Dermoids and epidermoids are benign inclusion cysts of ectoderm that may involve skull and underlying dural venous structures or brain. They may become infected. Primary skull involvement is rare and occurs when ectodermal rests are entrapped in the developing skull which causes these tumors to arise within the diploë and expand both inner and outer tables. Because they are not neoplastic, they grow at a linear rate (instead of exponential). Usually midline.
Epidermoid tumors contain only the outer layer of skin, and are therefore lined with stratified squamous epithelium and the resultant byproduct, keratin.
Dermoid tumors contain all elements of skin including hair follicles (which may produce hair in the tumor) sweat glands (sebaceous glands (apocrine) and sweat glands (eccrine)).2 Teratomas are true neoplasms and may also contain bone, cartilage, teeth and nails.

Presentation
These lesions may present as a result of mass effect from continued growth.
They may rupture (more common with dermoids than epidermoids), and can cause chemical meningitis (from the irritating properties of fat and keratin), or, if infected, bacterial meningitis.

Radiographic evaluation
1. skull x-ray: these osteolytic lesions have well-defined, sclerotic margins
2. some imaging is required to evaluate possible intracranial involvement
   a) CT: the lesions are hypodense (keratin contains fats), and non-enhancing
   b) MRI: like CSF they are low intensity on T1WI and high signal on T2WI, but unlike CSF they are high signal on DWI>MRI (p. 762)

Treatment
Treatment is surgical. Radiation and chemotherapy are not indicated.
When possible, the goal is to avoid rupture during removal in order to avoid chemical and/or bacterial meningitis.
Bone margins are curetted. Search must be made for a tract leading to the intracranial cavity which must be followed if found. Preparation for dural sinus repair must be made for lesions overlying the sagittal sinus (including torcular Herophili).
Endoscopic surgery may be an option for some skull base lesions.
50.1.5 Langerhans cell histiocytosis

General information

Histiocytic disorders may be classified as follows:
1. malignant (true histiocytic lymphoma)
2. reactive (benign histiocytosis)
3. Langerhans cell histiocytosis (LCH)
   b) multifocal unisystem: seen mostly in children. Fever, bone & skin lesions
   c) multifocal multisystem: nee Letterer-Siwe disease (a fulminant, malignant lymphoma of infancy).3 Hand-Schüller-Christian triad: DI (from invasion of pituitary stalk), exophthalmos (from intraorbital tumor) and lytic bone lesions (particularly of cranium).

This section deals with unifocal Langerhans cell histiocytosis, formerly AKA eosinophilic granuloma.

Clinical

Generally a condition of youth, 70% of patients are < 20 yrs age. In a series of 26 patients,3 age range was 18 mos-49 yrs (mean: 16 yrs).

Most common presenting symptom: tender, enlarging skull mass (> 90%). May be asymptomatic and incidentally discovered on skull x-ray obtained for other reasons. Blood tests were normal in all except 1 who had eosinophilia of 23%

Parietal bone was the most common site (42%), frontal bone next (31%)3 (some series show frontal bone was the most common).

Evaluation

Skull x-rays

Classic radiographic finding: round or oval non-sclerotic punched out skull lesion with sharply defined margins, involving both inner and outer tables (the disease begins in diploic space), often with beveled edges. A central bone density is occasionally noted (rare, but diagnostic). No abnormal vascularity of adjacent bone. No periosteal reaction. Differentiate from hemangioma by absence of sunburst appearance.

CT scan

Characteristic appearance of a soft tissue mass within area of bony destruction having a central density.4 Differentiate from epidermoid which has dense surrounding sclerosis.

Pathology

Gross: pinkish gray to purple lesion extending out of bone and involving pericranium. Dural involvement occurs in only 1 of 26 patients, but with no dural penetration.

Microscopic: numerous histiocytes, eosinophils, and multinucleated cells in a reticulin fiber network. No evidence that this is a result of an infection.

Treatment

Tendency toward spontaneous regression, however, most single lesions are treated by curettage. Multiple lesions are usually associated with extracalvarial bony involvement and are often treated with chemotherapy and/or low dose radiation therapy. Very radiosensitive.

Outcome

After a mean 8 years follow-up, 8 patients (31%) developed additional lesions, 5 of these were ≤ 3 yrs age (all of 5 patients < 3 yrs age)3 (may suggest a form of multifocal LCH, thus young patients should be followed closely). Recurrences were local in one case, and in others involved other bones (including the skull, femur, lumbar spine) or brain (including the hypothalamus, presenting with diabetes insipidus and growth delay).
50.1.6 Chordoma

General information

Key concepts

- primary malignant tumor, usually of clivus or sacrum, with high recurrence rate
- histology: characteristic physaliphorous cells (containing intracellular mucin)
- generally slow-growing and radioresistant
- treatment of choice: wide en bloc resection when possible (piecemeal removal carries risk of inducing metastases), proton-beam radiation may help

Rare tumors (incidence of ≈ 0.51 cases/million) of the remnant of the primitive notochord (which normally differentiates into the nucleus pulposus of the intervertebral disks). Can arise anywhere along the neuraxis where there is remnant of notochord, however, cases tend to cluster at the two ends of the primitive notochord: 35% cranially in the spheno-occipital region (clivus), and 53% in the spine at the sacrococcygeal region. Less commonly, they may occur in the spine above the sacrum. They represent less than 1% of intracranial tumors and 3% of primary spine tumors. The metastatic rate is low (5–20%), but there is a high recurrence rate of 85% following surgery, and therefore aggressive RTX is usually employed post-op.

Pathology

Histologically, these tumors are considered low-grade malignancies. However, their behavior is more malignant because of the difficulty of total removal, a high recurrence rate, and the fact that they can metastasize (usually late). They are slow growing, locally aggressive and osseodestructive. Metastases occur in about 10% of sacral tumors, usually late and after multiple resections, and most often to lung, liver and bone. Malignant transformation into fibrosarcoma or malignant fibrous histiocytoma is rare. Physaliphorous cells are distinctive, vacuolated cells on histology that probably represent cytoplasmic mucus vacuoles seen ultrastructurally.

Radiographic appearance

Usually lytic with frequent calcifications. Enhances on CT with contrast. Rarely, may appear as a sclerotic vertebra (“ivory vertebra”).

Cranial chordomas

Peak incidence of cranial chordomas is 50–60 years of age. These tumors are rare in patients <30 years of age. Male:female distribution is ≈ equal.

Differential diagnosis: Primarily between other cartilaginous tumors of the skull base; see differential diagnosis of other foramen magnum region tumors (p. 1367):
1. chondrosarcomas
2. chondromas

Presentation: Usually produces cranial nerve palsies (usually oculomotor or abducens nerve).

Spinal chordomas

General information

Occur primarily in the sacrococcygeal region. Unlike cranial chordomas, sacrococcygeal chordomas show a male predominance, and these patients tend to be older. May also arise in C2. Chordomas constitute over 50% of primary bone tumors of the sacrum. May produce pain, sphincter disturbance or nerve root symptoms from local nerve root compression. It may occasionally extend cephalad into the lumbar spinal canal. It is usually confined anteriorly by the presacral fascia, and only rarely invades the wall of the rectum. A firm fixed mass may be palpable between the rectum and the sacrum on rectal exam.

Evaluation

Characteristic radiographic findings: centrally located destruction of several sacral segments, with an anterior soft-tissue mass that occasionally has small calcifications. CT and MRI show the bony destruction. This is usually difficult to see on plain x-rays. MRI also shows the soft-tissue mass.
Open or CT guided percutaneous posterior biopsy can confirm the diagnosis. Transrectal biopsy should be avoided because of the potential of rectal spread of tumor.\textsuperscript{14} Chest CT and bone scan: to R/O mets for staging purposes.

**Treatment**

**Surgery**

Wide en-bloc excision with postoperative radiation is usually the best option, although this may also be only temporarily effective. Decompression is best avoided since entering the mass serves to spread tumor (surgically induced metastases) which will then regrow. Chordomas located in C2 are usually not amenable to en bloc resection.\textsuperscript{15}

Sacral chordomas: The particulars of the surgical procedure are highly dependent on the extent of the lesion. These tumors may spread through the gluteal musculature, and if significant muscular excision is required, then a pedicle based rectus abdominis flap may be employed. A diverting colostomy may be required if it is necessary to resect the rectum or if a cephalic sacral resection is anticipated.\textsuperscript{16}

For chordomas caudal to the third sacral segment, most agree that a posterior approach is satisfactory. For more rostral lesions, some advocate a combined anterior-posterior approach. However, a posterior approach has been also been used for these.\textsuperscript{16}

Adverse effects of sacrectomy: if S2 nerve roots are the most caudal nerve roots spared, there is \(\approx 50\%\) chance of normal bladder and bowel control.\textsuperscript{16} If S1 or more cephalic roots are the most caudal nerve roots spared, most will have impaired bladder control and bowel problems.\textsuperscript{16}

**Radiation therapy (XRT)**

Best results were obtained with en bloc excision (even if marginal), sometimes combined with high-dose XRT\textsuperscript{7,17} (conventional XRT did not prevent recurrence when incorporated with palliative or debulking surgery\textsuperscript{7}, but it did lengthen the interval to recurrence\textsuperscript{17}). Early radiation was associated with longer survival.\textsuperscript{15} Higher XRT doses can be used in the sacrococcygeal region (4500–8000 rads) than in the cervical spine (4500–5500 rads) because of concerns of radiation injury to the spinal cord. IMRT and stereotactic radiosurgery have also been used.\textsuperscript{15}

Proton beam therapy, alone\textsuperscript{9} or combined with high-energy x-ray (photon) therapy\textsuperscript{19,20} may be more effective than conventional XRT alone. However, proton beam therapy requires travel to one of a very limited number of facilities with a cyclotron (in the U.S.: Boston, or Loma Linda, California) which may be difficult to arrange for what is typically \(\approx 7\) weeks of fractionated treatments.

**Chemotherapy**

Imatinib (Gleevec\textsuperscript{®}) (a tyrosine kinase inhibitor) has some antitumor effect in chordoma.\textsuperscript{21}

**Outcome**

Median survival is 6.3 years.\textsuperscript{15}

### 50.2 Non-neoplastic skull lesions

#### 50.2.1 General information

Includes:

1. osteopetrosis (p.1401)
2. Paget’s disease of the skull
3. hyperostosis frontalis interna (see below)
4. fibrous dysplasia (p.780)

#### 50.2.2 Hyperostosis frontalis interna

**General information**

See differential diagnosis (p.1379). Hyperostosis frontalis interna (HFI) is a benign irregular nodular thickening of the inner table of the frontal bone that is almost always bilateral. The midline is spared at the insertion of the falx. Unilateral cases have been reported,\textsuperscript{22} and in these cases one must R/O other etiologies such as meningioma, calcified epidural hematoma, osteoma, fibrous dysplasia, an epidural fibrous tumor,\textsuperscript{23} or Paget’s disease.
Epidemiology

The incidence of HFI in the general population is ≈ 1.4–5%\(^2^2\). HFI is more common in women (female: male ratio may be as high as 9:1) with an incidence of 15–72% in elderly women. A number of possible associated conditions have been described (most are unproven), the majority of which are metabolic, earning it the alias of metabolic craniopathy. Associated conditions include:

1. Morgagni's syndrome (AKA Morgagni-Stewart-Morel syndrome): headache, obesity, virilism and neuropsychiatric disorders (including mental retardation)
2. endocrinologic abnormalities
   a) acromegaly (p.725)\(^2^4\) (elevated growth hormone levels)
   b) hyperprolactinemia\(^2^4\)
3. metabolic abnormalities
   a) hyperphosphatemia
   b) obesity
4. diffuse idiopathic skeletal hyperostosis (DISH) (p.1129)

Clinical

HFI may present without symptoms as an incidental finding on radiographic evaluation for other reasons. Many signs and symptoms have been attributed to HFI including: hypertension, seizures, headache, cranial nerve deficits, dementia, irritability, depression, hysteria, fatigability and mental dullness. The incidence of headache may be statistically higher in patients with HFI than in the general population.\(^2^5\)

Evaluation

Blood tests to R/O some of the above noted conditions may be indicated in appropriate cases: check growth hormone, prolactin, phosphate, alkaline phosphatase (to R/O Paget’s disease).

Plain skull x-ray shows thickening of the frontal bone with characteristic sparing of the midline. Spread to parietal and occipital bone occasionally occurs.

CT demonstrates the lesion which usually causes 5–10 mm of bone thickening, but as much as 4 cm has been reported.

Bone scan: usually shows moderate uptake in HFI (generally not as intense as with bone mets). Also, indium-111 leukocyte scan (commonly used to detect occult infection) will show accumulation in HFI (a false positive).\(^2^6, 2^7\)

Treatment

In spite of a large number of published descriptive works in the medical literature primarily in the early and mid-20th century, little has been written about treatment of cases where symptoms are suspected to be due to HFI. In one report, removal of the thickened bone was accomplished without evidence of dural adhesions, and with improvement in the presenting hysteria.\(^2^2\)

Surgical technique

One technique described consists of using the craniotome to excise the thickened portion of the bone (a plain skull x-ray may be used to make a template), and then the thickened bone is thinned down with a high-speed drill, and the bone flap is then replaced. Alternatively, a cranioplasty with methylmethacrylate or custom-made implant fabricated using CT data may be performed.

50.2.3 Fibrous dysplasia

General information

Usually a benign condition in which normal bone is replaced by fibrous connective tissue (malignant transformation occurs in <1%). Does not appear to be heritable. Most lesions occur in the ribs or craniofacial bones, especially the maxilla.

Patterns of involvement

1. monostotic: most common
2. polyostotic: 25% with this form have >50% of the skeleton involved with associated fractures and skeletal deformities
3. as part of McCune-Albright syndrome (endocrine dysfunction, café au lait spots which tend to occur on one side of the midline and tend to be more jagged than those seen in neurofibromatosis (p.604), fibrous dysplasia, and precocious puberty primarily in females) and its variants

Clinical

Clinical manifestations of the fibrous dysplasia (FD) lesions include:
1. incidental finding (i.e. asymptomatic)
2. local pain
3. local swelling (rarely marked distortion resembling aneurysmal bone cyst may occur) or deformity
4. may predispose to pathologic fractures when they occur in long bones
5. cranial nerve involvement: including loss of hearing when the temporal bone is involved as a result of obliteration of the external auditory canal
6. seizures
7. serum alkaline phosphatase is elevated in about 33% calcium levels are normal
8. darkened hair pigmentation overlying skull lesions
9. spontaneous scalp hemorrhages
10. rarely associated with Cushing’s syndrome, acromegaly

3 forms of the FD lesions:
1. cystic (the lesions are not actually cysts in the strict sense): widening of the diploe usually with thinning of the outer table and little involvement of the inner table. Typically occurs high in calvaria
2. sclerotic: usually involves skull base (especially sphenoid bone) and facial bones
3. mixed: appearance is similar to cystic type with patches of increased density within the lucent lesions

Ground glass appearance on x-rays is due to the thin spicules of woven bone.

Treatment

There is no cure for FD. Local procedures (mostly orthopedic) are used for deformities or bone pain that is refractory to other treatment. Neurosurgical involvement may be required for skull lesions producing refractory pain or neurologic symptoms. Calvarial lesions may be treated with curettage and cranioplasty. Calcitonin may be used for widespread lesions with bone pain and/or high serum alkaline phosphatase levels.

References

51 Tumors of the Spine and Spinal Cord

51.1 General information
15% of primary CNS tumors are intraspinal (the intracranial:spinal ratio for astrocytomas is 10:1; for ependymomas it's 3–20:1).\footnote{There is disagreement over the prevalence, prognosis, and optimal treatment. Most primary CNS spinal tumors are benign (unlike the case with intracranial tumors). Most present by compression rather than invasion.} There is disagreement over the prevalence, prognosis, and optimal treatment. Most primary CNS spinal tumors are benign (unlike the case with intracranial tumors). Most present by compression rather than invasion.\footnote{Most primary CNS spinal tumors are benign (unlike the case with intracranial tumors). Most present by compression rather than invasion.}

51.2 Compartmental locations of spinal tumors
May be classified into 3 groups based on the compartment involved. Although metastases may be found in each area, they are most commonly extradural. Frequencies quoted below are from a general hospital; extradural lesions are less common in neurosurgical clinics because many of these tumors are managed by oncologists without requiring neurosurgical involvement.

