking and/or XRT (residual tumor in the region of the cavernous sinus may show little or no change over several years, and with these nonfunctional tumors, there is less harm in following them than if there is a harmful secretion product)
   c) parasellar tumor and/or young age: radical surgery A (often not curative)

46.2.3 Hormonally inactive macroadenomas – management

General information

Due to poor response rates to medication, when treatment is indicated, surgery and/or XRT are usually the initial treatment of choice (see below for XRT).

Medical management of hormonally inactive macroadenomas

Bromocriptine has been tried with mild reductions in tumor size in only ≈ 20% of patients. The poor results are probably due to the paucity of dopaminergic receptors on cell membranes in these tumors. Octreotide reduces tumor volume in ≈ 10% of cases. These agents have been used pre-op in some cases to try to decrease tumor size for surgery.
Follow-up recommendations for medically managed hormonally inactive macroadenomas

For asymptomatic microadenomas (<1 cm dia), recommend: F/U pituitary MRI at years 1, 2, 5 and ± 10 (can stop F/U after 10 and possibly 5 years if no growth).

For tumors >1 cm, recommend: check visual fields, pituitary bloodwork (to R/O pituitary insufficiency) and pituitary MRI at years 0.5, 1, 2 & 5, and any time symptoms develop.

Gonadotropin-secreting tumors

Rarely, a non-functional tumor may secrete gonadotropins (FSH, LH). This does not produce a clinical syndrome. Normal and neoplastic pituitary gonadotrophs have gonadotropin-releasing hormone (GnRH) receptors, and may respond to long-acting GnRH agonists (by down-regulating receptors) or GnRH antagonists, but significant reductions in tumor size does not occur.

Surgical indications for hormonally inactive pituitary macroadenomas

1. tumors causing symptoms by mass effect: visual field deficit (classically: bitemporal hemianopsia, panhypopituitarism
2. some surgeons recommend surgery for macroadenomas that elevate the chiasm even in the absence of endocrine abnormalities or visual field deficit because of the possibility of injury to the optic apparatus (see below for invasive pituitary macroadenomas)
3. acute and rapid visual or other neurologic deterioration. May represent ischemia of the chiasm, or tumor hemorrhage/infarction causing expansion (pituitary apoplexy). The major danger is blindness (hypopituitarism, while concerning, can be treated with replacement therapy). Visual loss usually requires emergent decompression. Some surgeons feel that a transcranial approach is necessary, but transsphenoidal decompression is usually satisfactory29,30
4. to obtain tissue for pathological diagnosis in questionable cases
5. Nelson’s syndrome (p. 724)
   a) surgery (transsphenoidal or transcranial): the primary treatment. The aggressiveness of the tumor sometimes requires total hypophysectomy
   b) XRT (possibly SRS) is used following subtotal excision
   c) medical therapy is usually ineffective. Agents that could be considered include31: dopamine agonists, valproic acid, somatostatin analogues, rosiglitazone, and serotonin agonists

46.2.4 Prolactinomas – management

General information

1. prolactin level (PRL) <500 ng/ml in tumors that are not extensively invasive (see below for invasive tumors): PRL may be normalized with surgery
2. PRL >500 ng/ml: the chances of normalizing PRL surgically are very low.32 Algorithm:
   a) if no acute progression (worsening vision…), an initial attempt at purely medical control should be made as the chances of normalizing PRL surgically with pre-op levels >500 ng/ml are very low32 (these tumors may shrink dramatically with bromocriptine)
   b) response should be evident by 4–6 weeks (significant decrease in PRL, improvement of visual deficits, or shrinkage on MRI)
   c) if tumor not controlled medically (~18% will not respond to bromocriptine): surgery followed by reinstitution of medical therapy may normalize PRL

Medical management with Dopamine agonists

Dopamine Agonists

Side effects33: (may vary with different preparations) nausea, H/A, fatigue, orthostatic hypotension with dizziness, cold induced peripheral vasodilatation, depression, nightmares and nasal congestion. Side effects are more troublesome during the first few weeks of treatment. Tolerance may be improved by bedtime dosing with food, slow dose escalation, sympathomimetics for nasal congestion, and acetaminophen 1–2 hrs before dosing to reduce H/A. Psychosis and vasospasm are rare side effects that usually necessitates discontinuation of the drug.
Drug info: Bromocriptine (Parlodel®)

A semi-synthetic ergot alkaloid that binds to dopamine receptors (dopamine agonist) on normal and tumor lactotrophs, inhibiting synthesis and secretion of PRL and other cell processes resulting in decreased cell division and growth. Bromocriptine lowers prolactin level regardless of the whether the source is an adenoma or normal pituitary (e.g. as a result of stalk effect) to <10% of pretreatment values in most patients. It also frequently reduces the tumor size in 6–8 weeks in 75% of patients with macroadenomas, but only as long as therapy is maintained and only for tumors that actually produce prolactin. Only ≈ 1% of prolactinomas continue to grow while the patient is on bromocriptine. Prolactinomas may enlarge rapidly upon discontinuation of the drug. However, permanent normoprolactinemia can occur (see below).

Pregnancy issues: bromocriptine can restore fertility. Continued therapy during pregnancy is associated with a 3.3% incidence of congenital anomalies and 11% spontaneous abortion rate which is the same as for the general population. Estrogen elevation during pregnancy stimulates hyperplasia of lactotrophs and some prolactinomas, but the risk of symptomatic enlargement of microadenomas and totally intrasellar macroadenomas is <3% vs. 30% risk for macroadenomas.34

Prolonged treatment with bromocriptine may reduce the chances of surgical cure if this should be chosen at a later date. With a microadenoma, one year of bromocriptine may reduce the surgical cure rate by as much as 50% possibly due to induced fibrosis.35 Thus, it is suggested that if surgery is to be done that it be done in the first 6 months of bromocriptine therapy. Shrinkage of large tumors due to bromocriptine may cause CSF rhinorrhea.36 Side effects: see above.

: Start with 1.25 mg (half of a 2.5 mg tablet) PO q hs (nighttime dosing reduces some side effects) (vaginal administration is an alternative). Add additional 2.5 mg per day as necessary (based on PRL levels), making a dosage change every 2–4 weeks for microadenomas, or every 3–4 days for macroadenomas causing mass effect. Initial recheck of prolactin level after about 4 weeks at a reasonable dose to verify response. To shrink large tumors or for extremely high PRL levels, higher doses are usually needed initially (e.g. 7.5 mg TID for ≈ 6 mos), and then lower doses may be able to maintain normal levels (typical maintenance dosage: 5–7.5 mg daily (range: 2.5–15 mg) which may be given as a single dose or divided TID). Supplied: 2.5 mg scored tabs; 5 mg capsules.

Drug info: Cabergoline (Dostinex®)

An ergot alkaline derivative that is a selective D2 dopamine agonist (bromocriptine (see above) affects both D2 and D1 receptors).37 The elimination half-life is 60–100 hrs which usually permits dosing 1–2 times weekly. Control of PRL and resumption of ovulatory cycles may be better than with bromocriptine.38 Side effects: (see above) H/A and GI symptoms are reportedly less problematic than with bromocriptine. Cardiac valve disease39 (incidence-rate ratio, 4.9; 95% CI) affecting the mitral, aortic, and tricuspid valves possibly leading to regurgitation (the drug activates 5-HT2B receptors which induces prolonged mitogenic effects in fibromyoblasts, which may lead to valvular fibrosis) which has not been observed at doses used for prolactinomas (is associated with doses used for Parkinson’s disease which are >10 × pituitary doses): recommendation: do not discontinue cabergoline for this reason if dose is <2 mg/wk. Contraindications: eclampsia or pre-eclampsia, uncontrolled HTN. Dosage should be reduced with severe hepatic dysfunction.

: Start with 0.25 mg PO twice weekly, and increase each dose by 0.25 mg every 4 weeks as needed to control PRL (up to a maximum of 3 mg per week). Typical dose is 0.5–1 mg twice weekly. Some combine the total dose and give it once weekly. Initial recheck of prolactin level after about 4 weeks to verify response. Supplied: 0.5 mg scored tablets.

Drug info: Pergolide (Permax®)

A long-acting ergot alkaloid dopamine agonist that reduces PRL levels for >24 hrs. Not available in the U.S. for use in humans. Once daily dosing improves compliance. Side effects: Withdrawn due to risk of cardiac valve disease (see cabergoline (Dostinex®) above).

Start with 0.05 mg PO q hs, and increase by 0.025–0.05 increments (up to a maximum of ≈ 0.25 mg/d) until desired PRL levels are achieved.
Response to medical treatment

Treatment response to DA is assessed with serial prolactin levels as shown in Table 46.7. It is uncommon for a prolactinoma to enlarge without an increase in prolactin level.\(^5\)

Discontinuation of dopamine agonists: Long-term therapy with DA agonists has some cytoidal effect on pituitary tissue. In an early report, discontinuation of treatment after 24 months was associated with >95% recurrence rate.\(^6\) Recent literature suggests a 20–30% chance of normoprolactinemia off medication in select patients.\(^7\)

Recommendations\(^8\): if response to DA agonist is satisfactory, treat for 1–4 years (microadenomas: check prolactin yearly, macroadenomas are more likely to grow and should be checked more often). Microadenomas or macroadenomas that are no longer visible on MRI are candidates for DA agonist withdrawal. For microadenomas: discontinue the drug; for macroadenomas: slowly taper the drug then discontinue. Recurrence rate is highest during 1st year, check prolactin levels and clinical symptoms every 3 months during the 1st year. Long-term follow up is required, especially for macroadenomas.

46.2.5 Acromegaly – management

See references.\(^2\)\(^3\)\(^4\)\(^5\)

Surgery

Surgery is the primary treatment modality for acromegaly when treatment is indicated.

1. asymptomatic elderly patients do not require treatment since there is little evidence that intervention alters life expectancy in this group
2. if no contraindications, surgery (usually transsphenoidal) is currently the best initial therapy (worse prognosis with macroadenomas) providing more rapid reduction in GH levels and decompression of neural structures (e.g. optic chiasm) and improves the efficacy of subsequent somatostatin analogues.\(^6\) Surgery is not recommended for elderly patients
3. medical therapy (p. 741): reserved for:
   a) patients not cured by surgery (reoperation doesn’t work very often for acromegaly). Note: the definition of “biochemical cure” with acromegaly is not standardized (p. 754), surgery is still helpful for those “not cured” and improves efficacy of other therapies; IGF-1 may take months to normalize after surgery
   b) or for those who cannot tolerate surgery (e.g. due to cardiomyopathy, severe hypertension, airway obstruction…, these contraindications may improve with medical therapy and then surgery can be reconsidered)
   c) or for recurrence after surgery or XRT
4. XRT (p. 745): for failure of medical therapy. Not recommended as initial treatment. NB: some practitioners use XRT for surgical failure, and employ medical therapy while waiting for XRT to have an effect. GH levels decline very slowly after XRT, see details & side effects (p. 739)

Medical therapy

Overview

1. dopamine agonists (DAs): although not mentioned in the AACE guidelines,\(^2\) it may be worth trying a DA to see if the tumor responds (≈ 20% respond). If responsive, DAs are especially well suited for GH tumors that cosecrete PRL
   a) bromocriptine: (see below) although it benefits only a minority, a first line drug since it is cheaper than pegvisomant or octreotide and is given PO
   b) cabergoline (see above)
   c) pergolide (see above)
   d) others: lisuride, depo-bromocriptine (bromocriptine-LAR)

</tr>
</tbody>
</table>
2. Somatostatin analogues: indications: as initial medical therapy, or if no response to DAs, some also use this pre-op to improve surgical success rate
   a) Octreotide & octreotide-LAR (see below)
   b) Lanreotide, lanreotide SR & long-acting aqueous gel lanreotide (Autogel)
3. GH antagonists: pegvisomant (see below) considered for failures to above (not a primary therapy)
4. Combination therapy: may be more effective than individual drugs. Pegvisomant or octreotide + dopamine agonist if no response to 1 drug alone

Specific agents

**Drug info: Bromocriptine (Parlodel®)**

Neoplastic somatotrophs may respond fortuitously to dopamine agonists and reduce growth hormone (GH) secretion. Bromocriptine lowers GH levels to <10 ng/ml in 54% of cases, to <5 ng/ml in only ≈12% Tumor shrinkage occurs in only <20% Higher doses are usually required than for prolactinomas. If effective, the drug may be continued but should be periodically withdrawn to assess the GH level; see Side effects (p. 739). Estimated annual cost: $3,200 in the U.S.