1. extradural (ED) (55%): arise outside cord in vertebral bodies or epidural tissues
2. intradural extramedullary (ID-EM) (40%): arise in leptomeninges or roots. Primarily meningiomas and neurofibromas (together = 55% of ID-EM tumors)
3. intramedullary spinal cord tumors (IMSC T) (5%): arise in SC substance. Invade and destroy tracts and grey matter

51.2.1 Spinal lymphoma
Lymphoma may occur in any of or all 3 compartments.
1. epidural
   a) metastatic or secondary lymphoma: the most common form of spinal lymphoma. Spinal involvement occurs in 0.1–10% of patients with non-Hodgkin’s lymphoma
   b) primary spinal epidural non-Hodgkin’s lymphoma: rare. Completely epidural with no bony involvement. The existence of this entity is controversial, and some investigators feel that it represents extension of undetected retroperitoneal or vertebral body lymphoma. May have a better prognosis than secondary lymphoma\footnote{May have a better prognosis than secondary lymphoma.}
2. intramedullary
   a) secondary (p.789)
   b) primary: very rare (see below)

51.3 Differential diagnosis: spine and spinal cord tumors

51.3.1 General information
See also Myelopathy (p.1407) for a list including not only tumors but also nonneoplastic causes of spinal cord dysfunction (e.g. spinal meningeal cyst, epidural hematoma, transverse myelitis...).

51.3.2 Extramedullary spinal cord tumors (55%)
Arise in vertebral bodies or epidural tissues
1. metastatic: comprise the majority of ED tumors
   a) most are osteolytic (cause bony destruction): see Spinal epidural metastases (p.814). Common ones include:
      • lymphoma: most cases represent spread of systemic disease (secondary lymphoma); some cases may be primary (see below)
      • lung
      • breast
      • prostate
   b) metastases that may be osteoblastic:
      • in men: prostate Ca is the most common
      • in women: breast Ca is the most common
2. primary spinal tumors (very rare)
   a) chordomas (p.778)
   b) osteoid osteoma (p.792)
   c) osteoblastoma (p.792)
d) aneurysmal bone cyst (ABC): an expansile tumor-like osteolytic lesion consisting of a highly vascular honeycomb of blood-filled cavities separated by connective tissue septa, surrounded by a thin cortical bone shell which may expand. Comprise 15% of spine tumors. Etiology is controversial. May arise from preexisting tumor (including: osteoblastoma, giant cell tumor, fibrous dysplasia, chondrosarcoma) or following acute fracture. In spine, there is a tendency to involve primarily the posterior elements. Peak incidence is in 2nd decade of life. Treatment usually consists of intralesional curettage. High recurrence rate (25–50%) if not completely excised.

e) chondrosarcoma: a malignant tumor of cartilage. Lobulated tumors with calcified areas.

f) osteochondroma (chondroma): benign tumors of bone that arise from mature hyaline cartilage. Most common during adolescence. An enchondroma is a similar tumor arising within the medullary cavity.

g) vertebral hemangioma (p. 794)

h) giant cell tumors (GCT) of bone: AKA osteoclastoma (p. 797)

i) giant cell (reparative) granuloma: AKA solid variant of ABC. Related to GCT. Occurs primarily in mandible, maxilla, hands and feet, but there are case reports of spine involvement. Not a true neoplasm – more of a reactive process. Treatment: curettage. Recurrence rate: 22–50% treated with re-excision.

j) brown tumor of hyperparathyroidism.

k) osteogenic sarcoma: rare in spine.

3. miscellaneous

a) plasmacytoma (p. 716)

b) multiple myeloma (p. 714)

c) unifocal Langerhans cell histiocytes (LHC), nee eosinophilic granuloma: osteolytic defect with progressive vertebral collapse; LHC is one cause of vertebral plana (p. 1392). C-spine is the most commonly affected region. Individual LHCs associated with systemic conditions (Letterer-Siwe or Hand-Schüller-Christian disease) are treated with biopsy and immobilization. Collapse or neurologic deficit from compression may require decompression and/or fusion. Low-dose RTX may also be effective.

d) Ewing’s sarcoma: aggressive malignant tumor with a peak incidence during 2nd decade of life. Spine mets are more common than primary spine lesions. Treatment is mostly palliative: radical excision followed by RTX (very radiosensitive) and chemotherapy.

e) chloroma: focal infiltration of leukemic cells

f) angiolipoma: ≈ 60 cases reported in literature

g) neurofibromas (p. 786): most are intradural, but some are extradural, usually dilate neural foramen (dumbbell tumors)

h) Masson’s vegetant intravascular hemangioendothelioma (p. 770).

51.3.3 Intradural extramedullary spinal cord tumors (40%)

1. meningiomas: usually intradural, but may be partly or, in 15% wholly extradural see below

2. neurofibromas: usually intradural, but may be partly or wholly extradural

3. many lipomas are extramedullary with intramedullary extension

4. miscellaneous: only ≈ 4% of spinal metastases involve this compartment

51.3.4 Intramedullary spinal cord tumors (5%)

1. astrocytoma (p. 789): 30%

2. ependymoma (p. 788): 30% including myxopapillary ependymoma (p. 789)

3. miscellaneous: 30% includes:

a) malignant glioblastoma

b) dermoid. In addition to the general population, dermoids present in a delayed fashion following ≈ 16% of myelomeningocele (MM) closures. An iatrogenic etiology has been debated, however a case of a congenital dermoid in a newborn with MM indicates that the origin is not always from incompletely excised dermal elements at the time of MM closure.

c) epidermoid

d) teratoma

e) lipoma

f) hemangioblastoma (p. 789)

g) neuroma (very rare intramedullary)

h) syringomyelia (not neoplastic)

4. extremely rare tumors

a) lymphoma
b) oligodendroglioma
c) cholesteatoma
d) intramedullary metastases: comprises only ≈ 2% of spinal mets
e) solitary fibrous tumors of the spinal cord: recognized in 1996. Probable mesenchymal origin. May also occur extramedullary (less common). Treatment is complete surgical excision. Prognosis is unclear. 14

51.4 Intradural extramedullary spinal cord tumors

51.4.1 Spinal meningiomas

See reference. 15

Epidemiology
Peak age: 40–70 years. Female: male ratio = 4:1 overall, but the ratio is 1:1 in the lumbar region. 82% thoracic, 15% cervical, 2% lumbar. 90% are completely intradural, 5% are extradural, and 5% both intra- and extra-dural. 68% are lateral to the spinal cord, 18% posterior, 15% anterior. Multiple spinal meningiomas occur rarely.

Clinical
Symptoms
Signs prior to surgery (only 1 of 174 patients was intact): 15
1. motor
   a) pyramidal signs only: 26%
   b) walks with aid: 41%
   c) antigravity strength: 17%
   d) flexion-extension with gravity removed: 6%
   e) paralysis: 9%
2. sensory
   a) radicular: 7%
   b) long tract: 90%
3. sphincter deficit: 51%

Outcome
Recurrence rate with complete excision is 7% with a minimum of 6 years follow-up (relapses occurred from 4 to 17 years post-op). 15

51.4.2 Spinal schwannomas

General information

Key concepts
- slow growing benign tumors
- most (75%) arise from the dorsal (sensory) rootlets
- early symptoms are often radicular
- recurrence is rare after total excision (except in neurofibromatosis)

Table 51.1 Symptoms of spinal meningiomas

Incidence: 0.3–0.4/100,000/yr. Most occur sporadically and are solitary, but they may also be associated with neurofibromatosis (p.603) primarily type 2 (NF2), but can occur with type 1.

**Configurations**

Most are entirely intradural, but 8–32% may be completely extradural,16,17 1–19% are a combination, 6–23% are dumbbell, and 1% are intramedullary.

Dumbbell tumors. Definition: tumors that develop an “hourglass” shape as a result of an anatomic barrier encountered during growth. Not all dumbbell tumors are Schwannomas, e.g. neuroblastoma (p.603). Most have a contiguous intraspinal, foraminal (usually narrower) and extraforaminal components (widening of the neural foramen is a characteristic finding, can be recognized even on plain films, and speaks to the longstanding benign nature of the lesion). The waist may also be due to a dural constriction.

Asazuma et al.18 classification system for dumbbell spinal Schwannomas is shown in Fig. 51.1.

Type I tumors are intradural and extradural and are restricted to the spinal canal. The constriction occurs at the dura.

Type II are all extradural, and are subclassified as: IIa do not extend beyond the neural foramen, IIb = inside spinal canal + paravertebral, IIc = foraminal + paravertebral.

Type IIIa are intradural and extradural foraminal, IIIb are intradural and extradural paravertebral.

Type IV are extradural and intravertebral. Type V are extradural and extralaminar with laminar invasion. Type VI show multidirectional bone erosion.

Cranio-caudal spread: IF & TF designate the number of intervertebral foramina involved, respectively (e.g. IF stage 2 = 2 foramens).

Schwannomas involving C1 & C2: May involve vertebral arteries and require additional caution.

**Clinical**

Patients typically present with local pain.

Neurologic deficits develop late. Tumors may cause radiculopathy (from nerve root compression), myelopathy (from spinal cord compression), radiculomyelopathy (from compression of both), or cauda equina syndrome (for tumors below conus medullaris).

**Pathology**

Composed of Antoni A (compact, interwoven bundles of long, spindly Schwann cells) and Antoni B tissue (sparse areas of Schwann cells in a loose eosinophilic matrix).

**Surgical approaches**

See reference.19

Posterior approaches: Types I, IIa, IIIa, some upper cervical IIIb and some VI are generally amenable to a posterior approach. IIa & IIb usually require total facetectomy for complete removal.18

Reconstruction with instrumentation may be needed if substantial posterior disruption occurs.

Anterior and combined anterior/posterior approaches: Asazuma et al.19 recommend a combined approach for Type IIb, IIc and IIIb lesions where the extraforaminal extension is large (viz. beyond the vertebral arteries). Reconstruction with instrumentation was required for some tumors (≈ 10% of all patients treated) which were type IV (2 patients), IIIb (1 pt) and VI (1 pt).

Nerve sacrifice

It is usually possible to preserve some fascicles of the nerve root, although sometimes section of the entire nerve root is required. New deficits may not occur since involved fascicles are often nonfunctional, and adjacent roots may compensate. The risk for motor deficit is higher for schwannomas than for neurofibromas, for cervical vs. lumbar tumors, and for cervical tumors with extradural extension.

**Outcome**

Recurrence is rare following gross total excision, except in the setting of NF2.
51.5 Intramedullary spinal cord tumors

51.5.1 Types of intramedullary spinal cord tumors

The following list excludes metastases (see below) and lipomas (of questionable neoplastic origin, and most are actually extramedullary intradural, see below). Note: in pediatrics, astrocytoma and ependymoma constitute 90% of intramedullary spinal cord tumors (IMSCT).
1. astrocytoma (nonmalignant): 30% (the most common IMSCT outside the filum terminale) tend to be eccentric
2. ependymoma: 30% tend to be more central, more uniform dense enhancement
3. miscellaneous: 30% including:
   a) malignant glioblastoma
   b) dermoid
   c) epidermoid (including iatrogenic from LP without stylet)\textsuperscript{21,22}
   d) teratoma
   e) hemangioblastoma (see below)
   f) hemangioma
   g) neuroma (very rarely intramedullary)
   h) extremely rare tumors
      • primary lymphoma (only 6 case reports, all non-Hodgkin type\textsuperscript{23})
      • oligodendroglioma, only 38 cases in world literature\textsuperscript{24}
      • cholesteatoma
      • paraganglioma
      • primary spinal embryonal tumor (“spinal PNET”) (p. 663)\textsuperscript{25}
      • pilomyxoid astrocytoma (p. 632)
      • metastasis

51.5.2 Differential diagnosis
Also see DDx for Myelopathy (p. 1407).
1. neoplasm (tumor): (see above for list). Enhancement: 91% enhance\textsuperscript{26}; of the 9% that do not, most were astrocytomas, 1 was a subependymoma; enhancement did not correlate with grade
2. nonneoplastic lesions
   a) vascular lesions (e.g. AVM): serpiginous linear flow-void. Spinal angiography may be useful\textsuperscript{2}
   b) demyelinating disease (e.g. multiple sclerosis):
      • usually does not extend > 2 vertebral levels
      • cord lesions in MS are most common in the cervical region
   c) inflammatory myelitis
   d) paraneoplastic myelopathy
   e) diseases causing pain over certain body segments (e.g. cholecystitis, pyelonephritis, intestinal pathology). To differentiate from these, look for dermatomal distribution, increase with Valsalva maneuver, and accompanying sensory and/or motor changes in LEs which suggest cord/radicular lesion. Radiographic studies are frequently required to differentiate
   f) diseases of vertebral structures, e.g. Paget’s disease, giant cell tumors of bone (p. 797), etc.

51.5.3 Specific types of intramedullary spinal cord tumors
Ependymoma
General information

**Key concepts**

- the most common glioma of lower cord, conus and filum (most ependymomas in conus and filum are myxopapillary ependymomas). More common in adults
- evaluation: includes imaging the entire neuraxis (usually with enhanced MRE: cervical, thoracic, lumbar & brain) because of potential for seeding through CSF
- associated cysts are common
- treatment: surgical excision (most are encapsulated)

The most common glioma of the lower spinal cord, conus and filum (below). Slow-growing. Benign. Slight male predominance; slight peak in 3rd to 6th decade. Over 50% in filum, next most common location is cervical. Histologically: papillary, cellular, epithelial, or mixed (in filum, myxopapillary ependymoma is most common, see below). Cystic degeneration in 46% May expand spinal canal in filum.\textsuperscript{27} Usually encapsulated and minimally vascular (papillary; may be highly vascular; may cause SAH). Symptoms present > 1 yr prior to diagnosis in 82% of cases.\textsuperscript{28}
Myxopapillary ependymoma
Ependymomas of the conus medullaris and the filum terminale are usually of the myxopapillary subtype. WHO grade I. Usually solitary. Histology: papillary, with microcystic vacuoles, mucosubstance; connective tissue. No anaplasia, but CSF dissemination occurs rarely (can seed intracranially following removal of spinal tumor20). Denovo intracranial lesions also occur rarely. Rare reports of systemic mets.1 Outside the CNS, may occur in sacrococcygeal subcutaneous tissues from heterotopic rests of ependymal cells.30
Surgical removal of filum tumors consists of coagulating and dividing the filum terminale just above and below the lesion — see Distinguishing features of the filum terminale intraoperatively (p.273) - and excising it in total. The filum is first cut above the lesion to prevent retraction upwards.

Astrocytoma
Uncommon in first year. Peak: 3rd – 5th decade. Male:female = 1.5:1. The ratio of low-grade:high-grade = 3:1 in all ages.27 Occurs at all levels, thoracic most common, then cervical. 38% are cystic; cyst fluid usually has high protein.

Dermoid and epidermoid
Epidermoids are rare before late childhood. Slight female predominance. Cervical and upper thoracic rare; conus common. Usually ID-EM, but conus/cauda equina may have IM component (completely IM lesions rare).

Lipoma
May occur in conjunction with spinal dysraphism, see Lipomyeloschisis (p.269). The following considers lipomas that occur in the absence of spinal dysraphism.
Peak occurrence: 2nd, 3rd and 5th decade. Technically hamartomas. No sex predominance. Usually ID-EM (a sub-type is truly IM and essentially replaces the cord31), cervicothoracic region is the most common location. NB: unlike other IMSCT’s, most common symptom is ascending mono- or para-paresis (c.f. pain). Sphincter disturbance is common with low lesions. Local subcutaneous masses or dimples are frequent. Malis recommends early subtotal removal at about 1 year age in asymptomatic patient.31 Superficial extrasacral removal is inadequate, as patients then develop dense scarring intraspinally leading to fairly rapid severe neurological damage with poor salvage-ability even after the definitive procedure.

Hemangioblastoma
Usually non-infiltrating, well demarcated, may have cystic caps. 33% of patients with spinal hemangioblastoma will have von Hippel-Lindau disease (p.703). Cannot incise nor core because of vascularity. Requires microsurgical approach similar to AVM, possibly with intraoperative hypotension.