For growth hormone tumors that respond to bromocriptine, the usual dosage is 20–60 mg/d in divided doses (higher doses are unwarranted). The maximal daily dose is 100 mg.

**Drug info: Octreotide (Sandostatin®)**

A somatostatin analogue that is 45 times more potent than somatostatin in suppressing GH secretion but is only twice as potent in suppressing insulin secretion, has a longer half-life (≈ 2 hrs after SQ injection, compared to ≈ minutes for somatostatin), and does not result in rebound GH hypersecretion. GH levels are reduced in 71% IGF-1 levels are reduced in 93% 50–66% have normal GH levels, 66% achieve normal IGF-1 levels. Tumor volume reduces significantly in about 30% of patients. Many symptoms including H/A usually improve within the first few weeks of treatment. Annual cost to the patient: at least ≈ $7,800 in the U.S. Usually given in combination with bromocriptine.

After 50 mcg SQ injection, GH secretion is suppressed within 1 hr, nadirs at 3 hrs, and remains reduced for 6–8 hrs (occasionally up to 12 hrs). Side effects: reduced GI motility and secretion, diarrhea, steatorrhea, flatulence, nausea, abdominal discomfort (all of these usually remit in 10 days), clinically insignificant bradycardia in 15% cholesterol cholelithiasis (in 10–25%) or bile sludge. Asymptomatic stones require no treatment and routine ultrasonography is not required. Mild hypothyroidism or worsening of glucose intolerance may occur.

Start with 50–100 mcg SQ q 8 hrs. Increase up to a maximum of 1500 mcg/d (doses >750 mcg/d are rarely needed). Average dose required is 100–200 mcg SQ q 8 hrs.

Sandostatin LAR Depot: long acting release (LAR) form given by IM injection. Give a test dose of short acting octreotide SQ in the office, and if no reaction (e.g. N/V...) begin LAR injections with 20 mg IM q 4 weeks, increase to 30 mg if GH >5 mU/L just before 4th dose. Control can achieved in some patients with dosing q 8–12 weeks.

**Drug info: Pegvisomant (Somavert®)**

A genetically engineered competitive GH-receptor antagonist. Treatment for ≥12 mos results in normal IGF-1 levels in 97% of patients. No change in pituitary tumor size has been observed. Indications: failure of somatostatin in patient with GH secreting adenoma (patient is switched to pegvisomant, it is not added to regimen). Side effects: significant but reversible liver function abnormalities occur in <1% Serum GH increases, probably as a result of loss of negative feedback on IGF-1 production. Antibodies to GH occurred in 17% but tachyphylaxis was not observed.

5–40 mg/d SQ (dose must be titrated to keep IGF-1 in the normal range, to avoid GH deficiency conditions).
46.2.6 Cushing’s disease – management

Management algorithm

1. if pituitary MRI shows a mass: transsphenoidal surgery
2. if pituitary MR is negative (up to 40% of patients with Cushing’s disease have negative MRI): perform inferior petrosal sinus (IPS) sampling (p. 735)
   a) if IPS sampling is positive: surgery
   b) if IPS sampling is negative: look for extra-pituitary source of ACTH (abdominal CT)
3. if pituitary surgery is performed but biochemical cure – see criteria (p. 753) – is not obtained with surgery:
   a) unlike acromegaly, a partial reduction is not helpful to the patient
   b) consider re-exploration if pituitary source is still suspected
   c) stereotactic radiosurgery or medical therapy (see below)
   d) adrenalectomy in appropriate patients (see below)

Transsphenoidal surgery

Transsphenoidal surgery is the treatment of choice for most (medical therapy is inadequate as initial therapy since there is no effective pituitary suppressive medication). Cure rates are ≈ 85% for microadenomas (i.e. tumors ≤ 1 cm dia), but are lower for larger tumors. Even with microadenomas, hemihypophysectomy on the side of the tumor is usually required for cure (the tumor is difficult to completely extirpate) with attendant increased risk of CSF leak. If this fails, consideration should then be for total hypophysectomy. Failure of total hypophysectomy prompts consideration for bilateral adrenalectomy (total hypophysectomy virtually eliminates risk of Nelson’s syndrome following adrenalectomy – see below).

Stereotactic radiosurgery

Often normalizes serum cortisol levels. Useful for: recurrence after surgery, inaccessible tumors (e.g. cavernous sinus)...

Adrenalectomy

Total bilateral adrenalectomy (TBA) corrects hypercortisolism in 96–100%31 (unless there is an extra-adrenal remnant), but lifelong glucocorticoid replacement are required and up to 30% develop Nelson’s syndrome (p. 724); incidence reduced by total hypophysectomy or possibly by pituitary XRT.

Indications: continued hypercortisolism with:
1. non-resectable pituitary adenoma
2. failure of medical therapy to control symptoms after transsphenoidal surgery
3. life-threatening Cushing’s disease (CD)
4. CD with no evidence of pituitary tumor; testing should include high-dose DMZ suppression test (p. 735) and/or inferior petrosal sinus sampling (p. 735)

Follow-up after TBA to rule-out Nelson’s syndrome: there is no standardized regimen. Suggestion: check serum ACTH levels q 3–6 months × 1 year, q 6 months × 2 years, q year thereafter. A pituitary MRI is done if an ACTH level is > 100 ng/L, otherwise, annual MRIs are sufficient48 × 3 years and then if ACTH levels remain low, get an MRI every other year.

Medical therapy

For patients who fail surgical therapy or for whom surgery cannot be tolerated, medical therapy and/or radiation are utilized. Occasionally may be used for several weeks prior to planned surgery to control significant manifestations of hypercortisolism, e.g. diabetes, HTN, psychiatric disturbances... (p. 723).

Ketoconazole (Nizoral®)33: an antifungal agent that blocks adrenal steroid synthesis. The initial drug of choice. Over 75% of patients have normalization of urinary free cortisol and 17-hydroxycorticosteroid levels. Side effects: reversible elevations of serum hepatic transaminase (in 15%), GI discomfort, edema, skin rash. Significant hepatotoxicity occurs in 1 of 15,000 patients. Watch Table 8.2.

Start with 200 mg PO BID. Adjust dosage based on 24-hr urine free cortisol and 17-hydroxycorticosteroid levels. Usual maintenance doses 400–1200 mg daily in divided doses (maximum of 1600 mg daily).
Aminogluthethimide (Cytadren®) inhibits the initial enzyme in the synthesis of steroids from cholesterol. Normalizes urinary free cortisol in ≈ 50% of cases. Side effects: dose-dependent reversible effects include sedation, anorexia, nausea, rash and hypothyroidism (due to interference with thyroid hormone synthesis).

Start with 125–250 mg PO BID. Effectiveness may diminish after several months and dose escalation may be needed. Generally do not exceed 1000 mg/d.

Metyrapone (Metopirone®): inhibits 11-β-hydroxylase (involved in one of the final steps of cortisol synthesis) may be used alone or in combination with other drugs. Normalizes mean daily plasma cortisol in ≈ 75% Side effects: lethargy, dizziness, ataxia, N/V, primary adrenal insufficiency, hirsutism and acne.

Usual dose range is 750–6000 mg/d usually divided TID with meals. Initial effectiveness may diminish with time.

Mitotane (Lysodren®): related to the insecticide DDT. Inhibits several steps in glucocorticoid synthesis, and is cytotoxic to adrenocortical cells (adrenolytic agent). 75% of patients enter remission after 6–12 months of treatment, and the medication may sometimes be discontinued (however hypercortisolism may recur). Side effects: may be limiting, and include anorexia, lethargy, dizziness, impaired cognition, GI distress, hypercholesterolemia, adrenal insufficiency (which may necessitate supernormal doses of glucocorticoids for replacement due to induced glucocorticoid degradation).

Start with 250–500 mg PO q hs, and escalate dose slowly. Usual dose range is 4–12 gm/d usually divided TID-QID. Initial effectiveness may diminish with time.

Cyproheptadine (Periactin®): a serotonin receptor antagonist that corrects the abnormalities of Cush in g’s disease in a small minority of patients, suggesting that some cases of “pituitary” Cush in g’s disease are really due to a hypothalamic disorder. Combined therapy with bromocriptine may be more effective in some patients. Side effects: sedation & hyperphagia with weight gain usually limit usefulness.

Usual dosage range: 8–36 mg/d divided TID.

46.2.7 Thyrotropin (TSH)-secreting adenomas – management

General information

1. transsphenoidal surgery has been the traditional first-line treatment. These tumors may be fibrous and difficult to remove.
2. for incomplete resection: post-op XRT is employed
3. if hyperthyroidism persists: medical therapy is added with agents including octreotide, bromocriptine (more effective for tumors that co-secrete PRL), and oral cholecystographic agents (which inhibit conversion of T4 to T3) e.g. iopanoic acid

Medical therapy

Normal and neoplastic anterior hypophyseal thyrotroph cells possess somatostatin receptors and most respond to octreotide (see below). Occasionally, beta-blockers or low-dose antithyroid drugs (e.g. Tapazole® (methimazole) ≈ 5 mg PO TID for adults) may additionally be required.

Octreotide (Sandostatin®)

Doses required are usually < than with acromegaly. TSH levels decline by > 50% in 88% of patients, and become normal in ≈ 75% T4 and T3 levels decrease in almost all, with 75% becoming normal. Tumor shrinkage occurs in ≈ 33%

Start with 50–100 mcg SQ q 8 hrs. Titrate to TSH, T4 and T3 levels.

46.3 Radiation therapy for pituitary adenomas

46.3.1 General information

Conventional EBXRT usually consists of 40–50 Gy administered over 4–6 weeks.

46.3.2 Side effects

Radiation injury to the remaining normal pituitary results in hypocortisolism, hypogonadism, or hypothyroidism in 40–50% of patients after 10 years. It may also injure the optic nerve and chiasm.
(possibly causing blindness), cause lethargy, memory disturbances, cranial nerve palsies, and tumor necrosis with hemorrhage and apoplexy. Cure rates but also complications are higher after proton beam therapy.

46.3.3 Recommendation

Radiation therapy should not be routinely used following surgical removal. Follow patient with yearly MRI. Treat recurrence with repeat operation. Consider radiation if recurrence cannot be removed and tumor continues to grow.

46.3.4 Sellar radiation therapy for nonfunctional pituitary tumors

In one series of 89 nonfunctioning pituitary tumors ranging 0.5–5 cm diameter (mean = 2 cm) not totally resected because of involvement of cavernous sinus (or other inaccessible sites), half were treated with radiation therapy (XRT). The recurrence rate was neither lower (and was actually higher) nor later in the XRT group. However, another series of 108 pituitary macroadenomas found the recurrence rates shown in Table 46.8 which tend to favor radiation therapy.

When used, doses of 40 or 45 Gy in 20 or 25 fractions, respectively, is recommended. The oncocytic variant of null cell pituitary tumors appears to be more radioresistant than the nononcocytic undifferentiated cell adenoma.

46.3.5 Sellar radiation therapy for acromegaly

Not the preferred initial treatment. Works better with lower initial GH levels. In most patients, GH levels begin to fall during the first year after XRT, dropping by ≈ 50% after 2 years, and decrease gradually thereafter, reaching ≤10 ng/ml in 70% of patients after 10 years. It takes up to 20 years for 90% of patients to achieve GH levels ≤ 5 ng/ml. During this latency period, patients are exposed to unacceptably high levels of GH (octreotide may be used while waiting). Patients are also still at risk for radiation side effects mentioned above. Options include: EBRT, stereotactic radiosurgery (about equally effective). Estimated cost: $20,000.

46.3.6 Sellar radiation therapy for Cushing’s disease

XRT corrects hypercortisolism in 20–40% and produces some improvement in another 40% Improvement may not be seen for 1–2 yrs post treatment.