Metastases
Most spinal mets are extradural, Intramedullary metastases are rare,32 accounting for 3.4% of symptomatic metastatic spinal cord lesions.33 Primaries include: small-cell lung Ca,34 breast Ca, malignant melanoma, lymphoma and colon Ca.33,35 Ca rarely presents first as an intramedullary spinal met.

51.5.4 Presentation
1. pain: the most common complaint. Almost always present in filum tumors (exception: lipomas).21 Possible pain patterns:
a) radicular: increases with Valsalva maneuver and spine movement. Suspect SCT if dermatome is unusual for disk herniation
b) local: stiff neck or back, Valsalva maneuver increases pain. Pain during recumbency (“nocturnal pain”) is classic for SCT
c) medullary (as in syrinx): oppressive, burning, dysesthetic, non-radicular, often bilateral, unaffected by Valsalva maneuver
2. motor disturbances
a) weakness is 2nd or 3rd most common complaint. Usually follows sensory symptoms temporarily
b) children present most frequently with gait disturbances
c) syringomyelic syndrome: suggests IMSCT. Findings: UE segmental weakness, decreased DTR, dissociative anesthesia (see below)

d) long-tract involvement → clumsiness and ataxia (distinct from weakness)

e) atrophy, muscle twitches, fasciculations

3. non-painful sensory disturbances

   a) dissociated sensory loss: decreased pain and temperature, preserved light touch, as in Brown-Séquard syndrome (p. 947). There is disagreement whether this is common or uncommon in IMSCT. ± non-radicular dysesthesias (early), with upward extension

   b) paresthesias: either radicular or “medullary” distribution

4. sphincter disturbances

   a) usually urogenital (anal less common) → difficulty evacuating, retention, incontinence, and impotence. Early in conus/cauda equina lesions, especially lipomas (pain not prominent)

   b) sphincter dysfunction common in age <1 yr due to frequency of lumbosacral lesions (dermoids, epidermoids, etc.)

5. miscellaneous symptoms:

   a) scoliosis or torticollis

   b) SAH

   c) visible mass over spine

**Time course of symptoms**

Onset usually insidious, but abruptness occurs (benign lesions in children occasionally progress in hours). The onset is often erroneously attributed to coincidental injury. Temporal progression has been divided into 4 stages:

1. pain only (neuralgic)
2. Brown-Séquard syndrome
3. incomplete transectional dysfunction
4. complete transectional dysfunction

Note: 78% (of 23) ependymomas, 74% (of 42) gliomas, all 7 dermoids, and 50% (of 8) lipomas reached the latter 2 stages before diagnosis (not affected by location in cross-sectional nor longitudinal dimension of SC (excludes conus lesions – more frequently diagnosed in 1st stage) (a pre-CT study).

**51.5.5 Diagnosis**

It is usually difficult to distinguish IMSCT, ID-EM and ED on clinical grounds. Schwannomas often start with radicular symptoms that later progress to cord involvement. Most IMSCTs are located posteriorly in cord which may cause sensory findings to predominate early.

**Diagnostic studies**

MRI: mainstay of diagnosis. Ependymomas enhance intensely and are often associated with hemorrhage and cysts. Cord edema may mimic a cyst.

Plain radiographs: vertebral body destruction, enlarged intervertebral foramina, or increases in interpedicular distances suggests ED SCT.

Lumbar puncture: Elevated protein is the most common abnormality seen in ≥ 95% The reported range with primary IMSCT's is 50–2,240 mg%. Glucose is normal except with meningeal tumor. SCT can cause complete block, indicated by:

- Froin’s syndrome: clotting (due to fibrinogen) and xanthochromia of CSF
- Queckenstedt's test (failure of jugular vein compression to increase CSF pressure, which it normally does in the absence of block)
- barrier to flow of myographic contrast media

Myelography (p. 818): classically shows fusiform cord widening (may be normal early). Distinct from ED tumors which produce hourglass deformity (with incomplete block) or paintbrush effect (with complete block), or ID-EM tumors which produce a capping effect with a sharp cutoff (meniscus sign).

CT: some IMSCTs enhance with IV contrast. Myelo-CT distinguishes IMSCT from ID-EM (poor in differentiating IMSCT subtypes).

Spinal angiography: rarely indicated, except in hemangioblastoma (may be suspected on myelography or MRI by linear serpiginous structures). MRI often obviates this test.
51.5.6 Management

General information

Asymptomatic lesions may be followed since there is significant risk of neurologic deficit with surgery. For symptomatic lesions, surgery should be performed as soon as possible (generally not as an emergency) after diagnosis since surgical results correlate with the preoperative neurologic condition, and it makes no sense to follow the patient as they develop progressive neurologic deficit (some of which may be irreversible).

Astrocytomas: For low grade lesions, if a plane can be developed between the tumor and spinal cord (when it can, it usually consists of a thin gliotic layer traversed by small blood vessels and adhesions), an attempt at total excision is an option. For high grade astrocytomas or for low-grade astrocytomas without a plane of separation, biopsy alone or biopsy plus limited excision is recommended.

For high-grade lesions, post-op RTX (± chemotherapy) is recommended. RTX is not supported following radical resection of low grade gliomas.

Ependymomas: An attempt at gross total removal should be attempted. XRT is not recommended following gross total removal.

51.5.7 Technical surgical considerations

1. position: usually prone, well padded and also securely taped to avoid undesirable movement if MEP monitoring is to be used. Other options include: lateral oblique, sitting
2. if a cystic component is suspected, partial aspiration with a 25 Ga needle once the spinal cord is exposed will decrease the pressure (avoid total aspiration which makes it more difficult to locate the tumor). If the cyst forms a “cap” at either end of the tumor, the dura does not need to be opened over the cyst as drainage can be accomplished with removal of tumor
3. adjunctive options include:
   a) intraoperative spinal cord monitoring (SSEP, and motor evoked potentials (MEPs)): SEPs almost always degrade with the initial myelotomy and do not correlate well with motor outcome (which is critical) (e.g. it is not unusual for SEPs to be lost during the initial myelotomy without correlation with outcome) and postoperative motor deficit may occur in spite of unaltered intraoperative SEPs and conversely SEPs may be lost without motor deficit. However, proof of improved outcomes with MEP monitoring is also lacking.
   b) intraoperative ultrasound: also controversial, favored by some experts. Astrocytomas are usually iso-echoic with spinal cord, whereas ependymomas are usually hyperechoic
4. a myelotomy is performed either in the midline or just to one side of the dorsal midline to avoid the posteromedian vein. Alternatively, if the tumor is known to be very superficial off the midline (which may be confirmed by ultrasound), entry may be made there. Tumors may cause distortion and displacement of the midline – look for dorsal root entry zones on both sides to identify the midline as the midpoint between root entry zones
5. 6–0 silk sutures are placed through the pial edge to gently retract the spinal cord open. Standard sized (i.e. non-micro) bayonet forceps can be used to gently spread tissues
6. copious irrigation is used whenever bipolar cautery is employed on the tumor/spinal cord, to minimize transference of heat to the spinal cord. Monopolar cautery should not be used.
7. either laser or ultrasonic aspiration (USA) are used to debulk tumor from within until the glial-tumor interface is reached. Charring from laser may make it more difficult to recognize the glial/tumor interface than USA, and the laser tends to be slower when debulking larger tumors
8. watertight dural closure is critical

51.5.8 Prognosis

No well designed studies give long term functional results with microsurgery, laser and radiotherapy. Better results occur with lesser initial deficits. Recurrence depends on totality of removal, and on growth pattern of the specific tumor.

Table 51.2 Key concepts in surgical removal of IMSC T

- in almost all cases, IMSC T's should be debulked from within using ultrasonic aspirator or laser (to avoid manipulation of neural tissue), and no attempt should be made initially to develop a plane between tumor and spinal cord (even for ependymomas, which of the 3 most common IMSC T's is the only one that actually has such a plane)
- if MEPs are monitored: it is suggested that tumor removal should be discontinued if the amplitudes drop to ≤50% of baseline
Ependymoma: total extirpation improves functional outcome, and myxopapillary ependymomas fare better than the “classic” type. Best functional outcome occurs with modest initial deficits, symptoms <2 years duration, and total removal. Survival is independent of extent of excision.

Astrocytomas: radical removal rarely possible (cleavage plane unusual even with microscope). Long term functional results poorer than ependymomas. There is 50% recurrence rate in 4–5 yrs.

51.6 Primary bone tumors of the spine

51.6.1 General information

Types of tumors.
1. metastatic: the most common malignancy of spine
   a) common osteolytic metastatic tumors (p.814) include:
      • lung
      • breast
      • prostate
      • lymphoma: most cases represent spread of systemic disease (secondary lymphoma), however some may be primary (p.783)
      • plasmacytoma (p.714)
      • multiple myeloma (p.714)
      • Langerhans cell histiocytosis: see differentiating features (p.784)
   b) metastases that may be osteoblastic:
      • in men: prostate Ca is the most common
      • in women: breast Ca is the most common
   c) Ewing’s sarcoma (p.784)
   d) chloroma: focal infiltration of leukemic cells
2. primary spinal tumors (very rare)
   a) benign
      • vertebral hemangioma (p.784)
      • osteoid osteoma (p.792)
      • osteoblastoma (p.792)
      • aneurysmal bone cyst (p.784): cavity of highly vascular honeycomb surrounded by a thin cortical shell which may expand
      • osteochondroma (chondroma) (p.784)
      • giant cell tumors of bone (p.797): AKA osteoclastoma. Almost always benign with pseudo-malignant behavior
   b) malignant
      • chondrosarcoma (p.784)
      • chordomas (p.778)
      • osteogenic sarcoma: rare in spine

51.6.2 Osteoid osteoma and osteoblastoma

General information

Key concepts

- both are benign bone tumors
- histologically identical, differentiation depends on size (<1 cm = osteoid osteoma, >1 cm = osteoblastoma)
- can occur in the spine and may cause neurologic symptoms (esp. osteoblastoma)
- high cure rate with complete excision

Two types of benign osteoblastic lesions of bone: osteoid osteoma (OO) and benign osteoblastoma (BOB), see Table 51.3. They are indistinguishable histologically, and must be differentiated based on size and behavior.

Characteristically cause night pain and pain relieved by aspirin (see Clinical below).

Osteoblastoma is a rare, benign, locally recurrent tumor with a predilection for spine, that may rarely undergo sarcomatous change (to osteosarcoma, only a handful of known cases of this). More vascular than OO.
Differential diagnosis

Lesions with similar symptoms and increased uptake on radionuclide bone scan:
1. benign osteoblastoma
2. osteoid osteoma: more pronounced sclerosis of adjacent bone than BOB
3. osteogenic sarcoma: rare in spine
4. aneurysmal bone cyst (p.784): typically trabeculae in central, lucent region
5. unilateral pedicle/laminar necrosis

Clinical

See Table 51.4 for signs and symptoms. Tenderness confined to vicinity of the lesion occurs in ≈ 60% 28% of patients with BOB presented with myelopathy. OO presented with neurologic deficit in only 22%

Evaluation

Bone scans are a very sensitive means for detecting these lesions. Once localized, CT or MRI may better define the lesion in that region.

Caution regarding needle biopsy: if the lesion turns out to be osteosarcoma, the contaminated needle tract can result in worse prognosis.

Osteoid osteoma

Radiolucent area with or without surrounding density, often isolated to pedicle or facet. May not show up on tomograms.

---

Osteoblastoma
Most are expansive, destructive lesions, with 17% having moderate sclerosis. 31% have areas of ↑ density, 20% surrounded by calcified shell. Often a contralateral spondylolysis.48

Treatment
In order to obtain a cure, these lesions must be completely excised. The role of radiation therapy is poorly defined in these lesions, but is probably ineffective.48

Osteoid osteoma
Cortical bone may be hardened and thickened, with granulomatous mass in underlying cavity.

Osteoblastoma
Hemorrhagic, friable, red to purple mass well circumscribed from adjacent bone. Complete excision → complete pain relief in 93% Curettage only → pain relief, with more likely recurrence. Recurrence rate with total excision is ≈ 10%.

51.6.3 Osteosarcoma
The most common primary bone cancer. More common in children, usually occurring near the ends of long bones, but also in the mandible, pelvis, and rarely in the spine.50 Spinal osteosarcoma usually occurs in the lumbosacral region in males in their 40s, sometimes arising from areas of osteoblastoma or Paget’s disease. If a percutaneous biopsy reveals osteosarcoma, the contaminated needle tract can increase the difficulty of subsequent surgery. Poor prognosis, median survival = 10 months.50

**Table 51.4 Signs and symptoms in 82 patients**

Key concepts
- the most common primary spine tumor. Benign
- rarely symptomatic (<1.2%), symptoms more commonly from compression fracture, disc herniation, and rarely neural compression from bone expansion
MRI: small lesions are hyperintense on T1WI and T2WI. Larger ones may be hypointense. CT or X-ray: striations (corduroy pattern) or “honeycomb” appearance. Bone scan: usually do not have increased uptake.

Treatment: incidental lesions require no routine follow-up. Biopsy when mets are a strong consideration. Treatment options (when indicated): XRT, embolization, vertebroplasty (better than kyphoplasty), surgery.

Vertebral hemangiomas (VH), AKA spinal hemangioma, cavernous hemangioma, or hemangiomatous angioma. Benign lesions of the spine. The most common primary tumor of the spine (10–12% of primary spinal bone tumors). Estimated incidence: 9–12%51,52 70% are solitary, 30% are multiple (up to 5 levels may be involved, often noncontiguous). Lumbar and lower thoracic spine are the most common locations, cervical and sacral lesions are rare. Lesions involve only the vertebral bodies in \( \approx 25\% \) posterior spinal arch in \( \approx 25\% \) and both areas in \( \approx 50\% \). Occasional cases of purely extradural lesions have been described.53 Intramedullary lesions are even less common.54 Typically found in post-pubertal females.

Malignant degeneration does not occur. Mature thin-walled blood vessels of varying sizes replace normal marrow, producing hypertrophic sclerotic bony trabeculations oriented in a rostral-caudal direction in one of two forms: cavernous (venous) or capillary (difference in subtype carries no prognostic significance).

Presentation
1. incidental: most VH are asymptomatic, these require no follow-up (see below)
2. symptomatic: only 0.9–1.2% are symptomatic. There may be a hormonal influence (unproven) that may cause symptoms to increase with pregnancy (could also be due to increased blood volume and/or venous pressure)55 or to vary with the menstrual cycle and may explain why symptoms rarely occur before puberty
   a) pain: occasionally VH may present with pain localized to the level of involvement with no radiculopathy. However, pain is more often due to other pathology (compression fracture, herniated disc, spinal stenosis…) rather than the VH itself
   b) progressive neurologic deficit: this occurs rarely, and usually takes the form of thoracic myelopathy. Deficit may be caused by the following mechanisms
      • subperiosteal (epidural) growth of tumor into the spinal canal
      • expansion of the bone (cortical “blistering”) with widening of the pedicles and lamina producing a “bony” spinal stenosis
      • compression by vessels feeding or draining the lesion
      • compression fracture of the involved vertebra (very rare)56
      • spontaneous hemorrhage producing spinal epidural hematoma (also very rare)
      • spinal cord ischemia due to “steal”

Evaluation
Plain x-rays: classically show coarse vertically oriented striations (corduroy pattern) or a “honeycomb” appearance. At least \( \approx \) one-third of the VB must be involved to produce these findings on plain x-ray (see Fig. 51.2 for demonstration of this finding on sagittal CT).

Bone scan: VH are usually not hot (unless a compression fracture has occurred), which may help distinguish VH from metastatic disease (which usually light up).

CT: diagnostic procedure of choice. “Polka-dot sign”58: multiple high density dots within the bone represents cross-sections through thickened trabeculae (Fig. 51.3).

MRI: small hemangiomas are focal, round, and hyperintense on T1WI and T2WI. More extensive lesions can be hypointense. MRI may help distinguish lesions that tend not to evolve (mottled increased signal on T1WI and T2WI, possibly due to adipose tissue) from those that tend to be symptomatic (isointense on T1WI, hyperintense on T2WI).