Tumors Involving Non-Neural Origin: Metastases, lymphomas, chordomas

47 Pituitary Adenomas – Surgical Management, Outcome, and Recurrence Management

47.1 Surgical treatment for pituitary adenomas

47.1.1 Medical preparation for surgery

1. stress dose steroids: given to all patients during and immediately after surgery
2. hypothyroidism: ideally, hypothyroid patients should have >4 weeks of replacement to reverse hypothyroidism, however:
   a) do not replace thyroid hormone until the adrenal axis is assessed; giving thyroid replacement to a patient with hypoadrenalism can precipitate adrenal crisis. If hypoadrenal, begin cortisol replacement first, may begin thyroid hormone replacement after 24 hours of cortisol
   b) surgery is done frequently on patients with hypothyroidism and appears to be tolerated well in the vast majority of cases

47.1.2 Surgical approaches – overview

1. transsphenoidal: an extra-arachnoid approach, requires no brain retraction, no external scar (aside from where a fat graft is procured, if used). Usually the procedure of choice. Indicated for microadenomas, macroadenomas without significant extension laterally beyond the confines of the sella turcica, patients with CSF rhinorrhea, and tumors with extension into sphenoid air sinus
   a) sublabial
   b) trans-nares: an alotomy may be used to enlarge the exposure through the nares if necessary
2. transethmoidal approach
3. transcranial approaches:
   a) indications: most pituitary tumors are operated by the transsphenoidal technique (see above), even if there is significant suprasellar extension. However, a craniotomy may be indicated for the following:
      i. minimal enlargement of the sella with a large suprasellar mass, especially if the diaphragma sellae is tightly constricting the tumor (producing a “cottage loaf” tumor) and the suprasellar component is causing chiasmal compression
      ii. extrasellar extension into the middle fossa that is larger than the intrasellar component
      iii. unrelated pathology may complicate a transsphenoidal approach: rare, e.g. a parasellar aneurysm
      iv. unusually fibrous tumor that could not be completely removed on a previous transsphenoidal approach
      v. recurrent tumor following a previous transsphenoidal resection
   b) choices of approach
      i. subfrontal: provides access to both optic nerves. May be more difficult in patients with prefixed chiasm
      ii. frontotemporal (pterional): places optic nerve and sometimes carotid artery in line of vision of tumor. There is also incomplete access to intrasellar contents. Good access for tumors with significant lateral extrasellar extension
      iii. subtemporal: usually not a viable choice. Poor visualization of optic nerve/chiasm and carotid. Does not allow total removal of intrasellar component

47.1.3 Transsphenoidal surgery

Booking the case: Transsphenoidal surgery

Also see defaults & disclaimers (p. 27) and pre-op orders (p. 751).
1. position: supine, horseshoe head rest or (especially if image guided navigation is used) pin headholder
2. equipment:
   a) microscope
   b) C-arm (if used)
   c) image guided navigation system (if used)
d) endoscopy cart for cases performed endoscopically (surgeon preference)
3. instrumentation: transsphenoidal instrument set (usually includes speculum, curettes, long instruments including bipolar)
4. some surgeons use ENT to perform the approach and closure and for follow-up
5. post-op: ICU
6. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: removal of pituitary tumor through the nose, possible placement of fat graft from abdomen
   b) alternatives: surgery through the skull (trans-cranial), radiation
   c) complications: CSF leak with possible meningitis, problems with pituitary hormones which may sometimes be permanent (which would require lifetime replacement therapy), injury to optic nerve with visual loss, injury to carotid artery with possible bleeding and/or stroke

Technique

General information
For pre- and post-op orders, see below.
Details of the surgery are beyond the scope of this text, see references.3,4,5,6

Intraoperative disasters
Usually related to loss of landmarks.3 Can be minimized using intraoperative navigation or fluoroscopy to verify location.
- injury of carotid artery:
  - typically injured in lateral aspect of opening. Bone may be dehiscent over the ICA
  - signaled by profuse arterial bleeding
  - can usually be packed off, if fat/fascia graft from thigh or abdomen is available it may be used; otherwise use e.g. woven surgical
  - the operation is halted, and a STAT post-op arteriogram must be done
  - if a pseudoaneurysm or site of injury is identified angiographically, it must be eliminated before a potentially lethal hemorrhage; accomplished either by endovascular techniques or by surgical trapping with clips above and below
- opening through the clivus and erroneous biopsy of the pons
- opening through the floor of the frontal fossa with injury to the olfactory nerves and entry into inferior frontal lobes

Overview of the procedure
1. lumbar drain: may be used with some macroadenomas to inject fluid in order to help bring the tumor down (see below), also may be used for post-op CSF drainage following transsphenoidal repair of CSF fistula
2. medications (in addition to pre-op meds, see below): intraoperatively 100 mg hydrocortisone IV q 8 hrs
3. positioning
   a) elevate thorax 10–15°: reduces venous pressure
   b) head stabilization: if image-guided navigation is to be used, the head is placed in a Mayfield headholder or a headband with registration array is attached and the head is placed on a horseshoe head rest. If no image guidance, a horseshoe headrest may be used
   c) position option 1: surgeon standing to right of patient
      - shoulder-roll
      - top of head canted slightly to left
      - neck position: For microscope: extend neck slightly with the head in either a Mayfield head-holder or on a horseshoe headrest. For endoscope: do not extend neck (more comfortable for holding instruments)
      - ET tube positioned down and to patient’s left (to get it out of the way)
      - microscope: observer’s eyepiece on the left
   d) position option 2: surgeon standing above patient’s head: head pointing straight up towards ceiling, neck slightly extended
   e) abdomen or right thigh is prepped for fat graft
4. C-arm fluoro: image-guided navigation can eliminate the need for fluoro. Orient the C-arm for a true lateral by aligning the mandibular rami and/or by superimposing the floor of the left and
right frontal fossae. If this proves difficult, lay a Penfield 4 on the nasion oriented from lateral canthus to lateral canthus, then aim the fluoro to shoot “down the barrel” of the Penfield 4

5. after approach to floor of sella is complete (see below), outline the upper and lower boundaries of the sella using image navigation or for fluoro using an instrument (e.g. suction tip) – obtain hard-copy of images for documentation purposes

6. opening the sellar floor:
   a) starting the opening: open exactly in the midline using the nasal septum as a landmark (NB: the septum of the sphenoid sinus is unreliable as a midline indicator, and often curves inferiorly towards one of the carotid arteries).
   • macroadenomas may have thinned the bone to the point that it just flakes off
   • otherwise, use a bayonetted chisel or high-speed diamond burr to start the opening
   b) use a Kerrison rongeur to expand the opening. CAUTION: stay away from the extreme lateral sella to avoid entering the cavernous sinus or injuring the carotid artery

7. coagulate the dura centrally in an “X” pattern (NOT “+” pattern) with bipolar cautery. Macro-adenomas may cause yellowish discoloration of the dura directly over the tumor

8. consider aspirating through dura with a 20 gauge spinal needle to R/O large venous sinus (dura often has bluish discoloration), aneurysm, or empty sella

9. incise the dura in the “X” pattern in the midline with a #11 scalpel on a bayonetted handle

10. tumor removal for macroadenoma:
    a) gently bring tumor into the field with ring curettes, and remove with pituitary rongeurs or aspirate with suction. Some tumors are very fibrous and may be difficult to remove
    b) do not pull on the lateral component of the tumor with pituitary rongeur due to risk of injuring carotid artery
    c) if the suprasellar component will not come down, it may be brought down by having the anesthesiologist inject 5 ml aliquots of saline into a lumbar drain while monitoring blood pressure and pulse.
    d) once the tumor is debulked internally, try to develop a plane between the tumor capsule and the pituitary. A good place to start looking is inferiorly where the dura can be separated from the tumor capsule and then followed on the surface. Sometimes the tumor capsule cannot be removed due to severe bleeding
    e) complete tumor removal is often not possible, and the goal of the surgery then is “containment”
    f) endoscopic techniques and image guided navigation may be employed to assist in removal of macroadenomas

11. tumor removal for microadenoma:
    a) if the side of the tumor is known, begin exploration of the gland on that side by making incision with #11 blade and using a dissector to try and locate the tumor (like a “grain of rice in a blueberry”)
    b) for Cushing’s disease, if no tumor is identified on pre-op MRI:
       • intraoperative ultrasound may help localize tumor in ≈ 70%of cases but a specialized U/S probe is required
       • if IPS sampling showed a lateralizing ACTH gradient: start with a paramedian incision on the side of the higher ACTH gradient; if no adenoma is encountered, the contralateral paramedian and then midline incisions are used to explore the gland
       • if IPS sampling and MRI do not suggest tumor location: the gland is explored sequentially with 2 paramedian incisions and then a midline incision
       • if the adenoma cannot be found, a hemihypophysectomy is performed on the side of higher ACTH levels if IPS sampling shows a lateralizing gradient, or on the side with more suspicious tissue on frozen section. Total hypophysectomy is not routinely performed
       c) most adenomas are purplish-grey and easily aspirated, however some may be more fibrous. The normal pituitary gland is firm and rubbery (the adenohypophysis is orange-pink, the neurohypophysis is a whitish-grey), and normally does not curette very easily
       d) use image guidance or fluoro to determine approximate location of diaphragma sellae. Do not go cephalad to this to avoid a CSF leak, to avoid entering the circular venous sinus in the dura here and to avoid trauma to the optic chiasm

12. after removal of macroadenoma, check depth of tumor bed on fluoro or image guidance, and make sure it correlates with approximate tumor volume on MRI

13. the sella may be packed in a number of ways, one method:
    a) if CSF leak occurs: place muscle or fat in defect within sella. Some recommend against the use of muscle because it always putrefies. Do not overpack to avoid recreating mass effect with the graft
b) recreate the floor of the sella using nasal cartilage placed within the sella. Alternatively, a nonporous Medpor® polyethylene transsphenoidal sellar implant (Porex Surgical Products http://www.porexsurgical.com) may be used

c) if CSF leak occurs pack sphenoid sinus with fat from abdomen (option: fat with fascia on surface)
d) fibrin glue may optionally be used to help hold any of these components in place

Approach to sphenoid sinus for microscopic removal
Often done by ENT co-surgeon. One method:
1. insert temporary speculum into nose. For this discussion, the right nares will be described
2. use endoscope to locate middle concha. Follow this posteriorly to identify os into sphenoid sinus which is usually located posterior to and slightly above the posterior extent of the middle concha
3. inject local anesthetic with epinephrine to blanch mucosa
4. insert sickle knife into os with sharp side facing the septum (medially) and incise the mucosa as the knife is drawn outward
5. use a Freer to dissect the thusly created mucosal flaps off the medial septum (pull one up, the other down)
6. break through the posterior part of the septum so that both sides of the floor of the sphenoid sinus are exposed. Cartilage or bone from this step is saved to use later in reconstructing the floor of the sella if desired
7. open the floor of the sphenoid and take it all the way to the right os (you will probably not see the left os)
8. place the Hardy speculum or equivalent
9. strip mucosa off the walls of the sphenoid sinus using a Blakely and slow pulling motion

Endoscopic tumor removal
There is no proof that removal is superior to microscopic approach through a speculum.
Advantages over microscopic removal: Visualization is better, especially within tumor bed.
Disadvantages: less familiarity with use of endoscopes by most neurosurgeons compared to ENT surgeons. Lack of 3D visualization (may be overcome using 3D endoscopes). Need for single handed technique (may be overcome by having assistant hold endoscope, or using an endoscope holder e.g. Mitaka), need for a binasal approach (if it is desired to use two hands for the actual surgery).