Spinal angiography: also may help distinguish nonevolutive (normal or slight increased vascularity compared to adjacent bone) from symptomatic (moderate to marked hypervascularity) lesions.

Therapeutic: if the feeding artery does not also supply the anterior spinal artery, it may be embolized preoperatively or sacrificed at surgery.
Treatment

See reference.51

Management guidelines:
1. asymptomatic VH require no routine follow-up or evaluation unless pain or neurologic deficit develop, which are rare occurrences in incidentally discovered VH
2. biopsy: may be indicated in cases where diagnosis is uncertain (e.g. when metastases are a strong consideration). In spite of highly vascular nature, there have been no reported bleeding complications with CT guided biopsy
3. those presenting with pain or neurologic deficit
   a) radiation therapy: may be used alone for painful lesions, preoperatively as a surgical adjunct, or post-op following incomplete removal. VH are radiosensitive and undergo sclerotic obliteration. Total dosage should be ≤40 Gy to reduce risk of radiation myelopathy. Improvement in pain may take months to years, and no radiographic evidence of response may occur
   b) embolization: provides more rapid relief of pain than RTX, can also be used pre-op as surgical adjunct. Risks spinal cord infarction if major radicular artery – e.g. artery of Adamkiewicz (p.87) – is embolized
   c) vertebroplasty (p.1011): may be better than kyphoplasty for VH because kyphoplasty destroys the trabecular bone
   d) surgery: for painful lesions that fail to respond to above measures, or for lesions with progressive neurologic deficit (see below)
Surgical treatment

For surgical indications, see above. Recommendations for surgical management are shown in Table 51.5.

Major risks of surgery: blood loss, destabilization of the spine, neurologic deficit (during surgery, or postoperatively usually from epidural hematoma). Recurrence rate is 20–30% after subtotal resection, usually within 2 yrs. Patients with subtotal resection should have RTX which lowers recurrence rate to ≈7%.

51.6.5 Giant cell tumors of bone

AKA osteoclastoma (cells arise from osteoclasts). In the same general category as aneurysmal bone cysts. Typically arise in adolescence. Most common in knees and wrists. Those that come to the attention of the neurosurgeon generally arise in the skull (especially the skull base, and in particular the sphenoid bone), or in the vertebral column (≈4% occur in sacrum).

Pathology

Lytic with bony collapse. Almost always benign with pseudomalignant behavior (recurrence is common, and pulmonary mets can occur).

Evaluation

Soft tissues are best evaluated with MRI. Spine CT is critical to assess degree of bony destruction and for surgical planning purposes.

Work-up includes chest CT because of possibility of pulmonary mets.

Treatment

Intratumoral curettage, possibly aided by pre-op embolization. Recurrence rate with this treatment (even if resection is subtotal) is only ≈20% Role of RTX is controversial because of the possibility of malignant degeneration (therefore use RTX only for non-resectable recurrence). Use of osteoclast inhibiting drugs – bisphosphonates, e.g. pamidronate (p.1122) –, has met with some success following subtotal resection.

For gross residual disease after resection, re-resection is a consideration.

Cryosurgery with liquid nitrogen has been employed in long bones. Its use is limited in neurosurgical cases because of risk of injury to adjacent neural structures (brain, spinal cord) and cryotherapy induced fractures, although it has been described for use in the sacrum.

Close follow-up is required due to propensity for recurrence. MRI or CT initially q 3 months is suggested.
References

52 Cerebral Metastases

52.1 General information

Key concepts

- Brain metastases are the most common brain tumor seen clinically.
- At the time of onset of neurologic symptoms, 70% will be multiple on MRI.
- With solitary brain lesions in a patient with a history of cancer, biopsy should almost always be done since 11% of these lesions will not be mets.
- Although median survival with maximal treatment is only 8 months (similar to GBM), long-term survivors do occur.

52.2 Metastases to the brain

Cerebral metastases are the most common brain tumor seen clinically, comprising slightly more than half of brain tumors (if one considers only imaging studies, they comprise ≈ 30%). In the U.S., the annual incidence of new cases of metastases is up to 170,000, compared to 17,000 for primary brain tumors. In patients with a history of cancer (Ca), develop cerebral mets. In patients with no Ca history, a cerebral met was the presenting symptom in 15% of these, 43-60% will have an abnormal chest x-ray (CXR) showing either a bronchogenic primary or other mets to lung. In 9% of cases, a cerebral met is the only detectable site of spread. Cerebral mets occur in only 6% of pediatric cancers.

The route of metastatic spread to the brain is usually hematogenous, although local extension can also occur.

Solitary mets

- CT (p.806): at the time of neurologic diagnosis, 50% are solitary on CT.
- MRI: if the same patients have an MRI, <30% will be solitary.
- On autopsy: mets are solitary in one–third of patients with brain mets, and 1–3% of solitary mets occur in the brain stem.

Increasing incidence of cerebral mets: May be due to a number of factors:
1. Increasing length of survival of cancer patients as a result of improvements in treatment of systemic cancer.
2. Enhanced ability to diagnose CNS tumors due to availability of CT and/or MRI.
3. Many chemotherapeutic agents used systemically do not cross the blood-brain barrier (BBB) well, providing a “haven” for tumor growth there.
4. Some chemotherapeutic agents may transiently weaken the BBB and allow CNS seeding with tumor.

52.3 Metastases of primary CNS tumors

52.3.1 Spread via CSF pathways

CNS tumors that more commonly spread via CSF pathways include the following (when these tumors spread to the spinal cord, they are often called “drop mets”):
1. High grade gliomas (p.619) (10–25%)
2. Primitive neuroectodermal tumors (PNET), especially medulloblastoma (p.664)
3. Ependymoma (p.642) (11%)
4. Choroid plexus tumors (p.648)
5. Pineal region tumors
   a) Germ cell tumors (p.659)
   b) Pineocytoma and pineoblastoma (p.659)
6. Rarely:
   a) Oligodendrogliomas (p.638) (≈ 1%)
   b) Hemangioblastomas (p.701)
   c) Primary CNS melanoma (p.701)
52.3.2 Extraneural spread

Although most CNS tumors do not spread systemically, there is some potential for extraneural spread with the following tumors:

1. medulloblastoma (cerebellar-PNET): the most common primary responsible for extraneural spread. May spread to lung, bone marrow, lymph nodes, abdomen
2. meningioma: rarely goes to heart or lungs
3. malignant astrocytomas rarely metastasize systemically
4. ependymomas
5. pineoblastomas
6. meningeal sarcomas
7. choroid plexus tumors
8. tumors that spread through CSF pathways (see above) may spread via a CSF shunt (e.g. to peritoneum with VP shunt or hematogenously with a VA shunt), however, this risk is probably quite small

52.4 Location of cerebral mets

Intracranial metastases may be either parenchymal (≈ 75%) or may involve the leptomeninges in a carcinomatous meningitis (p.811). 80% of solitary metastases are located in the cerebral hemispheres.

The highest incidence of parenchymal mets is posterior to the Sylvian fissure near the junction of temporal, parietal, and occipital lobes (presumably due to embolic spread to terminal MCA branches). Many tend to arise at the gray/white-matter interface.

The cerebellum is a common site of intracranial mets, and is the location in 16% of cases of solitary brain mets. It is the most common p-fossa tumor in adults, thus “a solitary lesion in the posterior fossa of an adult is considered a metastasis until proven otherwise.” Spread to the posterior fossa may be via the spinal epidural venous plexus (Batson’s plexus) and the vertebral veins.

52.5 Primary cancers in patients with cerebral metastases

52.5.1 General information

Accurately ascertaining the source of cerebral metastases in the U.S. is difficult because of lack of detailed coding. In over 2,700 adults with a primary cancer undergoing autopsy at Sloan-Kettering, the sources of cerebral metastases are shown in Table 52.1. Sources of brain metastases in pediatrics is shown in Table 52.2.

In adults, lung and breast Ca together account for >50% of cerebral mets. In patients with a metastatic brain tumor as the initial presentation (i.e. undiagnosed primary) compared to patients with a known primary, there is about the same number of brain lesions, but there was an increased frequency of extracranial mets. In up to 26% of cases, the primary tumor was never identified.

The autopsy incidence of cerebral mets for various types of primary cancers at Sloan-Kettering Cancer Center is shown in Table 52.3.

a A rare tumor that metastasizes frequently to brain (in 20–25% of cases)

b 16% in older series
52.5.2 Lung cancer

The lungs are the most common source of cerebral mets, and these are usually multiple. The lung primary may be so small as to render it occult.

Necropsy demonstrates cerebral mets in up to 50% of patients with small-cell lung Ca (SCLC) and non-squamous, non-small-cell lung Ca.\(^{15}\)

**Small-cell lung cancer (SCLC)**

AKA “oat cell” Ca. A neuroendocrine tumor. 95% arise in proximal airways, usually in mainstem or lobar bronchi. Typically younger (27–66 years) than other lung Ca. Strongly associated with cigarette smoking. Median survival: 6–10 months. Considered a systemic disease. Staged in 1 of 2 categories:

1. limited: confined to an area of the chest that can be encompassed by a single radiation port
2. extensive: metastasis outside the thorax or intrathoracic disease that cannot be contained in a single radiation port
Although SCLC comprises only \( \approx 20\% \) of primary lung cancers, it is more likely to produce cerebral mets than other bronchogenic cell types (brain mets are found in \( 80\% \) of patients who survive 2 yrs after diagnosis of SCLC).\(^9\)

**Treatment**

Very radiosensitive.

No identified brain mets: prophylactic cranial irradiation (PCI) with WBXRT reduces the incidence of symptomatic brain mets and increases survival (disease-free & overall).\(^{16,17}\) Typically 25 Gy in 10 fractions.

Brain mets: surgical resection considered for immediately life-threatening large lesions, XRT is used otherwise. Multiple SCLC brain lesions: XRT (initial treatment 30 Gy in 10 fractions) + chemotherapy.

Treatment of primary: usually not resected. Treated with chemotherapy ± XRT.

Recurrent brain mets after failure of initial treatment: 20 Gy in 10 fractions.

**Non-small-cell lung cancer (NSCLC)**

Includes: adenocarcinoma (the most common NSCLC), large cell, squamous cell, bronchoalveolar. Retrospective analysis of patients with NSCLC completely resected from lung found a 6.8% first recurrence rate in the brain.\(^{15}\) Staged with typical TNM system. Prognosis better than SCLC.

Treatment of lung primary:

1. grades I, II, IIIA: resection
2. higher grades (e.g. distal mets, excluding single brain met): XRT + chemotherapy

**Staging studies for known lung primary**

1. PET scan: can detect small malignancies. Useful in NSCLC to determine eligibility of resection of primary. Not useful in initial evaluation of SCLC
2. chest CT: usually includes adrenals and liver (thus abdomen and pelvis CT not necessary)
3. bone scan
4. brain: CT or MRI

When metastatic lung cancer is the suspected source of a newly diagnosed brain lesion, the lung lesion should be biopsied (if technically feasible) to rule out SCLC before obtaining tissue from the cerebral mass.

### 52.5.3 Melanoma

**General information**

Melanoma: the 5th most common cancer in men, 7th in women. Incidence is increasing. Most common sites of origin of melanoma metastases: skin, retina, brain – primary CNS melanoma (p. 701) –, nail bed. The primary site cannot be identified in up to \( \approx 14\% \) of cases.\(^{18}\) Extremely difficult to locate primary sites: intraocular, GI mucosa.

Brain mets are found in 10–70% of patients with metastatic melanoma in clinical studies, and in 70–90% on autopsy of patients who died from melanoma. Patients with melanoma who have neurosurgical lesions typically presented 14 months after primary lesion was identified. Once cerebral mets of melanoma are detected, median survival is \( \leq 6 \) months\(^{19,20,21}\) and the mets contributed to the death in 94% of cases.\(^{22}\) A small group with survival >3 yrs had a single surgically treated met in the absence of other visceral lesions.

**Evaluation**

Metastatic melanoma to the brain classically causes pia/arachnoid involvement on imaging. Hemorrhagic involvement is common.

CT: lesions may be slightly hyperdense to brain on unenhanced CT due to melanin. Enhancement is less constant than for other mets (e.g. bronchogenic Ca).

MRI: decreased signal on T2WI surrounded by intense halo of edema. Enhancing T1WI lesions in a patient with melanoma is highly suggestive of melanoma metastases.

Systemic work-up: systemic disease determines ultimate survival after treatment of melanoma mets to the brain in 70% of patients. Search for systemic mets should be done, including: CT of chest/abdomen/pelvis & bone scan. PET scan may be more sensitive for detecting metastatic spread...
than CT when there are clinical signs that the tumor has spread\(^23\); except for the brain, where brain MRI is more sensitive than CT or PET.

### Treatment

#### Surgical indications
1. Patients with 1-4 CNS metastases that can be completely resected when systemic disease is absent or slowly progressive: long-term survival is possible.
2. Patients with intracranial mets that cannot be completely removed or with uncontrolled systemic disease may be surgical candidates for the following:
   a) For symptomatic relief: e.g. lesion causing painful pressure
   b) Life-threatening lesion: e.g. large p-fossa lesion with 4th ventricle compression
   c) For hemorrhagic lesion causing symptoms by mass effect from the clot

Whole-brain radiation therapy (WBXRT). Melanoma is typically radioresistant. WBXRT provides 2–3 month survival benefit and may be considered for palliation in patients with multiple mets that preclude complete excision or SRS.

Stereotactic radiosurgery (SRS). Considered for ≤4 lesions all ≤3 cm diameter that are surgically inaccessible, with limited or quiescent systemic involvement. Relative contraindications: hemorrhagic lesions, lesions with significant mass effect surrounding edema.

### Chemotherapy

1. Alkylation agents:
   a) dacarbazine formerly the gold-standard treatment for melanoma. About equally as effective as its newer orally administered analog temozolomide (Temodar\(^\text{®}\)). Response rate: 10–20%
   b) Fotemustine appeared promising in phase II trials but only 6% responded in phase III (vs. 0% for dacarbazine)\(^24\)
2. Immunotherapy:
   a) ipilimumab: monoclonal antibody against cytotoxic T lymphocyte antigen-4 (CTLA-4) antigen. More effective in patients who do not require corticosteroids
   b) Interleukin-2 (IL-2): has shown minimal activity in brain mets, and trials have usually excluded patients with untreated or uncontrolled brain mets due to risk of cerebral edema and hemorrhage from capillary leak\(^25,26,27\)
3. BRAF inhibitors (BRAFI): inhibits BRAF kinase (a protein that participates in regulation of cell division & differentiation) – useful in tumors with BRAF oncogene mutation (as opposed to BRAF wildtype) which is common in melanoma
   a) dabrafenib: phase II trial (NCT01266967)\(^28\)
   b) vemurafenib: promising results in heavily treated patients. Phase II trial (NCT01378975)\(^29\)
4. Anti-PD-1 drug (monoclonal antibody to PD-1 programmed cell death receptor): pembrolizumab (Keytruda) approved for advanced or unresectable melanoma not responding to other drugs\(^30\)

Suggested algorithm for patients with metastatic melanoma to the brain (adapted,\(^31\) see Fig. 52.1). Patients with Karnofsky performance scale (KPS) score (p.1358) < 70 are likely to be poor surgical candidates.

Some key points:
1. Patients with rapidly progressive systemic disease: treat the systemic disease first, before the brain mets
2. Patients without systemic disease and 1-4 mets are candidates for surgery (based on the article by Bindal et al.\(^32\)) if they are all accessible and can all be removed. SRS is an alternative

### Outcome

1. In a patient with a single brain met (any type) and good Karnofsky performance score (> 70) and no evidence of extracranial disease, surgery + XRT had a median survival of 40 weeks vs. 15 weeks for XRT alone\(^33,34\)
2. For melanoma, retrospective studies have shown a benefit of treatment with either surgery or SRS only when all brain lesions are completely treated (selection bias possible in these studies)\(^14,35,36,37\)
3. Predictors of poor outcome in melanoma:
   a) >3 brain mets\(^30\)
   b) Development of brain mets after the diagnosis of extracranial disease\(^20\)
   c) Elevated lactate dehydrogenase > 2 × normal\(^21\)
d) presence of bone metastases\(^{21}\)
e) multiple brain mets and extensive visceral disease\(^{38}\)

52.5.4 Renal-cell carcinoma

AKA hypernephroma. Usually associated with spread to lungs, lymph nodes, liver, bone (high affinity for bone), adrenals, and contralateral kidney before invading the CNS (thus, this tumor rarely presents as isolated cerebral metastases). Look for hematuria, abdominal pain, and/or abdominal mass on palpation or CT. Response to XRT is only \(\approx 10\%\).

52.5.5 Esophageal cancer

Median survival is 4.2 months based on a review of 26 cases.\(^{39}\) Solitary brain met with good Karnofsky score and surgical treatment may indicate a better prognosis.

52.6 Clinical presentation

As with most brain tumors, signs and symptoms are usually slowly progressive compared to those from vascular events (ischemic or hemorrhagic infarcts) which tend to be sudden in onset and slowly resolve, or electrical events (seizures) which tend to be sudden in onset and rapidly resolve. There are no findings that would allow differentiation of a metastatic tumor from a primary neoplasm on clinical grounds.

Signs and symptoms include:

1. Those due to increased ICP from mass effect and/or blockage of CSF drainage (hydrocephalus):
   a) headache (H/A): the most common presenting symptom, occurs in \(\approx 50\%\)
b) nausea/vomiting

2. focal deficits:
   a) due to compression of brain parenchyma by mass and/or peritumoral edema (e.g. monopares-
      sis without sensory disturbance)
   b) due to compression of cranial nerve

3. seizures: occur only in ≈ 15% of cases

4. mental status changes: depression, lethargy, apathy, confusion

5. symptoms suggestive of a TIA (dubbed “tumor TIA”) or stroke, may be due to:
   a) occlusion of a vessel by tumor cells
   b) hemorrhage into the tumor, especially common with metastatic melanoma, choriocarcinoma,
      and renal-cell carcinoma

52.7 Evaluation

52.7.1 Imaging studies (CT or MRI)

Metastases usually appear as “non-complicated” masses (i.e. round, well circumscribed), often aris-
ing at the gray/white junction. Characteristically, profound white matter edema (“fingers of edema”) reach deep into brain from the tumor, usually more pronounced than that seen with primary (infiltrat-
ating) brain tumors. When multiple lesions are present (on CT or MRI of brains with multiple mets)
Chamber’s rule applies: “Whoever counts the most mets is right.” Mets usually enhance, and must be considered in the differential diagnosis of a ring-enhancing lesion.

MRI is more sensitive than CT, especially in the posterior-fossa (including brain stem). Detects multiple mets in up to ≈ 20% of patients who appear to have cases with single mets on CT.2

52.7.2 Lumbar puncture

Relatively contraindicated when there is a cerebral mass (may be indicated once mass lesion has been ruled out). May be most useful in diagnosing carcinomatous meningitis – see Carcinomatous meninitis (p.811) – and may be helpful in diagnosing lymphoma.

52.7.3 Metastatic work-up for patients with suspected brain metastases

When metastatic disease is suspected based on imaging or on surgical tissue, a search for a primary site and assessment for other lesions may be considered since it may provide alternative sites for tissue for histologic diagnosis, and it may guide treatment (e.g. widely disseminated metastases may preclude aggressive therapy). Metastatic work-up should include:

1. CT of the chest (more sensitive than CXR), abdomen and pelvis. Evaluates for primary and addi-
tional mets (to lung, adrenals, liver... CT has superseded CXR
2. radionuclide bone scan: for patients with bone pain or bone lesions or for tumors that tend to produce osseous metastases (especially: prostate, breast, kidney, thyroid & lung)
3. mammogram in women
4. prostate specific antigen (PSA) in men
5. PET scan: can detect small malignancies

Cancer of unknown primary site (CUP): If the metastatic work-up (see above) is negative, the path-
ology of a metastatic brain lesion as determined by biopsy may implicate specific primary sites.

Small-cell carcinoma metastatic to the brain is most likely from the lung. These tumors stain pos-
itive for neuroendocrine stains (p.600).

Adenocarcinoma: lung is the most common primary. Other sources: GI (mostly colon), breast. The primary site may remain occult even after extensive evaluation in up to 88%41 Immunostaining has been tried to identify the primary site but has not been found to be widely useful.

52.8 Management

52.8.1 General information

With optimal treatment, median survival of patients with cerebral mets is still only ≈ 26–32 weeks, therefore management is mostly palliative. Also see Outcome (p.810) for comparison of various treatments.
52.8.2 Confirming the diagnosis

NB: 11% of patients with abnormalities on brain CT or MRI with a history of cancer (within past 5 yrs) do not have cerebral metastases. Differential diagnoses include: primary brain tumor (glioblastoma, low grade astrocytoma), abscess, and nonspecific inflammatory reaction. If non-surgical treatment (e.g. chemotherapy or RTX) is being contemplated, the diagnosis should be confirmed by biopsy in almost all cases.

52.8.3 Management decisions

Prognostication

This is critical since many treatment decisions depend on overall prognosis.

RTOG RPA: Radiation Therapy Oncology Group recursive partitioning analysis classification\(^2\) (see Table 52.4; from 1200 patients with one or more brain metastases undergoing XRT). Conclusion: the specific tumor type, length of time since diagnosis, etc. are not as important prognostically as the Karnofsky Performance Scale (KPS) score (p.1358).

The applicability of RPA to melanoma mets to the brain is controversial (it has been both validated\(^43\) and disputed\(^37\)).

RPA Class 3 patients have been shown to be unlikely to benefit from any of numerous treatment modalities studied. Class 1 are more likely to benefit. Most patients are Class 2, and benefit is unclear.

Management algorithm

Table 52.5 shows a summary of management suggestions (details appear in following sections).

Also, surgical excision may be considered for patients with completely resectable brain mets who are candidates for chemotherapy with interleukin-2 (IL-2) for systemic disease (e.g. for renal-cell Ca or melanoma) since this drug in some case reports produces significant cerebral edema if there are cerebral mets as well.

52.8.4 Medical management

Initial treatment

1. anticonvulsants: e.g. Keppra® (levetiracetam): start with 500 mg PO or IV q 12 hours. Generally not needed for posterior fossa lesions
2. corticosteroids: many symptoms are due to peritumoral edema (which is primarily vasogenic), and respond to steroids within 24–48 hrs. This improvement is not permanent, and prolonged steroid administration may produce side effects; see Possible deleterious side effects of steroids (p.594).
   Typical dose for a patient with significant symptoms who is not already on steroids: dexamethasone (Decadron®) 10–20 mg IV, followed by 6 mg IV q 6 hrs for 2–3 days, after which it is converted to ≈ 4 mg PO QID. Once symptoms are controlled, this is tapered to ≈ 2–4 mg PO TID as long as symptoms do not worsen
3. H2 antagonists (e.g. ranitidine 150 mg PO q 12 hrs) or proton pump inhibitor (omeprazole)

\(^d\)i.e. not RPA class 1 or 3
Chemotherapy

See discussion of Limitations of chemotherapy in the brain (p. 595). If multiple lesions of known small-cell Ca are detected on cerebral imaging, treatment of choice is radiation plus chemotherapy.

52.8.5 Radiation therapy

General information

NB: not all brain lesions in cancer patients are mets (see above).

In patients not considered for surgery, steroids and radiation may be palliative. H/A are usually reduced, and in \( \approx 50\% \) of cases symptoms improve or completely resolve.\(^46\) This does not result in local control for the majority of these patients and they frequently succumb from progressive brain disease.

“Radiosensitivity” of various metastatic tumors to whole brain radiation therapy (WBXRT) are shown in Table 52.6. The usual dose is 30 Gy in 10 fractions given over 2 weeks. With this dose, 11% of 1-yr survivors and 50% of 2-yr survivors develop severe dementia.

Prophylactic cranial irradiation

Prophylactic cranial irradiation after resection of small-cell lung carcinoma (SCLC) reduces relapses in brain, but does not affect survival.\(^47\)

Post-op radiation therapy

WBXRT is usually recommended following craniotomy for metastatic disease,\(^48\) especially with SCLC where “micro-metastases” are presumed to be present throughout brain. (Note: some centers do not routinely administer post-op WBXRT (except for very radiosensitive tumors such as SCLC) but instead follow patients with serial imaging studies and administer XRT only when metastases are documented.)

Optimal dose is controversial. Early reports recommended 30–39 Gy over 2–2.5 weeks (3 Gy fractions) with or without surgery.\(^49\) This is acceptable in patients not expected to live enough to get long-term radiation effects. Recent recommendations are for smaller daily fractions of 1.8–2.0 Gy to reduce neurotoxicity.\(^50\) These low doses are also associated with a higher rate of recurrent brain metastases.\(^51\) Since 50 Gy are needed to achieve >90% control of micrometastases, some use 45–50 Gy WBXRT, plus a boost to the tumor bed to bring the total treatment up to 55 Gy, all with low fractions of 1.80–2.0 Gy.\(^52\)

</tbody>
</table>

\(^a\)adapted.\(^45\) Abbreviations: WBXRT = whole brain radiation therapy, SRS = stereotactic radiosurgery
Stereotactic radiosurgery

Inconsistent in its ability to reduce tumor size. Some retrospective studies show results comparable to surgery. Others do not. Does not obtain tissue for histological analysis, and generally cannot be used for lesions >3 cm. Also, see Stereotactic radiosurgery (p.811).

52.8.6 Surgical management

Solitary lesions

Indications favoring surgical excision of a solitary lesion:
1. primary disease quiescent
2. lesion accessible
3. lesion is symptomatic or life-threatening
4. primary tumor known to be relatively radioresistant (excision is rarely indicated for untreated brain metastases from SCLC because of its radiosensitivity)
5. for recurrent SCLC following XRT
6. diagnosis unknown: alternatively consider biopsy, e.g. stereotactic biopsy

Surgical resection in patients with progressive systemic disease and/or significant neurologic deficit is probably unjustified. Also, in newly diagnosed cancer patients, craniotomy may delay systemic treatment for weeks and the ramifications of this need to be considered.

Multiple lesions

Patients with multiple metastases generally have much worse survival than those with solitary lesions. Multiple metastases are usually treated with XRT without surgery. However, if total excision of all mets is feasible, then even multiple mets may be removed with survival similar to those having a single met removed (also see Table 52.5 for summary). If only incomplete excision is possible (i.e. cannot remove all mets, or portions of 1 or more must be left behind) then there is no improvement in survival with surgery, and XRT alone is recommended. The mortality of removing >1 met at a single sitting is not statistically significantly higher than removing a single met.

Situations where surgery may be indicated for multiple mets:
1. one particular and accessible lesion is clearly symptomatic and/or life threatening (life-threatening lesions include p-fossa and large temporal lobe lesions). This is palliative treatment to reduce the symptom/threat from that particular lesion
2. multiple lesions that can all be completely removed (see above)
3. no diagnosis (e.g. no identifiable primary): consider stereotactic biopsy

* SRS may be better than WBXRT for these
Stereotactic biopsy

Considered for:
1. lesions not appropriate for surgery. Includes cases with no definite diagnosis and:
   a) deep lesions
   b) multiple small lesions
2. patients not candidates for surgical resection
   a) poor medical condition
   b) poor neurologic condition
   c) active or widespread systemic disease
3. to ascertain a diagnosis
   a) when another diagnosis is possible: e.g. no other sites of metastases, long interval between primary cancer and detection of brain mets...
   b) especially if nonsurgical treatment modalities are planned (see above)

Intra-operative considerations for surgical removal

Most lesions present themselves on the surface of the brain or through the dura. For lesions not visible on the surface nor palpable immediately beneath the surface, intra-operative ultrasound or stereotactic techniques may be used to localize the lesion.

Metastases usually have a well defined border, thus a plane of separation from normal brain may be exploited, often allowing gross total removal.

52.9 Outcome

52.9.1 General information

Table 52.7 lists factors associated with better survival regardless of treatment. Also, the prognosis gets worse as the number of mets increases. Median survival even with best treatment in some studies is only ≈ 6 months. To put this into perspective, this is worse than with glioblastoma.

52.9.2 Natural history

By the time that neurologic findings develop, median survival among untreated patients is ≈ 1 month.

52.9.3 Steroids

Using steroids alone (to control edema) doubles survival to 2 mos (Note: this is based largely on pre-CT era data, and the tumors were therefore probably larger than in current studies).

52.9.4 Whole brain radiation therapy (WBXRT)

WBXRT + steroids increases survival to 3–6 mos. 50% of deaths are due to progression of intracranial disease.

52.9.5 Surgery ± WBXRT

Recurrence of tumor was significantly less frequent and more delayed with the use of post-op WBXRT. Length of survival was unchanged with supplemental use of WBXRT. There is also an

| Table 52.7 Factors associated with better prognosis for brain mets (with any treatment) |
|---------------------------------|---------------------------------|
| • Karnofsky score^ (KPS)>70    | • age <60 yrs                   |
| • metastases to brain only (no systemic mets) | • absent or controlled primary disease |
| • >1 yr since diagnosis of primary | • the fewer the number of brain mets |
| • female gender                 |                                 |

^the KPS (p. 1358) is probably the most important predictor; those with a score of 100 had median survival>150 weeks
additional loss of cognitive function in many cases, and patients are rarely independent after WB XRT.

In 33 patients treated with surgical resection of single mets and post-op WB XRT: median survival was 8 months; with 44% 1-yr survival. If no evidence of systemic Ca, 1-yr survival is 81% If systemic Ca is present (active or inactive), 1-yr survival is 20%. Patients with solitary mets and no evidence of active systemic tumor have the best prognosis. With total removal, no recurrence nor new parenchymal mets occurred within 6 months, and the major cause of death was progression of Ca outside the CNS. A randomized trial verified the improved longevity and quality of survival of patients with solitary mets undergoing surgical excision plus WB XRT vs. WB XRT alone (40 weeks vs. 15 weeks median survival). The surgical mortality was 4% (≈ same as 30-day mortality in the RTX-only group). More patients treated with WB XRT alone die of their brain mets than those who underwent surgery. Following total removal and post-op WB XRT, 22% of patients will have recurrent brain tumor at 1 year. This is better than surgery without XRT (with reported failure rates of 46% and 85%).

52.9.6 Stereotactic radiosurgery (SRS)

There has not been a randomized study to compare surgery to SRS. Retrospective studies suggest that SRS may be comparable to surgery. However, a prospective (non-randomized, retrospectively matched) study found a median survival of 7.5 mos with SRS vs. 16.4 mos with surgery, and a higher mortality from cerebral disease in the SRS group (with the mortality due to the SRS treated lesions and not new lesions). A local control rate of ≈ 88% has been reported, with one study also recommending WB XRT following the SRS for better regional control.

Actuarial control rates at 1 year following SRS + WB XRT were 75–80% and appear to be similar to surgery + WB XRT. However, SRS was unreliable in reducing tumor size.

52.9.7 Multiple mets

Patients with multiple mets that were totally removed have a survival that is similar to those having single mets surgically removed (see above).

52.10 Carcinomatous meningitis

52.10.1 General information

Carcinomatous meningitis (CM) AKA (lepto)meningeal carcinomatosis (LMC). Found in up to 8% of patients autopsied with systemic cancer. CM may be the presenting finding in up to 48% of patients with cancer (before the diagnosis cancer is known). Most common primaries: breast, lung, then melanoma. Always include lymphomatous meningitis in the differential diagnosis; see CNS lymphoma (p. 710).

52.10.2 Clinical

Simultaneous onset of findings in multiple levels of neuraxis. Multiple cranial nerve findings are frequent (in up to 94% most common: VII, III, V & VI), usually progressive. Most frequent symptoms: H/A, mental status changes, lethargy, seizure, ataxia. Non-obstructive hydrocephalus is also common. Painful radiculopathies can occur with “drop mets.”