47.1.4 Peri-operative complications
1. hormonal imbalance:
   a) acute post-op concerns:
      • alterations in ADH: transient abnormalities are common – see typical post-op patterns (p.752) – including DI DI lasting > 3 mos is uncommon
      • cortisol deficiency → hypopituitarism → hypothyroidism → hypogonadism
   b) long-term: hypopituitarism in ≈ 5%(retrospective series^{10})
      • TSH deficiency → hypothyroidism → myxedema coma if severe
      • adrenal insufficiency
      • deficiency of sex hormones → hypogonadotrophic hypogonadism
2. secondary empty sella syndrome (chiasm retracts into evacuated sella → visual impairment)
3. hydrocephalus with coma^{11}: may follow removal of tumors with suprasellar extension (transsphenoidally or transcranially). Consider ventriculostomy placement if hydrocephalus is present (even if not symptomatic). Possible etiologies:
   a) traction on the attached 3rd ventricle
   b) cerebral edema due to vasopressin release from manipulation of the pituitary and/or stalk
   c) tumor edema following resection
4. infection
   a) pituitary abscess^{12,13}
   b) meningitis
5. CSF rhinorrhea (fistula): 3.5%incidence^{14}
6. carotid artery rupture: rare. May occur intraoperatively (see above) or in delayed fashion after surgery, often ≈ day 10 post-op (due to breakdown of fibrin around carotid, or possibly due to rupture of a pseudoaneurysm created at surgery)
7. entry into cavernous sinus with possible injury of any structure within
8. nasal septal perforation
47.1.5 Frontotemporal (pterional) approach

A right sided approach is usually employed (less risk to dominant hemisphere). Exceptions: when the left eye is the side of worse vision; if there is predominant left sided tumor extension; if there is other pathology on the left (e.g. aneurysm).

Positioning is that same as for ACoA aneurysm with the exception: when the left eye is the side of worse vision; if there is predominant left sided tumor extension; if there is other pathology on the left (e.g. aneurysm). The frontal lobe is elevated, and the temporal tip is gently retracted posteriorly. Bridging veins to the temporal tip must be coagulated to avoid rupture, as for any pterional approach. The approach is similar to that for an ACoA aneurysm (i.e. more emphasis is placed on frontal lobe elevation than on temporal tip retraction), except that unlike ACoA aneurysm, exposure of the ICA is not needed because proximal control is not necessary.

The tumor capsule can usually be seen between the two optic nerves. The capsule is coagulated with bipolar cautery, and is incised. The tumor is then debulked from within. By staying within the capsule, risk of injury to the pituitary stalk and optic chiasm is minimized. Significant amounts of tumor can be removed by aspiration if it is soft and suckable.

Caution: the blood supply to the optic chiasm is from the inferior aspect. Skeletonizing the chiasm or attempting to tease away tumor adherent to it may worsen vision.

47.1.6 Peri-operative management

Pre-op orders
1. Polysporin® ointment (PSO) applied in both nostrils the night before surgery
2. Antibiotics, one of the following regimens may be used:
   a) chloramphenicol 500 mg IVPB at 11 PM & 6 AM
   OR
   b) chloramphenicol 500 mg PO at MN & IV at 6 AM; ampicillin 1 gm PO at MN & IV at 6 AM
   OR
   c) Unasyn® 1.5 gm (1 gm ampicillin + 0.5 gm sulbactam) IVPB at MN & 6 AM
3. Steroids, either:
   a) hydrocortisone sodium succinate (Solu-Cortef®) 50 mg IM at 11 PM & 6 AM. On call to OR: hang 1 L D51LR+20 mEq KCl/L+50 mg Solu-Cortef at 75 ml/hr
   OR
   b) hydrocortisone 100 mg PO at MN & IV at 6 AM
4. Intra-op: continue 100 mg hydrocortisone IV q 8 hrs

Post-op orders
1. Intake & output (I’s & O’s) q 1 hr; urine specific gravity (SG) q 4 hr and anytime urine output (UO) > 250 ml/hr
2. Activity: BR with HOB @ 30°.
3. Diet: ice chips PRN. Patient is not to drink through a straw (to avoid negative pressure on sphenoid sinus with risk of aggravating CSF fistula)
4. No incentive spirometry (to avoid negative pressure on sphenoid sinus with risk of aggravating CSF fistula)
5. IVF: base IV D5 1/2 NS + 20 mEq KCl/L at appropriate rate (75–100 ml/hr)
   PLUS: replace UO > base IV rate ml for ml with 1/2 NS.
   NB: if patient receives significant fluids intra-operatively, then they may have an appropriate post-op diuresis, in which case consider replacing only 2/3 of UO > base IV rate with 1/2 NS
6. Meds
   a) Antibiotics: continue chloramphenicol 500 mg IVPB q 6 hr (also continue ampicillin if used pre-op), change to PO when tolerated, D/C when nasal packing removed
   b) Steroids (some surgeons routinely use post-op steroids until the adequacy of endogenous steroids is established, especially with Cushing’s disease, see below). Either:
      • hydrocortisone 50 mg IM/IV q 6 hrs, on POD #2 change to prednisone 5 mg PO q 6 hrs × 1 day, then 5 mg PO BID, D/C on POD #6
      OR
      • hydrocortisone 50 mg IM/IV/PO BID, taper 10 mg/dose/day to physiologic dose of 20 mg q AM and 10 mg q PM until adrenal axis assessed
   c) Diabetes insipidus (DI): patients are placed on “DI watch” (monitoring U.O. and serum and urine labs) see below for typical patterns.
   Diagnostic criteria: U.O. > 250 ml/hr × 1–2 hrs, and SG < 1.005 (usually < 1.003) (dilute urine), often with elevation of serum Na”
If DI develops, attempt to keep up with fluid loss with IVF (see above); if rate is too high for IV or PO replacement (>300 cc/hr × 4 hrs or >500 cc/hr × 2 hrs), check urine S.G. and if < 1.005 then give a vasopressin preparation (see below, or see Table 5.7). Caution: danger of over-treating in case of triphasic response (see below), therefore use EITHER:
- 5 U aqueous vasopressin (Pitressin®) IVP/IM/SQ q 6 hrs PRN
- desmopressin (DDAVP®) injection SQ/IV titrated to UO. Usual adult dose:
  0.5–1 ml (2–4 mcg) daily in 2 divided doses
  AVOID
- avoid tannate oil suspension, because it is a long acting preparation (and may overtreat) and has erratic absorption
- intranasal DDAVP (100 mcg/ml): range 0.1–0.4 ml (10–40 mcg) intranasally BID (typically 0.2 ml BID) PRN
- clofibrate (Atromid S®) 500 mg PO QID (does not always work)

7. labs: renal profile with osmolarity q 6 hrs, 8 A.M. serum cortisol
8. nasal packs: remove on post-op day 3–6

**Urinary output: patterns of postoperative diabetes insipidus**

Manage diabetes insipidus (DI) as described above in post-op orders. Post-op DI generally follows one of three patterns\(^ {15}\); see Diabetes insipidus for details (p.120):
1. transient DI: lasts until \( \approx 12–36 \) hrs post-op then normalizes
2. “prolonged” DI: lasts months, or rarely may be permanent
3. “triphasic response” (least common). 3 stages:
   a) DI (short duration): due to injury to posterior pituitary
   b) normalization or SIADH-like picture: due to release of ADH from neuron endings form hypothalamus. It is during this phase that there is a risk of severe iatrogenic hyponatremia from overtreatment initiated during the initial DI phase
   c) DI (long-term)

**Discontinuation of steroids post-op**

Simple management schemes

Some surgeons do not routinely assess ACTH reserve post-op for patients that were not hypocortisolemic pre-op:
- taper and stop hydrocortisone 24–48 hrs post-op. Then, check 6 AM serum cortisol level 24 hrs after discontinuing hydrocortisone and interpret the results as shown in Table 47.1.\(^ {16}\)
- If there is any question about reserve, the patient can be discharged on hydrocortisone 50 mg PO q AM and 25 mg PO q 4:00 PM until adrenal reserve can be formally assessed (see below)

**Assessment of postoperative ACTH (corticotropic) reserve**

Simple assessment protocol for patients who go home on hydrocortisone and were not on it pre-op.
- taper hydrocortisone over 2–3 weeks down to 20 mg po q AM and 10 mg q 4 PM (a little higher than maintenance to provide for some stress coverage) for several days
- then hold the PM dose and check an 8 AM serum cortisol the next day

**Table 47.1 Interpretation of 6 AM cortisol levels**

<table>
<thead>
<tr>

<td>ACTH deficient</td>
<td></td>
</tr>
</tbody>
</table>

\(^ * \)perform cosyntropin stimulation test (p.735) 1 month post-op; D/C steroids if normal; if subnormal, then permanent replacement required
to avoid adrenal insufficiency in patients with incompetent reserve: as soon as the blood is drawn
have the patient take their morning dose and resume regular dosing until the test results are
available
• If this 8 AM cortisol shows any significant adrenal function, then taper the patient off
hydrocortisone

Metyrapone (Metoprine®) test
This test more accurately assesses the hypothalamic-pituitary-adrenal axis and is useful if there is
suspicion of reduced reserve of pituitary ACTH production. Metyrapone inhibits 11-ß-hydroxylation
in the adrenal cortex, reducing production of cortisol and corticosterone with concomitant increase
of serum 11-deoxycortisol precursors and its 17-OHCS metabolites which appear in the urine. In re-
response, a normal pituitary increases ACTH production.
1. All patients should have a cosyntropin stimulation test (p.735) first to rule-out primary adrenal
insufficiency.
2. Do not do this test if there is known primary adrenal insufficiency.
3. Do not do this test as an outpatient.
4. Test protocol
   a) give 2–3 grams metyrapone PO at midnight
   b) check serum 11-deoxycortisol level the next morning
   c) a normal response is a 11-deoxycortisol level >7 mcg/dl
   d) CAUTION: in patients with very little reserve, the reduced cortisol may provoke adrenal insuf-
      ficiency (this test is safer than the higher doses used for urinary 17-OHCS testing)

Postoperative CT/MRI scan
A study using CT in 12 patients with macroadenomas following transsphenoidal surgery without rad-
ation therapy demonstrated that the maximal height of the pituitary “mass” did not return to normal
immediately post-op (even with total tumor removal), rather a period of 3–4 months was required.17

47.2 Outcome following transsphenoidal surgery

47.2.1 General information
In a series of 108 macroadenomas, gross total removal was unusual in tumors with >2 cm suprasellar
extension.14

47.2.2 Visual deficit
In cases with compression of the optic apparatus, there can be significant improvements in vision
following surgery.14,18

47.2.3 Biochemical outcome

Prolactinomas
In a series of 108 macroadenomas, endocrinologic cure was attained in 25% of prolactin-secreting
tumors.14

Acromegaly
Criteria of biochemical cure
The criteria for biochemical cure of acromegaly is not standardized. There may be a discord
between IGF-1 levels and mean GH levels.19 Many use a GH cutoff level; range of levels
described: <2.5–5 ng/ml. Others feel that an elevated IGF-1 represents lack of cure even if GH<5. However, normal IGF-1 levels may not be mandatory.\textsuperscript{20} Still others require a normal IGF-1 AND a normal response to an oral glucose suppression test (OGST) (p.736). Low GH levels that do not also suppress to <1 ng/ml after an OGST are considered controlled but not cured (even with normal IGF-1 levels).\textsuperscript{21} If asymptomatic, expectant management with close follow-up is recommended.\textsuperscript{21}

### Outcome with acromegaly

Transsphenoidal surgery results in biochemical cure in 85% of cases with adenomas <10 mm diameter, no evidence of local invasion, and random GH levels <40 ng/ml pre-op. Overall, \( \approx 50\% \) of all acromegals undergoing transsphenoidal surgery had a biochemical cure.\textsuperscript{22} Only 30% of macroadenomas and very few with marked suprasellar extension have surgical cure. Patients not cured with surgery require lifelong medical suppression. These tumors may also recur years later after apparent cure. Patients should be monitored every 6–12 months for recurrence.\textsuperscript{21}

### Cushing’s disease

There are numerous methodologies for determining biochemical cure for Cushing’s disease. One difficulty is that exogenous steroids are often given post-op to avoid potential hypoadrenalism or Addisonian crisis or for nausea. Some options:

1. **Immediate post-op early morning cortisol levels**:\textsuperscript{8}
   a) all steroids are withheld post-op (including dexamethasone as an antiemetic) unless biochemical and/or clinical evidence of hypocortisolism (clinical signs: nausea, anorexia, H/A, arthralgias). Requires close monitoring and administration of steroids if symptoms develop
   b) serum ACTH and cortisol levels are drawn between 6–9:00 AM on post-op days 1 & 2
e) early remission defined as a lowest cortisol level \( \leq 140 \text{nmol/L (} \leq 5 \text{mcg/dl)} \)
   - 97\%(31/32) patients with early remission had sustained remission with mean follow-up of 32 months
   - only 12.5\%(1/8) without early remission showed evidence of sustained remission
   - this has been used to select patients for possible early re-exploration
   - early ACTH levels usually drop, but do not consistently become subnormal and are not reliable in predicting sustained remission\textsuperscript{8}

2. **Provocative tests**
   a) overnight low-dose dexamethasone suppression test: an AM cortisol level on post-op day 3 that is \( \leq 8 \text{mcg/dl} \) after an overnight 1 mg dexamethasone suppression test is predictive of sustained remission in 97\%\textsuperscript{23}
   b) CRH stimulation test\textsuperscript{24}

3. **Measurements usually conducted 3 days to 2 weeks post-op following 24 hours of steroid cessation after initial post-op coverage with glucocorticoids**
   a) 24-hour urinary free cortisol
   b) serum cortisol: the criteria of a cortisol level \( <50 \text{nmol/1(<1.8 mcg/dl)} \)\textsuperscript{25,26,27} is probably too stringent\textsuperscript{28,29,8}
   c) serum ACTH

The overall remission rate since 1980 is 64–93\% with the highest rates (86–98\%) in patients with noninvasive microadenomas identifiable on MRI.\textsuperscript{8}

Following effective treatment, all of the following usually improve but may not normalize:

1. HTN and hyperglycemia: within \( \approx 1 \text{ year} \)
2. osteoporosis related to CD: over \( \approx 2 \text{ years} \)
3. psychiatric symptoms
Thyrotropin (TSH)-secreting adenomas

Following debulking, small amounts of residual tumor may continue to produce sufficient TSH for hyperthyroidism to persist. Following surgery + XRT, only ≈ 40% achieve a cure (as defined as no residual tumor at surgery or on imaging, and normal free T3 with TSH levels at or below normal).

47.3 Management of recurrent pituitary adenomas

Recurrence incidence: ≈ 12% with most recurring 4–8 years post-op (in the same series). For tumors demonstrating significant regrowth or symptoms following initial resection, consideration for re-resection may be given. Once the tumor is debulked, consideration should be given to XRT, either immediately following the second operation, or, if recurrence after a second operation then almost certainly after a third debulking.

References

48 Cysts and Tumor-Like Lesions

48.1 Rathke’s cleft cyst

Rathke’s cleft cyst (RCC) are nonneoplastic lesions that are thought to be remnants of Rathke’s pouch. They are primarily intrasellar, and are found incidentally in 13–23% of necropsies. The adenohypophysis arises from proliferation of the anterior wall of Rathke’s pouch, and so RCC have a similar lineage to pituitary adenomas and are rarely found together. RCC are often discussed in contrast to craniopharyngiomas (CP) (see above). Some features are compared in Table 48.1.

RCC usually appear as low-density cystic lesions on CT. One half show capsular enhancement. MRI appearance is variable. Rule of thumb: a lesion with a nodule in the sella is usually a RCC.

48.2 Colloid cyst

48.2.1 General information

Key concepts

- slow-growing benign tumor comprising < 1% of intracranial tumors
- classically occurs in the anterior 3rd ventricle, blocking foramina of Monro → obstructive hydrocephalus involving only the lateral ventricles (≈ pathognomonic)
- enhances minimally or not at all on CT/MRI
- natural history: risk of sudden death has been described, but is controversial
- treatment, when indicated, is surgical. Main options: transcallosal, transcortical/transventricular (only if hydrocephalus), ventriculoscopically

AKA neuroepithelial cysts. Comprise 2% of gliomas, and about 0.5–1% of all intracranial tumors. Usual age of diagnosis: 20–50 yrs.

48.2.2 Pathogenesis

Origin: unknown. Implicated structures include: paraphysis (evagination in roof of third ventricle, rudimentary in humans), diencephalic ependyma in the recess of the postvelar arch, ventricular neuroepithelium. Comprised of a fibrous epithelial-lined wall filled with either mucoid or dense hyloid substance. A slow growing, benign tumor.

Most commonly found in the third ventricle in the region of the foramina of Monro, but may be seen elsewhere, e.g. in septum pellucidum.

48.2.3 Clinical signs and symptoms

Symptoms are shown in Table 48.2. Signs are shown in Table 48.3, most commonly presents either with signs of intermittent acute intracranial hypertension (classically attributed to movement of the cyst on its pedicle causing episodic obstruction of the foramina of Monro, rarely born out at
operation) or with chronic hydrocephalus (from chronic obstruction). Most cysts < 1 cm diameter do not produce hydrocephalus and are asymptomatic.

Sudden death. A high rate of sudden death has been reported with colloid cysts (20% in pre-CT era\(^4\)) but is probably overestimated. The obsolete theory was that these tumors are mobile and thus could shift position and acutely block CSF flow with resultant herniation. Progressive obstruction from tumor growth does often produce chronic hydrocephalus, and it is possible that at some point

*38 patients with colloid cysts, pre-CT era\(^4\)*
the brain may decompensate in some cases. Changes in CSF dynamics resulting from procedures (LP, ventriculography...) may have also contributed. Another proposed mechanism is disturbance of hypothalamic-mediated cardiovascular reflex control.

48.2.4 Evaluation

Imaging (MRI or CT) demonstrates the tumor usually located in the anterior 3rd ventricle. Here, it often blocks both foramina of Monro causing almost pathognomonic hydrocephalus involving only the lateral ventricles (sparking the 3rd and 4th). Differential diagnosis includes basilar artery aneurysms, hamartomas, primary or secondary neoplasm, and xanthogranulomas.

MRI: usually the optimal imaging technique. However, there are cases where cysts are iso-intense on MRI and CT is superior (scrutinize the midline T1WI MRI images). When the lesion is identifiable, MRI clearly demonstrates the location of the cyst and relation to nearby structures, usually obviating an angiogram. MRI appearance: variable. Usually hyperintense on T1WI, hypointense on T2WI. Some data suggests that symptomatic patients are more likely to display T2 hyperintense cysts on MRI, indicating higher water content which may reflect a propensity for continued cyst expansion. Enhancement: minimal, sometimes involving only capsule.

CT scan: findings are variable. Most are hyperdense (however, iso- and hypo-dense colloid cysts occur), and about half enhance slightly. Density may correlate with viscosity of contents, hyperdense cysts were harder to drain percutaneously. CT is usually not quite as good as MRI, especially with isodense cysts. These tumors calcify only rarely.

LP: contraindicated prior to placement of shunt due to risk of herniation.

48.2.5 Treatment

General information

Optimal treatment remains controversial. Initially, shunting without treating the cyst was advocated. The nature of the obstruction (both foramina of Monro) requires bilateral ventricular shunts (or, unilateral shunt with fenestration of the septum pellucidum). Presently, one form or another of direct surgical treatment is usually recommended for some or all of the following reasons:

1. to prevent shunt dependency
2. to reduce the possibility of tumor progression
3. since the mechanism of sudden neurologic deterioration may be due to factors such as cardiovascular instability from hypothalamic compression and not due to hydrocephalus

Surgical treatment

Management options

Also see Approaches to the third ventricle (p.1461).

1. transcallosal approaches: not dependent on dilated ventricles. Higher incidence of venous infarction or fomiceal injury (see below)
2. transcortical approach (p.1466): higher incidence of post-op seizures (≈5%). Not feasible with normal sized ventricles (e.g. in patient with VP shunt)
3. stereotactic drainage: see below
4. ventriculoscopic removal: see below

A meta-analysis of 1278 patients comparing endoscopic and various microsurgical techniques found that the microsurgical group had a significantly greater extent of resection (96.8% vs 58.2%), lower rates of recurrence (1.48% vs 3.91%), and lower rates of reoperation than the endoscopic group (0.38% vs 3.0%). Both groups had similar rates of mortality (1.4% vs 0.6%) and shunt dependency (6.2% vs 3.9%). Overall, the complication rate was lower in the endoscopic group than in the microsurgical group (10.5% vs 16.3%). Within the microsurgery group, the transcallosal approach had a lower overall morbidity rate (14.4%) than the transcortical approach (24.5%).
Using natural history for treatment decisions

A review of 58 asymptomatic patients (average age 57 yr) with incidentally discovered colloid cysts of the third ventricle with mean follow up of 79 months demonstrated the incidence of symptomatic worsening at 2, 5, and 10 year follow up to be 0%0% and 8% respectively. Of the 34 patients who obtained follow up imaging, 32 demonstrated no change in cyst size or ventricular caliber. The average age of these patients was significantly higher than that of the patients undergoing surgery for symptomatic lesions (57 vs 41) and thus may reflect a patient cohort with differing natural histories.14

NB: Many “asymptomatic” patients may have headaches at diagnosis. Careful evaluation of headache etiology (i.e. posttraumatic, migraineous, tension, etc) should be undertaken to determine whether the headaches are due to the colloid cyst or if the cyst is asymptomatic.

Pollock et al.10 reviewed 155 patients with newly diagnosed colloid cysts, performing a recursive partitioning analysis, and divided patients into three classes as shown in Table 48.4.

Additionally, a significantly greater number Class III patients had hyperintense cyst contents on T2 weighted imaging (44% vs 13%) and that symptomatic patients were more likely to have increased T2 signal (44% vs 8%) compared to asymptomatic counterparts. The authors suggest that asymptomatic patients with low T2 signal containing cysts may reflect a group with low potential for cyst expansion and development of cyst related symptoms (even in the presence of ventriculomegaly) – thus they may represent a population that may be safely managed in a nonoperative fashion.10 Nevertheless, most surgeons would recommend surgery for a patient with ventriculomegaly and symptoms such as headache even if they may not be definitely related.

Transcallosal approach

Access to the 3rd ventricle via either the foramen of Monro or by interforrnical approach. Since colloid cysts tend to occur exactly at the foramen of Monro, it is rarely necessary to enlarge the foramen to locate the tumor. See Transcallosal approach to lateral or third ventricle (p.1462).

Stereotactic drainage of colloid cysts

May be useful,15 especially in patients with normal ventricles from shunting, but the contents may be too viscous,15 and the tough capsule may make blind penetration difficult. Total or even subtotal aspiration may not require further treatment in some patients; however, recurrence rate is higher than with surgical removal.17

Early morbidity was relatively high from this procedure (not widely reported in literature) possibly from vascular injury or mechanical trauma; this has improved. May be more feasible with intraoperative ventriculography18 or with a ventriculoscope19 (some say this is the initial procedure of choice,20 with craniotomy reserved for treatment failures).

Two features that correlate with unsuccessful stereotactic aspiration21:
1. high viscosity: correlates with hyperdensity on CT (low viscosity correlated with hypo- or isodense CT appearance; no MRI finding correlated with viscosity)
2. deflection of the cyst from tip of aspirating needle due to small size

Stereotactic technique:\(^2\):  
1. insertion point of stereotactic needle is just anterior to right coronal suture  
2. start with sharp-tipped 1.8 mm probe, and advance to 3–5 mm beyond target site (to accommodate for displacement of cyst wall)  
3. use a 10 ml syringe and apply 6–8 ml of negative aspiration pressure  
4. if this does not yield any material, repeat with a 2.1 mm probe  
5. although complete cyst evacuation is desirable, if this cannot be accomplished an acceptable goal of aspiration is re-establishment of patency of the ventricular pathways (may be verified by injecting 1–2 cc of iohexol)

48.3 Epidermoid and dermoid tumors

48.3.1 General information

AKA epidermoid or dermoid cysts. Both are usually developmental, benign tumors that may arise when retained ectodermal implants are trapped by two fusing ectodermal surfaces. The growth rate of these tumors is linear, like skin (rather than exponential, as with neoplastic tumors). They may occur in the following locations:

1. calvaria: skull involvement (p.776) occurs when ectodermal rests are included in the developing cranium, epidural extension may occur with growth  
2. intracranial: the most common sites include  
   a) suprasellar: commonly produce bitemporal hemianopsia and optic atrophy, and only occasionally pituitary (endocrine) symptoms (including DI)  
   b) sylvian fissure: may present with seizures  
   c) cerebellopontine angle (CPA): may produce trigeminal neuralgia, especially in young patient  
   d) basilar-posterior fossa: may produce lower cranial nerve findings, cerebellar dysfunction, and/or corticospinal tract abnormalities  
   e) within the ventricular system: occur within the 4th ventricle more commonly than any other

3. scalp

4. within the spinal canal:  
   a) most arise in the thoracic or upper lumbar spine  
   b) epidermoids of the lower lumbar spine may occur iatrogenically following LP; see Lumbar puncture (p.1504)  
   c) dermoids of the spinal canal are usually associated with a dermal sinus tract (p.270) and may produce recurrent bouts of spinal meningitis.