52.10.3 Diagnosis

Lumbar puncture

Perform only after mass lesion has been ruled out with cranial CT or MRI. Although the initial LP may be normal, CSF is eventually abnormal in >95%

1. cytolology to look for malignant cells (requires ≈ 10 ml for adequate evaluation for CM). Repeat if negative (45%positive on first study, 81% eventually positive after up to 6 LPs). May need to pass CSF through a millipore filter
2. bacterial and fungal cultures (including unusual organisms, e.g. cryptococcus)
3. tumor markers: carcinoembryonic antigen, alpha-fetoprotein
4. protein/glucose: elevated protein is the most common abnormality. Glucose may be as low as \( \approx 40 \text{ mg}\% \text{in about a third of patients} \)

**MRI**

Contrast enhanced MRI is more sensitive in showing meningeal enhancement.\(^{54}\)

**CT**

May show (mild) ventricular dilatation, enhancement of basal cisterns. Sulcal enhancement may also occur with involvement of the convexities.

**Myelo graphy**

Spinal seeding (“drop mets”) will produce filling defects on myelography.

**52.10.4 Survival**

Untreated: < 2 months. With radiation therapy + chemotherapy: median survival is 5.8 mos (range 1–29). Chemotherapy may be given intrathecally. About half of patients die of CNS involvement, and half die of systemic disease.

moma to the Brain (Break MB). 2014

53 Spinal Epidural Metastases

53.1 General information

Key concepts

- suspected in a cancer patient with back pain that persists in recumbency
- occurs in ≈ 10% of all cancer patients
- 80% of primary sites: lung, breast, GI, prostate, melanoma and lymphoma
- many treatments reduce pain. Surgery + XRT in selected cases increases chances of preserving ambulation & produces a modest improvement in survival
- if no neurologic compromise or bony instability, usual treatment: biopsy (CT- or fluoro-guided) followed by XRT (surgical indications Table 53.4)
- surgery not helpful for: total paralysis >8 hrs, loss of ambulation >24 hrs, and not recommended for prognosis <3–4 months survival, poor medical condition (poor PFTs...), or radiosensitive tumor

Spinal epidural metastases (SEM) occur in up to 10% of cancer patients at some time,¹ and are the most common spinal tumor. 5–10% of malignancies present initially with cord compression.² For other etiologies of spinal cord compression, see items marked with a dagger (†) under Myelopathy (p.1407).

Routes of metastasis to spine:
1. arterial
2. venous: via spinal epidural veins (Batson’s plexus³)
3. perinervous (direct spread)

The usual route of spread is hematogenous dissemination to the vertebral body with erosion back through pedicles and subsequent extension into the epidural space (i.e. anterior epicenter). Less commonly may initially metastasize to lateral or posterior aspect of canal. Most metastases (mets) are epidural, only 2–4% are intradural, and only 1–2% are intramedullary. Distribution between cervical, thoracic and lumbar spine is proportional to the length of the segment, thus the thoracic spine is the most common site (50–60%).

53.2 Primary tumors that metastasize to the spine

Table 53.1 shows primary tumor types that give rise to SEM. The majority are common primaries that tend to metastasize to bone (lung, breast, prostate, renal-cell and thyroid). Rare tumors that may go to bone include the myxoid subtype of liposarcoma⁴ (17% of these patients develop bone mets, 5-year median survival is 16%).

53.3 Presentation

Pain: the most common initial symptom. Occurs in up to 95% of patients with SEM.⁶⁷ Types of pain:
1. local pain: typically aching, experienced at the level of involvement. Increased pain with recumbency (especially at night) is characteristic
2. radicular: tends to be sharp or shooting, referred into dermatome of the involved nerve root.
   Commonly bilateral in thoracic region
3. mechanical: usually exacerbated by movement
   Neck-flexion, straight-leg-raising, coughing, sneezing, or straining may also aggravate the pain.
   Motor or autonomic dysfunction: the second most common presentation. Up to 85% of patients have weakness at the time of diagnosis. Leg stiffness may be an early symptom. Bladder dysfunction (urinary urgency, hesitancy or retention) is the most common autonomic manifestation; others include constipation or impotence.
   Sensory dysfunction: anesthesia, hypesthesia, or paresthesias usually occur with motor dysfunction. Cervical or thoracic cord involvement may produce a sensory level.
Other presentations: pathologic fracture. Bone metastases can sometimes produce hypercalcemia (a medical emergency).

The greater the neurologic deficit when treatment is initiated, the worse the chances for recovery of lost function. 76% of patients have weakness by the time of diagnosis.1 15% are paraplegic on initial presentation, and <5% of these can ambulate after treatment. Median time from onset of symptoms to diagnosis is 2 months.8

53.3.1 Metastases to the upper cervical spine

For differential diagnosis, see Foramen magnum lesions (p.1367), and Axis (C2) vertebra lesions (p.1391).

Metastases to the Cl–2 region comprise only ≈ 0.5% of spinal mets.9 They typically present initially with suboccipital and posterior cervical pain, and as the lesion progresses patients develop a characteristic pain that makes it difficult to sit up (some will hold their heads in their hands to stabilize it). Possibly as a result of the capacious spinal canal at this level, only ≈11–15% of patients present with neurologic symptoms. 15% develop spinal cord compression,10 and quadriplegia from atlantoaxial subluxation occurred in ≈ 6%.10

Anterior approaches for stabilization at this location are difficult. Pathologic fractures due to osteoblastic types of tumors (e.g. prostate, some breast) may heal with radiation treatment and immobilization. For others, good pain relief and stabilization may be achieved with radiation followed by posterior fusion.10

53.4 Evaluation and management of epidural spinal metastases

53.4.1 General information

There is no difference in outcome between lesions above or below the conus; thus spinal cord, conus medullaris, or cauda equina mets are considered together here as epidural spinal cord compression (ESCC). Features that help distinguish conus lesions from cauda equina are shown in Table 53.2

53.4.2 Grading function

There is prognostic significance in the presenting neurologic condition. Grading scales such as that of Brice and McKissock (Table 53.3) have been proposed, but are not widely used. The ASIA grading scale is more commonly applied.
53.4.3 Diagnostic tests

MRI in evaluating SEM

MRI without and with contrast is the diagnostic test of choice in most situations.

MRI findings in spinal epidural metastases:
1. vertebral mets are slightly hypointense compared to normal bone marrow on T1 WI, and are slightly hyperintense on T2WI
2. axial cuts typically show lesion involving the posterior vertebral body with invasion into one or both pedicles
3. when myelopathy or radiculopathy are present, there is usually tumor extension into the spinal canal (may not occur in lesions presenting only with local pain)
4. DWI images may help differentiate osteoporotic compression fracture from pathologic fracture

Plain x-rays

Most spinal mets are osteolytic, but at least 50% of the bone must be eroded before plain x-rays will be abnormal. Not very specific. Possible findings: pedicle erosion (defect in “owl’s eyes” AKA “winking owl sign” on LS or thoracic spine AP view) or widening, pathological compression fracture, vertebral body (VB) scalloping, VB sclerosis, osteoblastic changes (may occur with prostate Ca, Hodgkin’s disease, occasionally with breast Ca, and rarely with multiple myeloma)

Plain CT in evaluating SEM

Very good for bone detail. Often helpful for surgical planning. By itself, has low sensitivity for spinal cord compression by tumor. Sensitivity is increased with intrathecal contrast (CT-myelogram).

CT-myelogram (CT-myelo)

Indicated when MRI cannot be done (contraindications, unavailability...).
Advantages over MRI:
- Can obtain CSF (when performing LP to inject contrast) for cytological study
- Excellent bony detail
- Can be performed in patients with pacemaker/AICD, claustrophobia...

Disadvantages of myelography over MRI:
- Invasive
- May require second procedure (C1–2 puncture) if there is a complete block (providers proficient in this technique are becoming fewer)
- Risk of neurologic deterioration from LP in patient with complete block
- Cannot detect lesions that do not cause bony destruction or distortion of the spinal subarachnoid space
- Up to 20% of patients with SEM have at least two sites of cord compression, MRI can evaluate region between two complete blocks, myelography cannot
- Cannot demonstrate paraspinous lesions
- Does not image spinal cord parenchyma

Positron emission tomography (PET) scan
PET scan using [18F]-fluorodeoxyglucose may be used for whole-body work-up for bone mets in patients with known cancer. Sensitivity is high, but spatial resolution and specificity are low, so often must be used with CT and/or MRI.

Metastatic work-up for patients with suspected spine metastases
- CT of chest, abdomen and pelvis: assess tumor burden, staging, prognostication (which factors into decisions regarding surgery). Has superseded CXR to rule out lung lesion (primary or other mets)
- Bone scan: looks for other sites of skeletal involvement
- Serum prostate specific antigen (PSA) in males
- Mammogram in females
- For multiple myeloma (p. 715)
- Careful physical exam of lymph nodes

53.4.4 Management algorithm

General information
Management is dependent on the degree and rapidity of neurologic involvement. Patients may be categorized into one of the three groups that follows which outlines the subsequent steps. In a patient with suspected spine mets, the goals of management are:
- Assessment of neurologic involvement and timeline of neurologic changes.
- Delineate the degree of spinal involvement
- Determine a histologic diagnosis: this affects management
- Preserve or restore neurologic function
- Preserve or restore spinal stability
- Control pain

The tools that are employed in the assessment and stabilization phase are listed under diagnostic tests above. The section that follows discusses the rapidity with which they are implemented.

A metastatic work-up (p. 817) is undertaken as time permits (a preliminary work-up, e.g. CXR and physical exam, may be all that can be initially obtained for patients in Group I, whereas more complete work-up can be done in others).

Group I – rapid progression or severe deficit

**Signs / symptoms**

Signs/symptoms of new or progressive (hours to days) cord compression (e.g. urinary urgency, ascending numbness). These patients have a high risk of rapid deterioration and require immediate evaluation.
Management

1. dexamethasone (DMZ) (Decadron®): reduces pain in 85% may produce transient neurologic improvement. Optimal dose is not known. No difference was found comparing 100 mg IV bolus to 10 mg.\textsuperscript{16} Suggestion: 10 mg IV or PO q 6 hrs × 72 hrs, followed by lower dose of 4–6 mg q 6 hrs. Steroids may temporarily mask lymphoma (on imaging and at surgery), however, in this group the benefit of giving steroids usually outweighs this pitfall

2. radiographic evaluation
   a) STAT MRI (above)
   b) plain x-rays of entire spine: 67–85% will be abnormal (see above)
   c) if time permits, plain CT scan through involved levels and at least 2 levels above and below to evaluate bone for surgical planning
   d) emergency myelogram: indicated if MRI cannot be done (include possible C1–2 puncture on the consent). Start with a so-called “blockogram” to R/O complete block: instill small volume of contrast, e.g. iohexol (Omnipaque\textsuperscript{™}) (p.219) via LP and run the dye all the way up the spinal column; CSF is usually xanthochromic with complete block, see Froin’s syndrome (p.790)
      - if there is not a complete block: withdraw 10 cc of CSF and send for cytology, protein & glucose. One may then inject more contrast to complete the study
      - if complete block: do not remove CSF (pressure shifts via LP caused neurologic deterioration in ≈ 14% of patients with complete block\textsuperscript{17} whereas there was no deterioration after C1–2 puncture). In some cases, contrast can be “squeezed” past a “complete” block by injecting 5–10 ml of room air through a millipore filter,\textsuperscript{18} alternatively, perform a lateral C1–2 puncture (p.1511) and instill water soluble contrast to delineate the superior extent of the lesion
      - with myelography, epidural lesions classically produce hourglass deformity with smooth edges if block is incomplete, or paintbrush effect (feathered edges) if block is complete, unlike the sharp margins (capping or meniscus sign) of intradural extramedullary lesion, or fusiform cord widening of intramedullary tumors
      - bone scan if time permits. Abnormal in ≈ 66% of patients with spine mets

3. treatment based on results of radiographic evaluation
   a) if no epidural mass; treat primary tumor (e.g. systemic chemotherapy). Local radiation therapy (XRT) to bony lesion if present. Analgesics for pain
   b) if epidural lesion, either surgery or start XRT (usually 30–40 Gy in 10 treatments over 7–10 d with ports extending 2 levels above and below lesion). XRT is usually as effective as laminectomy with fewer complications; for further discussion see Treatment for SEM (p.819). Thus, surgery instead of XRT is considered only for the indications shown in Table 53.4
   c) urgency of treatment (surgery or XRT) is based on degree of block and rapidity of deterioration:
      - if > 80% block or rapid progression of deficit: emergency treatment ASAP (if treating with XRT instead of surgery, continue DMZ next day at 24 mg IV q 6 hrs x 2 days, then taper during XRT over 2 wks)
      - if < 80% block: treatment on “routine” basis (for XRT, continue DMZ 4 mg IV q 6 hrs, taper during treatment as tolerated)

Group II – mild and stable signs and symptoms

**Signs / symptoms**

Mild and stable signs/symptoms of cord compression (e.g. isolated Babinski), or either plexopathy or radiculopathy without evidence of cord compression. Admit and evaluate within 24 hrs.

**Management**

1. for suspected ESCC, manage as in Group I except on less emergent basis. Use low dose dexamethasone (DMZ) unless radiographic evaluation shows >80% block or if suspicion of lymphoma is high and tissue will be obtained relatively soon
2. for radiculopathy alone (radicular pain, weakness or reflex changes in one myotome or sensory changes in one dermatome): if plain x-rays show bony lesion then 70–88% will have ESCC on myelography. If the plain film is normal, only 9–25% will have ESCC. Obtain MRI or myelogram and manage as for suspected ESCC
3. for plexopathy (brachial or lumbosacral): pain is the most common early symptom, distribution not limited to single dermatome, commonly referred to elbow or ankle. May mask coexistent radiculopathy, distinguish by EMG (denervation of paraspinal muscles occurs in radiculopathy) or presence of proximal signs and symptoms (Horner’s syndrome in cervical region, ureteral obstruction in lumbar region). Management:
   a) MRI is initial diagnostic procedure (CT if MRI unavailable): C4 through T4 for brachial plexopathy, L1 through pelvis for lumbosacral plexopathy
   b) if CT shows bony lesion or paraspinal mass (with negative CT, plain films and bone scan are rarely helpful; however, if done, and plain x-ray shows malignant appearing bony lesion, or if bone scan shows vertebral abnormality, perform MRI or myelogram within 24 hrs) (give dexamethasone if ESCC suspected or MRI/myelogram delayed). Management as in Group I based on degree of block, XRT ports extended laterally to include any mass shown on CT
   c) if no bony nor paraspinal lesion on MRI/CT, primary treatment of plexus tumor; analgesics for pain

Group III – pain without neurologic involvement

**Signs / symptoms**

Back pain without neuro signs/symptoms. Can be evaluated as outpatient over several days (modify based on ability of patient to travel, reliability, etc.).

53.4.5 Treatment for SEM

**Treatment goals and outcome**

No treatment for SEM significantly prolongs life. Treatment goals are palliative: pain control, preservation of spinal stability, and maintenance of sphincter control and ability to ambulate.

The most important factor affecting prognosis, regardless of treatment modality, is ability to walk at the time of initiation of therapy. Loss of sphincter control is a poor prognosticator and is usually irreversible.

The main decision is between surgery + post-op XRT, or XRT alone. As yet, no chemotherapy has been found to be useful for SEM (may help with primary). Surgery alone appears least effective for pain control (36% compared to 67% for surgery + XRT, and 76% for XRT alone). Surgery has the attendant complications of anesthetic risk, post-op pain, wound problems in 11% (further complicated by radiation),19 and mortality in 5–6% after laminectomy and 10% after anterior approach with stabilization.20 Therefore, surgery appears best reserved for situations described in Table 53.4.

**Medical therapy**

Chemotherapy is ineffective for SEM.
Bisphosphonates reduce the risk of vertebral compression fractures (VCF) by \( \approx 50\% \) but the effect seems to abate after \( \approx 2–3 \) years.

Promising agents undergoing trials include: denosumab, a RANK ligand (RANKL) inhibitor (p.1011) that may counteract RANKL which is overexpressed in response to lytic bony metastases.\(^{22}\)

The efficacy seems better than the bisphosphonates.

**Vertebroplasty/kyphoplasty**

Vertebroplasty/kyphoplasty (p.1011) reduces pain associated with pathologic fractures in up to 84\% \( ^{23} \) with an associated increase in functional outcome.\(^{24}\) Kyphoplasty appears to offer comparable pain relief to vertebroplasty with lower rates of cement leakage.\(^{24}\)

Relative contraindication: spinal cord compression. Unless the diagnosis has already been verified, a biopsy should be taken through one of the pedicles prior to injecting PMMA.