48.3.2 Comparison of dermoids and epidermoids

Distinguishing features between the two tumors are shown in Table 48.5.

48.3.3 Epidermoid cysts

General information

**Key concepts**

- usually arise from ectoderm trapped within or displaced into the CNS
- predilection for: CP angle, 4th ventricle, suprasellar region, spinal cord
- sometimes AKA cholesteatoma (not to be confused with cholesterol granuloma)
- grow at linear rate (unlike exponential rate of true neoplasms)
- imaging: CSF-like mass (high-signal on DWMRI is the best test to differentiate)
- may produce aseptic meningitis (Mollaret’s meningitis is one form)
- treatment: surgical excision. XRT has no role

AKA cholesteatoma (not cholesterol granuloma, (see below), AKA pearly tumor, AKA ectodermal inclusion cyst (see Table 48.5 for comparison to dermoids). Although epidermoids and cholesteatomas are histologically identical (both arise from epithelium entrapped in an abnormal location, epidermoids are intradural, cholesteatomas are extradural), the term cholesteatoma is most often used to describe the lesion in the middle ear where the entrapped epithelium usually arises from chronic middle ear infections which lead to a retraction pocket (rarely, may instead be congenital).

May arise from any of the following:

1. displaced dorsal midline ectodermal cell rests trapped during neural tube closure between gestational weeks 3–5
2. multipotential embryonic cell rests
3. epithelial cell rests carried to the CPA with the developing otic vesicle
4. epidermal cells displaced into CNS, e.g. by LP – see Lumbar puncture (p.1504) – or repeated percutaneous cranial subdural taps

**Epidemiology**

Epidermoids comprise 1% of intracranial tumors, and ≈ 7% of CPA tumors. Peak age of occurrence: 40 years. No gender difference.

**Histology**

Epidermoids are lined by stratified squamous epithelium, and contain keratin (from desquamated epithelium), cellular debris, and cholesterol. Growth occurs at a linear rate like normal skin, unlike the exponential growth of true neoplasms. The cyst contents may be liquid or may have a flaky consistency. They tend to spread along normal cleavage planes and surround vital structures (cranial nerves, ICA...). Bony destruction occurs in a minority, usually with larger tumors. Rare degeneration to squamous cell cancer primarily in cases of repeated recurrences after multiple surgeries.

**Distinction from cholesterol granuloma**

Epidermoid cysts are sometimes mistakenly equated with cholesterol granulomas, possibly because of the similarity between the terms cholesteatoma and cholesterol granuloma. However, these are distinct lesions. Cholesterol granulomas usually occur following chronic inflammation (usually in pneumatized portions of the temporal bone: petrous apex, mastoid air cells, middle ear space). Some differences are delineated in Table 48.6.

**Presentation**

1. may present as any mass lesion in the same location
2. CPA lesions can produce V, VII or VIII neuropathies
3. recurrent episodes of aseptic meningitis caused by rupture of the cyst contents, which may also lead to hydrocephalus.
   a) Symptoms include fever and meningeal irritation.
b) CSF shows pleocytosis, hypoglycorrhachia, elevated protein, and negative cultures. Cholesterol crystals may be seen and can be recognized by their amorphous birefringent appearance.

c) Mollaret’s meningitis is a rare variant of aseptic meningitis which includes the finding of large cells in the CSF that resemble endothelial cells (which may be macrophages) that may be seen in some patients with epidermoid cysts.

**Imaging**

MRI – Fig. 48.1: mimics CSF on T1 WI (low signal, may be slightly > CSF) and T2 WI (high signal). Tumors are usually also high signal on T2 WI, but most enhance with contrast on T1 WI (epidermoids do not enhance). An epidermoid may pass from the posterior fossa through the incisura to the middle fossa.

Diffusion weighted imaging (DWI) is the best test to differentiate epidermoids from CSF (e.g. as in similar appearing arachnoid cyst). Epidermoids show intense signal on DWI as a result of restriction of water movement.

**Treatment**

Caution when removing epidermoid cysts to minimize spilling contents as they are quite irritating and may cause severe chemical meningitis (Mollaret’s meningitis, see above). Berger advocates intraoperative irrigation with hydrocortisone (100 mg/L of LR) to reduce the risk of post-op communicating hydrocephalus. Peri-operative IV steroids and copious saline irrigation during surgery may provide similar results. The tumor is not in the cyst wall, and the surgical plan is generally to remove as much as possible but to leave capsule adherent to critical structures such as brainstem and blood vessels as the morbidity of removal is high and a small residual does not preclude satisfactory outcome.

In spite of adequate removal, it is not unusual to see persistent brainstem distortion on post-op imaging. Post-op radiation is not indicated as the tumor is benign and XRT does not prevent recurrence.

**Table 48.6 Characteristics of epidermoid & cholesteatoma vs. cholesterol granuloma**

48
48.4 Craniopharyngioma

48.4.1 General information

Craniopharyngiomas (CP) are tumors that develop from residual cells of Rathke’s pouch (p. 149), and tend to arise from the anterior superior margin of the pituitary. They are lined with stratified squamous epithelium. Some CP may arise primarily within the third ventricle. Almost all CP have solid and cystic components; fluid in the cysts varies, but usually contains cholesterol crystals. CP do not undergo malignant degeneration; but difficulty in cure makes them malignant in behavior. CP are distinct from Rathke’s cleft cyst, but share some similarities (see below).

Calcification: microscopically 50% Plain x-ray: 85% in childhood, 40% in adults.

48.4.2 Epidemiology

Incidence: 2.5–4% of all brain tumors; about 50% occur in childhood (9% of Matson’s series). Peak incidence: age 5–10 yrs.

48.4.3 Anatomy

Arterial supply: usually small feeders from ACA and A-comm, or from ICA and P-comm (do not receive blood from PCA or BA-bifurcation unless blood supply of floor of third ventricle is parasitized).

48.4.4 Surgical treatment

Pre-op endocrinologic evaluation

As for pituitary tumor (p. 730). Hypoadrenalism may be corrected rapidly, but hypothyroidism takes longer; either condition can increase surgical mortality.

Approach

Usually via large right frontotemporal flap as low as possible along base of frontal fossa (lateral sphenoid wing rongeured/drilled). Approach to tumor is extra-axial, whether subfrontal or frontotemporal. All tumors should be aspirated (even if they appear solid radiographically). Then, with microscope, possible approaches include:

1. subchiasmatic: through space between optic nerves and anterior to chiasm. It was thought that a “prefixed chiasm” (i.e., congenitally short optic nerves with chiasm unusually close to the planum sphenoidale) was more common in patients with CP, making this approach more difficult. However, in reality the chiasm is probably bowed anteriorly by the tumor within the third ventricle giving the illusion of a prefixed chiasm in most cases
2. opticocarotid (between right ICA and right optic nerve/tract)
3. lamina terminalis (tumor often needs to be brought down and removed subchiasmatically)
4. lateral to carotid artery
5. transfrontal-transphenoidal: drill off tuberculum sellae

Alternative approaches to frontotemporal
1. pure transphenoidal: if dark fluid is aspirated with no CSF evident, it is possible to leave a stent from the tumor cavity to the sphenoid air-sinus to permit continued drainage
2. transcallosal: strictly for tumors limited to the third ventricle
3. a combined subfrontal/pterional approach capitalizes on the advantages of each (head is positioned with slight lateral rotation)

Spare the following structures: small arterial feeders to undersurface of the chiasm (major supply) and tract; at least a remnant of pituitary stalk (recognized by unique pattern of longitudinal striations which are the long portal veins). If the tumor easily pulls down from above then this is permissible, however do not pull too hard or else hypothalamic injury may result.

1. steroids: these patients are all considered hypo-adrenal. Give hydrocortisone in physiologic doses (for mineralocorticoid activity) in addition to dexamethasone (glucocorticoid that treats edema) taper. Taper steroids slowly to avoid aseptic (chemical) meningitis.
2. diabetes insipidus (DI) (p.752): often shows up early. May be part of a “triphasic response.” Best managed initially with fluid replacement. If necessary, use short acting vasopressin (prevents iatrogenic renal shutdown if a SIADH-like phase develops during vasopressin therapy)

48.4.5 Radiation
Controversial. Side effects: include endocrine dysfunction, optic neuritis, dementia. Post-op XRT probably helps prevent regrowth when residual tumor is left behind, however, in pediatric cases it may be best to postpone XRT (to minimize deleterious effect on IQ), recognizing that reoperation may be necessary for recurrence.

48.4.6 Outcome
5–10% mortality in most series, most from hypothalamic injury (unilateral hypothalamic lesions are rarely clinically evident; bilateral injuries may produce hyperthermia and somnolence; damage to anterior osmoreceptors may — loss of thirst sensation). Five year survival is ≥ 55–85% (range from 30–93% has been reported).

48.4.7 Recurrence
Most recurrences are in <1 year, few >3 yrs (very delayed recurrence usually follow what was thought to be “total” removal). Morbidity/mortality is higher with re-operation.

References

49 Pseudotumor Cerebri and Empty Sella Syndrome

49.1 Pseudotumor cerebri

49.1.1 General information

Key concepts

- papilledema and symptomatic ICP elevation >20 cm H₂O in the absence of intracranial mass or infection. Often associated with dural sinus thrombosis
- a preventable cause of (often permanent) blindness from optic atrophy
- more common in obese females of childbearing age than general population
- recommended work-up:
  - preferred imaging studies: brain MRI (without & with contrast) and MRV. Imaging should be normal (allowed exception: slit-like ventricles)
  - LP. Findings: opening pressure (>25 cm H₂O) & normal CSF analysis
  - ophthalmologic eval: test visual fields, acuity, and check for papilledema
- usually self-limited, recurrence is common, chronic in some patients
- risk of blindness is not reliably correlated to duration of symptoms, papilledema, H/A, Snellen visual acuity, or number of recurrences
- treatment for patients failing medical management (weight loss, Diamox…):
  - optic nerve sheath fenestration (ONSF) is best for visual loss without H/A
  - CSF shunt may be better than ONSF for H/A associated with visual loss

Pseudotumor cerebri (PTC) AKA idiopathic intracranial hypertension (IIH), AKA benign intracranial hypertension, (plus numerous other obsolete terms) is a condition (or perhaps a heterogeneous group of conditions) characterized by increased intracranial pressure with no evidence of intracranial mass, hydrocephalus, infection (e.g. meningitis, especially chronic ones such as fungal meningitis), or hypertensive encephalopathy. Some, but not all, authors exclude patients with intracranial hypertension in the presence of dural sinus thrombosis. PTC is thus a diagnosis of exclusion. There is a juvenile and an adult form.

In general, the term pseudotumor cerebri is preferred (what was old is new!) because it encompasses cases where there is a known etiology as well as idiopathic cases (the concept of “secondary idiopathic intracranial hypertension” is an oxymoron).

49.1.2 Epidemiology

1. female: male ratio reported ranges from 2:1 to 8:1 (no gender difference in juvenile form)
2. obesity is reported in 11–90% of cases, and is not as prevalent in men
3. incidence among obese women of childbearing years: 19–21/100,000, (whereas incidence in general population: 1–2/100,000)
4. peak incidence in 3rd decade (range: 1–55 years). 37% of cases are in children, 90% of these are age 5–15 years. Very rare in infancy
5. frequently self limited (recurrence rate: 9–43%)
6. severe visual deficits develop in 4–12% unrelated to duration of symptoms, degree of papilledema, headache, visual obscuration, and number of recurrences. Perimetry is the best means to detect and follow visual loss

49.1.3 Pathogenesis

Pathogenesis is not fully understood. Increased cerebral edema & brain water content, increased venous pressure & cerebral blood volume, and reduced CSF absorption have all been demonstrated. Theories that also explain the high prevalence in obese females:

1. mechanical theory: obesity → ↑ intraabdominal pressure → ↑ central venous pressure → ↑ CSF resorption → ↑ ICP (however, other studies have indicated that elevated venous pressure may actually be an epiphenomenon to a primary increase in ICP)
2. hormonal theory: adipocytes convert androstenedione → estrone → ↑ CSF production
49.1.4 Diagnostic criteria

Modified Dandy’s criteria are shown in Table 49.1. More specifically, four diagnostic criteria:

1. CSF pressure: >20 cm H₂O (pressures >40 are not uncommon). Some recommend that the pressure should be >25 to exclude normals. Note: Diurnal variations in CSF pressure may occasionally cause a falsely low (i.e. normal) reading. If clinical suspicion is high, an LP at a different time of day or continuous ICP monitoring may be required.

2. CSF composition: normal glucose and cell count. Protein is normal, or in ≈ two thirds of cases it is low (<20 mg%).

3. Symptoms & signs are those of elevated ICP alone (i.e. papilledema & H/A) with no focal findings. Allowed exception: abducent nerve palsy which may be due to increased ICP (p. 567)

4. Normal radiologic studies of the brain (CT or MRI) with the allowed exceptions of:
   a) the occasionally seen slit ventricles (the incidence may be no higher in PTC than in age-matched controls) or empty sella
   b) Infantile form may have generous ventricles and large fluid spaces over brain
   c) Intra-orbital abnormalities may be seen: see below

49.1.5 Clinical

Symptoms

See references.7,10

1. Classic (major) symptoms
   a) H/A (the most common symptom): 94–99% Typically retro-ocular and pulsatile. May ↑ with eye movement. Severity does not correlate with degree of CSF pressure elevation. Occasionally worse in A.M.
   b) Nausea: 32% (actual vomiting is less common)
   c) Visual loss (PTC below):
      • Transient visual obscuration (TVO)
      • Permanent afferent visual pathway injury
   d) Diplopia (more common in adult, usually due to VI nerve palsy): 30%

2. Minor symptoms11
   a) Neck stiffness: 30–50%
   b) Tinnitus (the causal relationship with IIH has been demonstrated by resolution of these symptoms with reduction of CSF pressure): up to 60% Usually pulse synchronous. Described as rushing noise. May be unilateral (in these, may be reduced by ipsilateral jugular vein compression + ipsilateral head rotation)
   c) Ataxia: 4–11%
   d) Acral paresthesias: 25%
   e) Retrolubular eye pain on eye movements
   f) Arthralgia: 11–18%
   g) Dizziness: 32%
   h) Fatigue
   i) Reduced olfactory acuity

Signs

Signs are generally restricted to visual system. Conspicuously absent: altered level of consciousness in spite of high ICP

1. Eye findings – also PTC below
   a) Papilledema:
      • Present in almost ≈ 100%
• idiopathic intracranial hypertension without papilledema (IIHWOP)\(^2\): a variant of IIH. Visual loss tends not to occur
• usually bilateral, occasionally unilateral\(^3\)
• may be mild (subtle nerve fiber elevation)

b) abducens nerve (Cr. N. VI) palsy: 20% a false localizing sign (p.567). The esotropia ranges from < 5 prism diopters dysconjugate angle in primary gaze to > 50\(^4\)

c) visual acuity: relatively insensitive assessment of visual function
d) visual field defect: 9%
  • early changes: peripheral fields & nasal quadrant defect
  • enlarged blind spot (66%) and concentric constriction of peripheral fields (blindness is very rare at presentation)

2. infantile form may have only enlarging OFC, frequently self limited, usually requires only follow-up without specific treatment

Note. Worsening of any of the above symptoms with postural changes that increase ICP (bending over, Valsalva maneuver…) is characteristic in idiopathic intracranial hypertension.

Visual loss in PTC

General information
Quoted range of occurrence in PTC: 48–68% (lower numbers generally come from population based samples). A prospective study found changes by Goldman perimetry in 96% of 50 patients.\(^5\) The only parameter associated with worsening vision is recent weight gain.

Pathomechanics
Increased ICP is transmitted along optic nerve sheath → circumferential compression of the retinal ganglion cell axons at the level of the lamina cribrosa.\(^6\)

Manifestations
1. transient visual obscurations (TVO): graying or blacking out of vision. Lasts ≈ 1 second. Uni- or bi-lateral. Typically occur with eye movement, bending over or valsalva maneuver. Directly proportional to severity of papilledema. Frequency of TVOs parallels ICP elevation, but doesn’ correlate with permanent visual loss

2. visual loss in PTC may occur early or late, may be sudden or gradually progressive, and is not reliably correlated to duration of symptoms, papilledema, H/A, Snellen visual acuity, or number of recurrences. It may escape detection until profound.
   a) early: usually constriction of fields and loss of color (perimetry is the best test for following vision in PTC)
   b) late: central vision is affected. Findings include: concentric constrictions, enlargement of the blind spot, inferior nasal defects, arcuate defects, cecocentral scotomas...

49.1.6 Associated conditions

General information
Some cases of PTC are idiopathic (IIH). However, often what is considered “IIH” may actually be secondary to some other condition (e.g. transverse sinus thrombosis, see below). Many conditions cited as being associated with PTC may be coincidental. Four criteria suggested to establish a cause-effect relationship are shown in Table 49.2.\(^8\)

Table 49.2 shows a scale\(^9\) to rank the likelihood of association between various conditions and IIH based on the number of the criteria met in Table 49.2.

Other conditions not included in this list that meet minimal criteria but are unconfirmed in case-control studies\(^2\) include:
1. other drugs: isotretinoin (Accutane®), trimethoprim-sulfamethoxazole, cimetidine, tamoxifen
2. systemic lupus erythematosus (SLE)

Table 49.2 Criteria for causality of PTC by another condition\(^8\)

- meets Dandy’s criteria (Table 49.1)
- the condition should be proven to increase ICP
- treatment of the condition should improve the IIH
- properly controlled studies should show an association between the condition and IIH
Conditions that may be related by virtue of increased pressure in the dural sinuses (see below):
1. otitis media with petrosal extension (so-called otitic hydrocephalus)
2. radical neck surgery with resection of the jugular vein
3. hypercoagulable states

Venous hypertension and sinovenous abnormalities

Venous hypertension has often been proposed as a unifying underlying cause of PTC. Abnormalities of the dural sinuses, including thrombosis, stenosis,17 obstruction, or elevated pressure (reaching levels as high as 40 mm Hg) have been demonstrated in a number of studies. While these findings may underlie a significant number of cases, they may in actuality be epiphenomena (e.g. venous hypertension may be due to compression of the transverse sinuses by elevated intracranial pressurea), and it is unlikely that such abnormalities will explain all cases.
49.1.7 Differential diagnosis

1. True mass lesions: tumor, cerebral abscess, subdural hematomas, rarely gliomatosis cerebri may be undetectable on CT and will be misdiagnosed as PTC.
2. Cranial venous outflow impairment (some authors consider these as IIH)\(^1^8\)
   a) Dural sinus thrombosis (p.1308)
   b) Congestive heart failure
   c) Superior vena cava syndrome
   d) Unilateral or bilateral jugular vein or sigmoid sinus obstruction
   e) Hyperviscosity syndromes
   f) Masson’s vegetant intravascular hemangioendothelioma\(^2^0\): an uncommon, usually benign lesion that may rarely involve the neuraxis (including intracranial occurrence). Not definitely neoplastic. Organizing thrombi develop endothelialized projections into the vessel lumen.
   Must be distinguished from other conditions such as angiosarcoma
3. Chiari I malformation (CIM): may produce findings similar to PTC. 6% of PTC patients have significant tonsillar ectopia, and \(\approx\) 5% of patient with CIM have papilledema\(^1^4\)
4. Infection (CSF will be abnormal in most of these): encephalitis, arachnoiditis, meningitis (especially basal meningitis or granulomatous infections, e.g. syphilitic meningitis, chronic cryptococcal meningitis), chronic brucellosis
5. Inflammatory conditions: e.g. neurosarcoidosis (p.189), SLE
6. Vasculitis: e.g. Behçet’s syndrome
7. Metabolic conditions: e.g. lead poisoning
8. Pseudopapilledema (anomalous elevation of the optic nerve head) associated with hyperopia and drusen. Retinal venous pulsations are usually present. Especially deceptive when a patient with migraines has pseudopapilledema: treat the H/A
9. Malignant hypertension: may produce H/A & bilateral optic disc edema which can be indistinguishable from papilledema. May also produce hypertensive encephalopathy (p.194). Check BP in all PTC suspects
10. Meningeal carcinomatosis
11. Guillain-Barré syndrome (p.184): CSF protein is usually elevated
12. Following head trauma

49.1.8 Evaluation recommendations

Overview
Most tests are intended to rule out conditions that may mimic (or produce) PTC:
1. Cerebral imaging: cerebral CT or MRI (see below) scan without and with contrast
2. LP:
   a) Measure opening pressure (OP) with patient in lateral decubitus position
   b) CSF analysis to rule-out infection (e.g. fungus, TB or Lyme disease), inflammation (e.g. sarcoidosis, SLE) or neoplasm (e.g. carcinomatous meningitis)
      - Protein/glucose
      - Cell count
      - Routine & fungal cultures
      - Cytology if suspicion of carcinomatous meningitis
3. Routine labs: CBC, electrolytes, PT/PTT
4. W/U for sarcoidosis or SLE if other findings suggestive (e.g. cutaneous nodules, hypercoagulable state...)
5. Neuro-ophthalmologic evaluation is recommended. Includes: visual field testing using quantitative perimetry, with evaluation of size of blind spot, slit-lamp examination ± fundus photographs
6. Check BP to R/O malignant HTN → hypertensive encephalopathy (p.770)

CT
CT without and with IV contrast is usually adequate to R/O intracranial mass as a possible cause of intracranial hypertension, but may miss cases of dural sinus thrombosis. MRI & MRV are preferred.
MRI

Intracranial abnormalities are usually absent or minimal (slit ventricles, empty sella in 30–70%). However, intraorbital findings may be more substantial and include\textsuperscript{14}:

1. flattening of the posterior sclera: occurs in 80%
2. enhancement of the prelaminar optic nerve: in 50%
3. distention of the perioptic subarachnoid space: in 45%
4. vertical tortuosity of the orbital optic nerve: in 40%
5. intraocular protrusion of the prelaminar optic nerve: in 30%

Venography

MR venography (MRV) has largely replaced conventional venography to rule out dural sinus or venous thrombosis.

49.1.9 Treatment and management

Natural history

Spontaneous resolution is common, sometimes within months, but usually after \(\approx 1\) year. Papilledema persists in \(\approx 15\%\) Permanant visual loss occurs in 2–24% (depending on criteria used and degree to which it is sought). Persistent H/A may occur in some. Recurs in \(\approx 10\%\) after initial resolution\textsuperscript{14}.

Interventions

Overview

Studies are often difficult to interpret especially since spontaneous remission is common.