**Radiation therapy**

Radiosensitive tumors: Table 52.6 lists radiosensitivity of metastatic tumors (to brain or spine). Other radiosensitive tumors that metastasize to the spine include: myxoid liposarcoma.\(^{25}\)

Treatment\(^{26}\): Dose: range =25–40 Gy. Typical plan: 30 Gy delivered in 3 Gy fractions over 10 days (2 working weeks) to ports extending at least 1 vertebral level above and below the extent of the lesion. Timing: for initial treatment, try to start XRT within 24 hours of diagnosis; for post-op XRT, within about 14 days following surgery.

There is a theoretical risk of radiation induced edema causing or accelerating neurologic deterioration. This has not been borne out by experimental studies with the usual small daily fractions utilized. Deterioration is more likely to be due to tumor progression.\(^{27}\) The spinal cord is usually the dose limiting structure in treating SEM.

Increased doses are being made possible with the application of the added precision of stereotactic radiosurgery techniques to spinal metastases.\(^{28}\)

**Surgical treatment**

See Table 53.4 for indications for surgery.

Pre-op embolization by interventional radiologist may facilitate resection with less blood loss for highly vascular tumors such as: renal-cell, thyroid, and hepatocellular. Blood supply is through the intercostal arteries, and care must be taken to avoid embolizing vessels providing significant blood supply to the spinal cord, especially the artery of Adamkiewicz (p.87).

**Approaches**

Laminectomy alone is poor for spinal metastases when the pathology is anterior to the cord because of poor access to the tumor and the destabilizing effect of laminectomy when metastatic involvement of the vertebral body is significant.\(^{29,30}\)

Deterioration in one of the 3 major criteria (pain, continence, ambulation) occurred in 26\% of patients treated with laminectomy alone, 20\% of laminectomy + XRT, and 17\% of XRT alone (roughly comparable). There is a 9\% incidence of spinal instability\(^{19}\) following laminectomy without stabilization.

In a randomized controlled trial by Patchell et al.,\(^{31}\) approaches directed at the location of the tumor (e.g. costotransversectomy, transthoracic approach...) with stabilization where necessary, produced better results than simple laminectomy, and surgery + XRT was superior to XRT alone (see Table 53.5). This study found a modest increase in survival, but more significant maintenance or regaining of lost ambulation. However, operative mortality with anterior decompression and stabilization was \( \approx \) double (10\%) that of laminectomy with (5\%) or without (6\%) stabilization in a literature review.\(^{20}\)

Solitary spinal metastases with indolent tumors (e.g. renal cell Ca) may be candidates for attempted cure with en bloc resection (total spondylectomy).\textsuperscript{3,32}

Laminectomy is still appropriate with isolated involvement of the posterior elements. For anterior pathology, if the posterior elements are intact, a transsthoracic approach with corpectomy and stabilization (e.g. with methylmethacrylate and Steinmann pins,\textsuperscript{34} or with cage graft and lateral plate) followed by XRT improves neurologic function in $\approx 75\%$ and pain in $\approx 85\%$ A posterolateral approach (e.g. costotransversectomy) may be used for anterolateral tumor.\textsuperscript{35} Combining a corpectomy and removal of the pedicle and posterior elements destabilizes the spine, therefore posterior instrumentation prior to performing the corpectomy is required, followed by cage graft.\textsuperscript{36-39,40,41,42} To access a VB via a costotransversectomy, the rib of the like numbered VB and the one below need to be removed.

54 General Information, Grading, Initial Management

54.1 General information

54.1.1 Introduction

56–60% of patients with GCS score ≤8 have 1 or more other organ system injured.\(^1\) 25% have “surgical” lesions. There is a 4–5% incidence of associated spine fractures with significant head injury (mostly Cl to C3).

When a detailed history is unavailable, remember: the loss of consciousness may have preceded (and possibly have caused) the trauma. Therefore, maintain an index of suspicion for e.g. aneurysmal SAH, hypoglycemia, etc. in the differential diagnosis of the causes of trauma and associated coma.

Brain injury from trauma results from two distinct processes:
1. primary brain injury: occurs at time of trauma (cortical contusions, lacerations, bone fragmentation, diffuse axonal injury, and brainstem contusion)
2. secondary injury: develops subsequent to the initial injury. Includes injuries from intracranial hematomas, edema, hypoxemia, ischemia (primarily due to elevated intracranial pressure (ICP) and/or shock), vasospasm

Since impact damage cannot be influenced by the treating neurosurgeon, intense interest has focused on reducing secondary injuries, which requires good general medical care and an understanding of intracranial pressure (p.856).

54.1.2 Delayed deterioration

\(\approx 15\%\) of patients who do not initially exhibit signs of significant brain injury may deteriorate in a delayed fashion, sometimes referred to as patients who “talk and deteriorate” or when more lethal, patient who “talk and die”.\(^2\) Etiologies:

1. \(\approx 75\%\) will exhibit an intracranial hematoma
   a) may be present on initial evaluation and can then worsen
   b) may develop in a delayed fashion
      • delayed epidural hematoma (EDH) (p.894)
      • delayed subdural (SDH) (p.898)
      • delayed traumatic contusions (p.892)
2. posttraumatic diffuse cerebral edema (p.848)
3. hydrocephalus
4. tension pneumoencephalus
5. seizures
6. metabolic abnormalities, includes:
   a) hyponatremia
   b) hypoxia: etiologies include pneumothorax, MI, CHF...
   c) hepatic encephalopathy
   d) hypoglycemia: including insulin reaction
   e) adrenal insufficiency
   f) drug or alcohol withdrawal
7. vascular events
   a) dural sinus thrombosis (p.1308)
   b) carotid (or rarely, vertebral) artery dissection (p.1324)
   c) SAH due to rupture of aneurysm (spontaneous or posttraumatic) or carotid-cavernous fistula (CCF) (p.1256)
      d) cerebral embolism: including fat embolism syndrome (p.835)
8. meningitis
9. hypotension (shock)

54.2 Grading

Despite many (valid) criticisms, the initial post-resuscitation Glasgow Coma Scale (GCS) score (Table 18.1) remains the most widely used and perhaps best replicated scale employed in for the assessment of head trauma. Problems with this type of scale is that it is an ordinal scale that is non-parametric (i.e. does not represent precise measurements of discrete quantities), it is non-linear, and
it is not an interval scale, so that for example, a decrease of 2 points in one parameter is not necessarily equal to a decrease in 2 points of another.\textsuperscript{3} Thus, performing mathematical manipulations (e.g. adding components, or calculating mean values), while often done, is not statistically sound.\textsuperscript{4}

There are a number schemes to stratify the severity of head injury. Any such categorization is arbitrary and will be imperfect. A simple system based only on GCS score is as follows:

- GCS 14–15 = mild
- GCS 9–13 = moderate
- GCS ≤8 = severe

An example of a more involved system\textsuperscript{3} incorporates other factors in addition to the GCS score as shown in Fig. 54.1.

### 54.3 Transfer of trauma patients

It is sometimes necessary for a neurosurgeon to accept a trauma patient in transfer from another institution that is not equipped to handle major neurologic injuries, or to transfer patients to other facilities for a variety of reasons. Table 54.1 lists factors that should be assessed and stabilized (if possible) prior to transfer. These items should also be evaluated in trauma patients on whom a neurosurgeon is consulted in his or her own E/R as well as in patients with other CNS abnormalities besides trauma (e.g. SAH).

54.4 Management in E/R

54.4.1 General measures

Blood pressure and oxygenation

Practice guideline: IBP and oxygenation

Level II: monitor IBP and avoid hypotension (SBP < 90 mm Hg)
Level III: monitor oxygenation and avoid hypoxia (PaO₂ < 60 mm Hg or O₂ saturation < 90%)

Hypotension

Hypotension (shock) is rarely attributable to head injury except:
- in terminal stages (i.e. with dysfunction of medulla and cardiovascular collapse)
- in infancy, where enough blood can be lost intracranially or into the subgaleal space to cause shock
- where enough blood has been lost from scalp wounds to cause hypovolemia (exsanguination)

Hypotension (defined as a single SBP < 90 mm Hg) doubles mortality, hypoxia (apnea or cyanosis in the field, or PaO₂ < 60 mm Hg on ABG) also increases mortality, and the combination of both triples mortality and increases the risk bad outcome. SBP < 90 mm Hg may impair CBF and exacerbate brain injury and should be avoided (p.870).

Early use of paralytics and sedation (prior to ICP monitoring)

Practice guideline: Early sedation and paralysis

Level III: sedation and neuromuscular blockade (NMB) can be helpful for transporting the head-injured patient, but they interfere with the neuro exam
Level III: NMB should be used when sedation alone is inadequate

The routine use of sedatives and paralytics in neurotrauma patients may lead to a higher incidence of pneumonia, longer ICU stays, and possibly sepsis. These agents also impair neurologic assessment. Use should therefore be reserved for cases with clinical evidence of intracranial hypertension (see Table 54.2), for intubation, or where use is necessary for transport or to permit evaluation of the patient (e.g. to get a combative patient to hold still for a CT scan).

Intubation and hyperventilation

Indications for intubation in trauma; also see Practice guideline: Intubation – indications (p.827):
1. depressed level of consciousness (patient cannot protect airway): usually GCS ≤ 7
2. need for hyperventilation (HPV): see below
3. severe maxillofacial trauma: patency of airway tenuous or concern for inability to maintain patency with further tissue swelling and/or bleeding
4. need for pharmacologic paralysis for evaluation or management

Table 54.2 Clinical signs of ICHHTN

| 1. pupillary dilatation (unilateral or bilateral) |
| 2. asymmetric pupillary reaction to light |
| 3. decerebrate or decorticate posturing (usually contralateral to blown* pupil) |
| 4. progressive deterioration of the neurologic exam not attributable to extracranial factors |

*Items 1-3 represent clinical signs of herniation. The most convincing clinical evidence of ICHHTN is the witnessed evolution of 1 or more of these signs. ICHHTN may produce a bulging fontanelle in an infant.

* "blown pupil": fixed & dilated pupil
Practice guideline: Intubation – indications

Level III: secure the airway (usually by endotracheal intubation) in patients with GCS ≤ 8 who are unable to maintain their airway or who remain hypoxic despite supplemental O₂

Cautions regarding intubation:
1. if basal skull fracture through cribriform plate is possible, avoid nasotracheal intubation (to avoid intracranial entry of tube). Use orotracheal intubation
2. prevents assessment of patient’s ability to verbalize e.g. for determining Glasgow Coma Scale score. This ability should be noted (none, unintelligible, inappropriate, confused, or oriented) prior to intubation
3. risk of pneumonia: see Practice guideline: Antibiotics for intubation (p.827) regarding antibiotics

Practice guideline: Antibiotics for intubation

Level II: periprocedural antibiotics for endotracheal intubation reduce the risk of pneumonia, but do not alter length of stay or mortality

Hyperventilation (HPV)

Practice guideline: Early/prophylactic hyperventilation

Level III: prophylactic hyperventilation (PaCO₂ ≤ 25 mm Hg) is not recommended

Level III
- hyperventilation (HPV) before ICP monitoring is established should be reserved as a temporizing measure for patients with signs of transtentorial herniation (see Table 54.2) or progressive neurologic deterioration not attributable to extracranial causes
- HPV should be avoided during the first 24 hrs after TBI (when CBF is often dangerously decreased)

1. since HPV may exacerbate cerebral ischemia, HPV should not be used prophylactically (p.872)
2. prior to ICP monitoring, HPV should only be used briefly when CT or clinical signs of IC-HTN are present (see Table 54.2 for clinical signs)
   a) when appropriate indications are met: HPV to PaCO₂ = 30–35 mm Hg
   b) HPV should not be used to the point that PaCO₂ < 30 mm Hg (this further reduces CBF but does not necessarily reduce ICP)
3. acute alkalosis increases protein binding of calcium (decreases ionized Ca²⁺). Patients being hyperventilated may develop ionized hypocalcemia with tetany (despite normal total [Ca])

Mannitol in E/R

Practice guideline: Early use of mannitol

Level III: the use of mannitol before ICP monitoring is established should be reserved for patients who are adequately volume-resuscitated with signs of transtentorial herniation (see Table 54.2) or progressive neurologic deterioration not attributable to extracranial causes

Indications in E/R, see also more details (p.873):
1. evidence of intracranial hypertension (see Table 54.2)
2. evidence of mass effect (focal deficit, e.g. hemiparesis)
3. sudden deterioration prior to CT (including pupillary dilatation)
4. after CT, if a lesion that is associated with increased ICP is identified
5. after CT, if going to O.R.
6. to assess “salvageability”: in patient with no evidence of brainstem function, look for return of brainstem reflexes

Contraindications:
1. prophylactic administration is not recommended due to its volume-depleting effect. Use only for appropriate indications (see above)
2. hypotension or hypovolemia: hypotension can negatively influence outcome. Therefore, when intracranial hypertension (IC-HTN) is present, first utilize sedation and/or paralysis, and CSF drainage. If further measures are needed, fluid resuscitate the patient before administering mannitol. Use hyperventilation in hypovolemic patients until mannitol can be given
3. relative contraindication: mannitol may slightly impede normal coagulation
4. CHF: before causing diuresis, mannitol transiently increases intravascular volume. Use with caution in CHF, may need to pre-treat with furosemide (Lasix®)

---

**Prophylactic antiepileptic drugs (AEDs)**

**Practice guideline: Prophylactic anticonvulsants after TBI**

Level III: prophylactic phenytoin, carbamazepine, phenobarbital or valproate do not prevent late PTS

Level II: AEDs (e.g. phenytoin, valproate, or carbamazepine) may be used to decrease the incidence of early PTS (within 7 days of TBI) in patients at high risk of seizures after TBI (see Table 54.3), however, this does not improve outcome

Routine use of prophylactic antiepileptic drugs (AEDs) in traumatic brain injury (TBI) is ineffective in preventing the late development of posttraumatic seizures (PTS) i.e. epilepsy, and has been shown to not be useful except in certain circumstances. See details on using (p.463) and discontinuing (p.463) prophylactic AEDs following TBI. Table 54.3 reiterates the markers for patients at increased risk of early PTSs.

---

**54.4.2 Neurosurgical exam in trauma**

**General information**

It is not possible to outline a physical exam that is universally applicable. Major trauma must be assessed rapidly, often under chaotic circumstances, and must be individualized based on patient’s medical stability, type of injury, degree of combativeness, use of pharmacologic paralytics (p.826), the needs of other caregivers attending to other organ injuries, the need to triage in the event of multiple patients requiring simultaneous attention...

The following describes some features that should be assessed under certain circumstances with the understanding that this must be individualized. This addresses only craniospinal injuries, and assumes that general systemic injuries (internal bleeding, myocardial and/or pulmonary

contusion... as well as orthopedic injuries (long bone and pelvic fractures...) will be treated by other members of a “trauma team.” Although organized here in outline form, the most efficient order of examination is usually dictated by circumstances unique to each situation.