1. all patients must have repeated thorough ophthalmologic exams (see above)
2. stop possible offending drugs
3. weight loss: a weight loss of 6% usually results in complete resolution of papilledema\textsuperscript{21}. However, resolution may be too slow for acutely threatened vision. Weight loss is also associated with reduction of other health risks of obesity. Symptoms recur if the weight is regained
   a) dieting: uncontrolled studies\textsuperscript{22} suggest that this is effective, but it is rarely accomplished or sustained
   b) bariatric surgery: gastric bypass, laparoscopic banding...
4. treatment of asymptomatic PTC patients is controversial as there is no reliable predictor for visual loss. Close follow up with serial formal visual field evaluation is necessary. Intervention is recommended in unreliable patients, or whenever visual fields deteriorate. It is possible to lose vision without H/A or papilledema
5. most cases remit by 6–15 weeks, however relapse is common
6. medical treatment
   a) fluid and salt restriction
   b) diuretics (slows CSF production) – see below
   c) if ineffective, add steroids (options: dexamethasone (Decadron\textsuperscript{\textregistered}) 12 mg/day, prednisone 40–60 mg/day, or methylprednisolone 250 mg IV q 6 hrs). May ↑ CSF resorption in cases of inflammation or venous thrombosis. Can be used as temporizing agents for patients awaiting surgery. A reduction in symptoms should occur by 2 weeks, after which time the steroid should be tapered over 2 weeks. Long-term use is not recommended due to, among other things, associated weight gain
7. surgical therapy\textsuperscript{23} only for cases refractory to above, or where visual loss is progressive or is severe initially or unreliable patient:
   a) serial LPs until remission (25% remit after 1st LP\textsuperscript{24}): remove up to 30 ml to halve OP, perform qod until OP <20 cm H\textsubscript{2}O, then decrease to q wk (no patient who had remission by 2nd LP had OP >350 on 1st LP). Use a large gauge needle (e.g. 18 Ga) which may help promote a post-LP CSF leak into subcutaneous tissues. LPs may be difficult in obese patients. Revisions may be required in up to 50% Side effects: include sciatica from nerve root irritation, acquired cerebellar tonsillar herniation (p.418), spinal H/A (from intracranial hypotension)
   b) Shunts: see below
   c) optic nerve sheath fenestration: see below
   d) older treatment less commonly practiced today: subtemporal decompression (advocated by Dandy) or suboccipital decompression. Usually bilateral silver-dollar size craniectomies under
temporalis muscle to floor of middle fossa, open dura, cover brain with absorbable sponge, close fascia and muscle watertight, anticonvulsants were started due to risk of post-op seizures

8. interventional procedures: venous sinus stenting may be considered for refractory cases.

9. patients should be followed at least two years (with repeat imaging, e.g. MRI) to R/O occult tumor

Diuretics

1. carbonic anhydrase (CA) inhibitors:
   a) acetazolamide (Diamox®): start at 125–250 mg PO q 8–12 hrs, or long acting Diamox Sequels® 500 mg PO BID. Increase by 250 mg/day until symptoms improve, side effects occur, or 2 gm/day reached. Side effects: (in high doses): acral paresthesias, nausea, metabolic acidosis, altered taste, renal calculi, drowsiness. Rare: Stevens-Johnson syndrome, toxic epidermal necrolysis, agranulocytosis. Contraindicated with allergy to sulfa or a history of renal calculi
   b) methazolamide (Neptazane®): better tolerated but less effective. 50–100 mg PO BID-TID. This branded product is no longer on the market. Side effects: similar to acetazolamide
   c) topiramate (Topamax®): anticonvulsant with secondary inhibition of CA. 200 mg PO BID. Side effects: Similar to acetazolamide, but can be used in sulfa allergic patients

2. furosemide (Lasix®)
   a) start: 160 mg per day in adults, adjust per symptoms and eye exam (not to CSF pressure)
   b) if ineffective, double (320 mg/day)
   c) monitor K+ levels and supplement as needed

Shunts

1. lumbar shunt: usually lumboperitoneal; see insertion technique (p.1517). May be difficult in obese patient. May need a horizontal-vertical valve (p.418) to prevent H/A from intracranial hypotension. Alternative: lumbopleural shunt

2. other shunts may be used, especially when arachnoiditis precludes use of lumbar subarachnoid space, e.g.:
   a) VP shunt: often difficult since the ventricles are frequently small or slit-like. Stereotactic techniques may make this more technically feasible
   b) cisterna magna shunt: may shunt to vascular system

Optic nerve sheath fenestration (ONSF)

See references. Generally better for protection of vision and reversal of papilledema than for other symptoms (e.g. H/A). Performed via medial or less commonly a lateral orbitotomy or transconjunctival medial approach. May reverse or stabilize visual deterioration and sometimes (but not always) lowers ICP (by continued CSF filtration) and may protect the contralateral eye (if not, contralateral ONSF must be performed). Has succeeded in cases where visual loss progressed after LP shunting, possibly due to poor communication between orbital and intracranial subarachnoid spaces. Side effects: potential adverse include: pupillary dysfunction, peripapillary hemorrhage, chemosis, chorioretinal scarring, diplopia (usually self-limited) from medial rectus disruption. Repeat fenestration is needed in 0–6%

Management recommendations for specific situations

Weight loss should be attempted in all.

1. PTC patients with H/A and no visual loss: medical therapy to control ↑ ICP and H/A. ONSF not recommended. Shunting is an option if medical management fails

2. PTC with visual loss without H/A:
   a) mild visual loss: acetazolamide 500–1500 mg/d, follow-up q 2 weeks
   b) moderate visual loss: acetazolamide 2000–3000 mg/d, follow-up q week
   c) severe visual loss, moderate visual loss that doesn’t respond to acetazolamide, or optic disc at risk:
      ● methylprednisolone 250 mg IV q 6 hrs + acetazolamide 1000 mg PO BID
      ● if no improvement: ONSF. Consider shunt if ICP > 300 mm H2O
   d) PTC with visual loss AND H/A: for patients with surgical indications, either surgical procedure is appropriate. Shunting may relieve both problems simultaneously. ONSF may be more reliable to relieve the visual problems (the failure rate may be lower than the shunt malfunction rate) but is not as good for the H/A
3. IIHWOP: symptomatic treatment for H/A, diuretics
4. PTC in children and adolescents:
   a) may be seen with withdrawal of steroids used for asthma
   b) search for and correction of underlying etiology (offending drugs listed above, hypercalcemia, cancer...)
   c) acetazolamide has been used with success
5. PTC in pregnancy:
   a) women who first present with PTC during pregnancy: resolution of PTC following delivery is common
   b) women who become pregnant during therapy:
      • 1st trimester: observation, limitation of weight gain, serial LPs. Acetazolamide should be avoided because of teratogenicity
      • 2nd & 3rd trimester: acetazolamide has been used safely, but involvement of high-risk obstetrician specialist is advised
6. pseudopapilledema (associated with drusen, etc., in the absence of intracranial hypertension): no interventions.\(^\text{14}\) Reassurance and H/A management are employed

49.2 Empty sella syndrome

49.2.1 General information
Empty sella syndrome (ESS) can be “primary” or “secondary.”

49.2.2 Primary empty sella syndrome

General information
Occurs in the absence of prior treatment of a pituitary tumor (medical, surgical or XRT). Herniation of the arachnoid membrane into the sella turcica\(^\text{33}\) which can act as a mass, probably as a result of repeated CSF pulsation. The sella can become enlarged (see Sella turcica (p. 216), for normal dimensions) and the pituitary gland may become compressed against the floor.

Frequent association: female sex (female: male ratio = 5:1), obesity and HTN. The frequency of intrasellar arachnoid herniation is higher in patients with pituitary tumors and in those with increased intracranial pressure for any reason – including idiopathic intracranial hypertension (p. 766) – than in the general population.

These patients usually present with symptoms that do not suggest an intrasellar abnormality including: headache (the most common symptom), dizziness, seizures... Occasionally patients may develop CSF rhinorrhea,\(^\text{34}\) deterioration of vision (acuity or field deficit resulting from kinking of optic chiasm due to herniation into the sella), or amenorrhea-galactorrhea syndrome.

 Clinically evident endocrine disturbances are rare with primary ESS, however up to 30% have abnormal pituitary function tests, most commonly reduced growth hormone secretion following stimulation. Mild elevation of prolactin (PRL) and reduction of ADH may occur, probably from compression of the stalk. These patients show a normal PRL rise with TRH stimulation (whereas patients with prolactinomas do not).

Treatment
Surgical treatment is usually not indicated, except in the case of CSF rhinorrhea. In this setting, it is necessary to determine if there is increased ICP, and if so, if there is an identifiable cause. Simple shunting for hydrocephalus runs the risk of producing tension pneumocephalus from air drawn in through the former leak site. This may necessitate transphenoidal repair with simultaneous external lumbar drainage, to be converted to a permanent shunt shortly thereafter. Hyperprolactinemia may be treated e.g. with bromocriptine (p. 740) if it interferes with gonadal function.

49.2.3 Secondary empty sella syndrome

Entities associated with secondary empty sella syndrome:
1. following trauma\(^\text{35}\)
2. after successful transphenoidal removal or XRT for a pituitary tumor\(^\text{35}\)
3. any cause of increased intracranial pressure, including: idiopathic intracranial hypertension (pseudotumor cerebri), Chiari malformation
Often presents with visual deterioration due to herniation of the optic chiasm into the empty sella. There may be hypopituitarism from the underlying cause.

Visual deterioration may be treated with chiasmoplasty (propping up the chiasm) usually by transsphenoidal approach and packing the sella with fat, muscle or cartilage. May be done endoscopically.\textsuperscript{36} Appears to be better for improving visual field deficits than loss of visual acuity.\textsuperscript{37}

50 Tumors and Tumor-Like Lesions of the Skull

50.1 Skull tumors

50.1.1 General information

See Skull lesions (p.1376) for differential diagnosis and evaluation (including non-neoplastic lesions). Considering only tumors, the differential diagnosis includes:

1. benign tumors
   a) osteoma: see below
   b) hemangioma: see below
   c) dermoid and epidermoid tumors: see below
   d) chondroma: occur mainly in conjunction with the basal synchondroses
   e) meningioma
   f) aneurysmal bone cyst

2. malignant tumors: malignancy is suggested by a single large or multiple (>6) small osteolytic lesions with margins that are ragged, undermined and lacking sclerosis
   a) bone metastases to the skull. Common ones include:
      ● prostate
      ● breast
      ● lung
      ● kidney
      ● thyroid
      ● lymphoma
      ● multiple myeloma/plasmacytoma (p.714)
   b) chondrosarcoma
   c) osteogenic sarcoma
   d) fibrosarcoma

50.1.2 Osteoma

General information

Osteomas are the most common primary bone tumor of the calvaria. They are benign, slow-growing lesions, that occur commonly in the cranial vault, mastoid and paranasal air sinuses, and the mandible. Lesions within air sinuses may present as recurrent sinusitis. More common in females, highest incidence is in 6th decade. Triad of Gardner’s syndrome: multiple cranial osteomas (of calvaria, sinuses, and mandible), colonic polyposis, and soft-tissue tumors.

See Localized increased density or hyperostosis of the calvaria (p.1379) for differential diagnosis.

Pathology

Consists of osteoid tissue within osteoblastic tissue, surrounded by reactive bone. Difficult to distinguish from fibrous dysplasia.

Radiographic evaluation

Skull x-ray: round, sclerotic, well demarcated, homogeneous dense projection. Usually arise from outer table of skull (inner table less common). May be compact or spongy (spongy osteoma may be radiolucent). Unlike meningiomas, diploë are preserved and vascular channels are not increased.

Osteomas are “hot” on nuclear bone scan.

Treatment

Asymptomatic lesions may simply be followed. Surgery may be considered for cosmetic reasons, or if pressure on adjacent tissues produces discomfort. Lesions involving only the outer table may be removed leaving the inner table intact.
50.1.3 Hemangioma

General information
Comprise ≈ 7% of skull tumors.1 These benign tumors commonly occur in the skull (discussed here) and spine (p. 794). Two types: cavernous (most common) and capillary (rare).

Radiographic evaluation
Skull x-ray: characteristically shows a circular lucency with honeycomb or trabecular pattern (seen in ≈ 50% of cases) or radial trabeculations producing a sunburst pattern (seen in ≈ 11% of cases).1 Sclerotic margins are evident in only ≈ 33%.1
CT: hypodense lesion with sclerotic spaced trabeculations. Nonenhancing.
Bone scan: typically hot.

Treatment
Accessible lesions may be cured by en bloc excision or curettage. The gross appearance is of a hard, blue-domed mass beneath the pericranium. Radiation may be considered for inaccessible tumors.

50.1.4 Epidermoid and dermoid tumors of the skull

General information
See also epidermoids and dermoids in general (p. 776).