General physical condition (oriented towards neuro assessment)

1. visual inspection of cranium:
   a) evidence of basal skull fracture (p.884):
      • raccoon’s eyes: periorbital ecchymoses
      • Battle’s sign: postauricular ecchymoses (around mastoid air sinuses)
      • CSF rhinorrhea/otorrhea (p.387)
      • hemotympanum or laceration of external auditory canal
   b) check for facial fractures
      • Le Fort fractures (p.887): palpate for instability of facial bones, including zygomatic arch
      • orbital rim fracture: palpable step-off
   c) periorbital edema, proptosis

2. cranio-cervical auscultation
   a) auscultate over carotid arteries: bruit may be associated with indicate carotid dissection
   b) auscultate over globe of eye: bruit may indicate traumatic carotid-cavernous fistula CCF; see Carotid-cavernous fistula (p. 1256)

3. physical signs of trauma to spine: bruising, deformity

4. evidence of seizure: single, multiple, or continuing (status epilepticus)

Neurologic exam

1. cranial nerve exam
   a) optic nerve function (p. 836)
      • if conscious: serial quantitation of vision in each eye is important. A Rosenbaum near vision card is ideal (see inside back cover), otherwise use any printed material. If patient cannot see this, check if they can count fingers. Failing this, check for hand motion vision and lastly perception. Children may develop transient cortical blindness lasting 1–2 days, usually after a blow to the back of the head
      • if unconscious: check for afferent pupillary defect (p.562), best demonstrated with swing-ing flashlight test (p. 561). Indicates possible optic nerve injury
     • funduscopic exam: check for papilledema, pre-retinal hemorrhages, retinal detachment, or retinal abnormalities suggestive of anterior optic nerve injury. If a detailed exam is required, pharmacologic dilatation with mydriatics (p. 563) may be employed, however, this precludes pupillary exam for a variable period of time, and should be undertaken advisedly
   b) pupil: size in ambient light; reaction to light (direct & consensual)
   c) VI: check for peripheral VII palsy (p. 884) (facial asymmetry of unilateral upper and lower facial muscles)
   d) VI: abducens palsy (p. 567) following trauma may occur as a result of ↑ ICP or with clival fractures (p.884)

2. level of consciousness/mental status
   a) Glasgow coma scale for quantitating level of consciousness in poorly responsive patient (see Table 18.1)
   b) check orientation in patient able to communicate

3. motor exam (assesses motor tracts from motor cortex through spinal cord)
   a) if patient is cooperative: check motor strength in all 4 extremities
   b) if uncooperative: check for appropriate movement of all 4 extremities to noxious stimulus (differentiate voluntary movement from posturing or stereotypical spinal cord reflex). This also assesses sensation in an unresponsive patient
   c) if any doubt about integrity of spinal cord: also check “resting” tone of anal sphincter on rectal exam, evaluate voluntary sphincter contraction if patient can cooperate, check anal wink with pinprick, and assess bulbocavernous reflex (p.943) (see Neurological assessment, for details)

4. sensory exam
   a) cooperative patient:
      • check pinprick on trunk and in all 4 extremities, touch on major dermatomes (C4, C6, C7, C8, T4, T6, T10, L2, L4, L5, S1, sacroccygeal)
      • check posterior column function: joint position sense of LEs
b) uncooperative patient: check for central response to noxious stimulus (e.g. grimace, vocalization, as opposed to flexion-withdrawal which could be a spinal cord mediated reflex)

5. reflexes
a) muscle stretch (“deep tendon”) reflexes if patient is not thrashing: e.g. preserved reflex indicates that a flaccid limb is due to CNS injury and not nerve root injury (and vice versa)
b) check plantar reflex for upgoing toes (Babinski sign)
c) in suspected spinal cord injury: the anal wink and bulbocavernous reflex are checked on the rectal exam (see above)

54.4.3 Indications for CT and admission criteria for TBI

General information
Numerous stratagems have been devised to determine what studies should be ordered for which patients. Patients with trivial injuries rarely need a CT scan, and those with severe head injuries obviously need one. Most of the effort centers around identifying the patient who appears to have a minor head injury but may be harboring or apt to develop a significant intracranial injury. An optimal protocol has not been developed, and a rigorous prospective application and further refinement of published systems is sadly lacking. In view of this state of affairs, the following is presented as a guideline.

Patients may be stratified into one of three groups based on the likelihood of intracranial injury as outlined in the following sections.20,21

Category 1. Low risk for intracranial injury

Criteria
Possible findings are shown in Table 54.4.

In this group, there is an extremely low likelihood of intracranial injury (ICI) (incidence of ICI: ≤ 8.5 in 10,000 cases with 95% confidence level).20

Management recommendations
CT scan is not usually indicated. Plain SXRs are not recommended: 99.6% of SXRs in this group are normal. Linear non-displaced skull fractures in this group require no treatment, although in-hospital observation (at least overnight) may be considered.

Patients in this group who meet Criteria for observation at home shown in Table 54.5 may be managed with observation at home with written head-injury discharge instructions, e.g. as illustrated Table 54.6.

Category 2. Moderate risk for intracranial injury

Criteria
Possible findings are shown in Table 54.7

Management recommendations
1. head CT scan (unenhanced): clinical grounds alone may miss important lesions in this group.8–46% of patients with minor head injury (MHI) have an intracranial lesion (the most frequent finding was hemorrhagic contusion).23
2. SXR (p.833): not recommended unless CT scan not available. Useless if normal. A SXR is helpful only if positive (a clinically unsuspected depressed skull fracture might be important)
3. observation
   a) at home, if the patient meets the criteria outlined in Table 54.5. Provide caregiver with written head-injury discharge instructions (sometimes called “subdural precautions”), as shown in Table 54.6

Table 54.4 Findings with low risk of ICI
- asymptomatic
- H/A
- dizziness
- scalp hematoma, laceration, contusion, or abrasion
- no moderate nor high risk criteria (see Table 54.7 and Table 54.8, no loss of consciousness, etc.)
- no history of loss of consciousness
Table 54.5 Criteria for observation at home

1. Head CT scan not indicated, or CT scan normal if indicated²²
2. initial GCS ≥ 14
3. no high risk criteria
4. no moderate risk criteria except loss of consciousness
5. patient is now neurologically intact (amnesia for the event is acceptable)
6. there is a responsible, sober adult that can observe the patient
7. patient has reasonable access to return to the hospital E/R if needed
8. no “complicating” circumstances (e.g. no suspicion of domestic violence, including child abuse)

Table 54.6 Sample discharge instructions for head injuries

Seek medical attention for any of the following:
1. a change in level of consciousness (including difficulty in awakening)
2. abnormal behavior
3. increased headache
4. slurred speech
5. weakness or loss of feeling in an arm or leg
6. persistent vomiting
7. enlargement of one or both pupils (the black round part in the middle of the eye) that does not get smaller when a bright light is shined on it
8. seizures (convulsions or fits)
9. significant increase in swelling at injury site

Do not take sedatives or pain medication stronger than acetaminophen (paracetamol in some countries) for 48 hours. Do not take aspirin or other anti-inflammatory medications because of interference with platelet function and theoretical increased risk of bleeding

Category 3. High risk for intracranial injury

Criteria
Possible findings are shown in Table 54.8.

Management recommendations

1. admit to hospital
2. STAT unenhanced head CT scan
3. if there are focal findings on neurologic examination
4. determine if intracranial monitor (p.858) is indicated
5. SX R  usually not recommended: a fracture is rarely surprising, and a SX R  is inadequate for assessing for intracranial injury. A SX R  is possibly useful for localizing a radio-opaque penetrating foreign body (knife blade, bullet…) for the O.R.

Other risk factors

Occipital vs. frontal fractures

Patients with occipital fractures may be at higher risk of significant intracranial injury (ICI). May be related to the fact that in forward trauma, one may protect oneself with the outstretched arms. Furthermore, the facial bones and air sinuses exert an impact absorbing effect. In 210 patients with facial fractures, the highest incidence of ICI was seen in those with upper facial fractures. Those with mandibular and midfacial region fractures (without upper facial involvement) had a lower likelihood of ICI, and those with mandibular region trauma only were least likely to have ICI.

54.5 Radiographic evaluation

54.5.1 CT scans in trauma

General information

An unenhanced (i.e. non-contrast) CT scan of the head usually suffices for patients seen in the emergency department presenting after trauma or with a new neurologic deficit. Enhanced CT or MRI may be appropriate after the unenhanced CT, but are not usually required emergently (exceptions include: significant brain edema due to suspected neoplasm that is not demonstrated without contrast).

The main emergent conditions to rule out (and brief descriptions):

1. blood (hemorrhages or hematomas):
   a) extra-axial blood: surgical lesions are usually ≥1 cm maximal thickness
      • epidural hematoma (EDH) (p.892): usually biconvex and often due to arterial bleeding. May cross dural barriers (unlike SDH) such as falx, tentorium
      • subdural hematoma (SDH) (p.891): usually crescentic, usually due to venous bleeding. May cover larger surface area than EDH (dural adherence to inner table limits extension of EDH). Chronology of SDH: acute = high density, subacute = isodense, chronic = low density
   b) subarachnoid blood (SAH): Trauma is the most common cause of SAH. Unlike aneurysmal SAH where blood is thickest near the circle of Willis, traumatic SAH (tSAH) usually appears as high density spread thinly over convexity and filling sulci or basal cisterns. However, when the history of trauma is not clear, an arteriogram may be indicated to R/O a ruptured aneurysm (that might have precipitated the trauma in some cases)
   c) intracerebral hemorrhage (ICH): increased density in brain parenchyma
   d) hemorrhagic contusion (p.891): often “fluffy” inhomogeneous high-density areas within brain parenchyma, usually adjacent to bony prominences (frontal and occipital poles, sphenoid wing). Typically less well defined than primary ICH
   e) intraventricular hemorrhage (p.1192): present in ≈10% of severe head injuries. Associated with poor outcome; may be a marker for severe injury rather than the cause of the poor outcome. Use of intraventricular rt-PA has been reported for treatment

2. hydrocephalus: enlarged ventricles may sometimes develop following trauma
3. cerebral swelling: obliteration of basal cisterns (p.921), compression of ventricles and sulci...
4. evidence of cerebral anoxia: loss of gray-white interface, signs of swelling
5. skull fractures:
   a) basal skull fractures (including temporal bone fracture)
   b) orbital blow-out fracture
   c) calvarial fracture (CT may miss some linear nondisplaced skull fractures)
● linear vs. stellate
● open vs. closed
● diastatic (separation of sutures)
● depressed vs. nondepressed: CT helps assess need for surgery

6. ischemic infarction: findings are usually minimal or subtle if <24 hrs since stroke
7. pneumocephalus: may indicate skull fracture (basal or open convexity)
8. shift of midline structures (due to extra- or intra-axial hematomas or asymmetric cerebral edema): shift can cause altered levels of consciousness (p. 921)

Indications for initial brain CT
1. presence of any moderate or high risk criteria (Table 54.7 and Table 54.8) which include: GCS ≤14, unresponsiveness, focal deficit, amnesia for injury, altered mental status (including those that are significantly inebriated), deteriorating neuro status, signs of basal or calvarial skull fracture
2. assessment prior to general anesthesia for other procedures (during which neurologic exam cannot be followed in order to detect delayed deterioration)

Follow-up CT
Routine follow-up CT (when there is no indication for urgent follow-up CT, see below):
1. many facilities perform a repeat head CT at 24 hours for patients who are clinically stable but had findings on initial head CT of: traumatic SAH, small SDH or EDH, intraparenchymal contusions
2. for patients with severe head injuries:
   a) for stable patients, follow-up CTs are usually obtained between day 3 to 5, (some recommend at 24 hrs also) and again between day 10 to 14
   b) some recommend routine follow-up CT several hours after the “time zero” CT (i.e. initial CT done within hours of the trauma) to rule-out delayed EDH (p. 894), SDH (p. 898), or traumatic contusions (p. 891)
3. for patients with mild to moderate head injuries:
   a) for those with an abnormal initial CT, the CT scan is usually repeated prior to discharge
   b) stable patients with mild head injury and normal initial CT do not require follow-up CT

Urgent follow-up CT: performed for neurological deterioration (loss of 2 or more points on the GCS, development of hemiparesis or new pupillary asymmetry), persistent vomiting, worsening H/A, seizures or unexplained rise in intracranial pressure (ICP) in patients with an ICP monitor.

54.5.2 Spine films
1. cervical spine: must be cleared radiographically from the cranio-cervical junction down through and including the C7-T1 junction. Spinal injury precautions (cervical collar…) are continued until the C-spine is cleared. The steps in obtaining adequate films are outlined in Spine injuries, Radiographic evaluation and initial C-spine immobilization (p. 952)
2. thoracic and lumbosacral LS-spine films should be obtained based on physical findings and on mechanism of injury; see Spine injuries, Radiographic evaluation and initial C-spine immobilization (p. 952)

54.5.3 Skull x-rays
A skull fracture increases the probability of a surgical intracranial injury (ICI) (in a comatose patient it is a 20-fold increase, in a conscious patient it is a 400-fold increase). However, significant ICI can occur with a normal skull x-ray (SXR) SXR (SXR was normal in 75% of minor head injury patients found to have intracranial lesions on CT, attesting to the insensitivity of SXRs). SXRs affect management of only 0.4–2% of patients in most reports.
A SXR may be helpful in the following:
1. in patients with moderate risk for intracranial injury (Table 54.7) by detecting an unsuspected depressed skull fracture (however, most of these patients will get a CT scan, which obviates the need for SXR)
2. if a CT scan cannot be obtained, a SXR may identify significant findings such as pineal shift, pneumocephalus, air-fluid levels in the air sinuses, skull fracture (depressed or linear)... (however, sensitivity for detecting ICI is very low)
3. with penetrating injuries: helps in visualization of some metallic objects
54.5.4 MRI scans in trauma

Usually not appropriate for acute head injuries. This is due to longer acquisition time, less access to patient during study, increased difficulty in supporting patient (requires special non-magnetic ventilators, cannot use most IV pumps...) and MRI is less sensitive than CT for detecting acute blood.\textsuperscript{35} There were no surgical lesions demonstrated on MRI that were not evident on CT in one study.\textsuperscript{36} There may be some additional benefit in combining CT with an MRI performed directly in the emergency department.\textsuperscript{37}

MRI may be helpful later after the patient is stabilized, e.g. to evaluate brainstem injuries, small white matter changes,\textsuperscript{38} e.g. punctate hemorrhages in the corpus callosum seen in diffuse axonal injury (p.848)… Spinal MRI is indicated in patients with spinal cord injuries.

Rapid sequence MRI may be useful for follow-up in pediatrics to minimize radiation exposure.

54.5.5 Arteriogram in trauma

Cerebral arteriogram (p.911): useful with non missile penetrating trauma.

54.6 Admitting orders for minor or moderate head injury

54.6.1 General information

Traditionally, mild head injury has been defined as GCS\geq13. However, the increased frequency of both surgical lesions and CT scan abnormalities in patients with GCS=13 suggests that they would be better classified with the moderate rather than mild head injuries.\textsuperscript{22} See Indications for CT and admission criteria for TBI (p.830) for admitting criteria.

54.6.2 Admitting orders for minor head injury (GCS\geq14)

1. activity: BR with HOB elevated 30–45°
2. neuro checks q 2 hrs (q 1 hr if more concerned; consider ICU for these patients). Contact physician for neurologic deterioration
3. NPO until alert; then clear liquids, advance as tolerated
4. isotonic IVF (e.g. NS+20 mEq KCl/L) run at maintenance (p.870): \approx 100 cc/hr for average size adult (peds: 2000 cc/m\textsuperscript{2}/d). Note: the concept of “running the patient dry” is considered obsolete
5. mild analgesics: acetaminophen (PO, or PR if NPO), codeine if necessary
6. anti-emetic: give infrequently to avoid excessive sedation, avoid phenothiazine anti-emetics (which lower the seizure threshold); e.g. use trimethobenzamide (Tigan\textsuperscript{\textregistered}) 200 mg IM q 8 hrs PRN for adults

54.6.3 Admitting orders for moderate head injury (GCS 9–13)

1. orders as for minor head injury (see above) except patient is kept NPO in case surgical intervention is needed (including ICP monitor)
2. for GCS=9–12 admit to ICU. For GCS=13, admit to ICU if CT shows any significant abnormality (hemorrhagic contusions unless very small, rim subdural…)
3. patients with normal or near-normal CIs should improve within hours. Any patient who fails to reach a GCS of 14–15 within 12 hrs should have a repeat CT at that time\textsuperscript{31}

54.7 Patients with associated severe systemic injuries

54.7.1 Intraabdominal injuries

Diagnostic peritoneal lavage (DPL) looking for bloody fluid or FAST (focused abdominal sonogram for trauma) are often used by trauma surgeons to assess for intra-abdominal hemorrhage. If negative and the patient is hemodynamically stable, the patient should be taken for cranial CT (with DPL – if the initial fluid is not bloody, the remainder of the lavage fluid may be collected for quantitative analysis as the head CT is being done).

Patients with grossly positive DPL or positive FAST and/or hemodynamic instability may need to be rushed to the O.R. for emergent laparotomy by trauma surgeons without benefit of cerebral CT. Neurosurgical management is difficult in these patients, and must be individualized. These guidelines are offered:
CAUTION: many patients with severe trauma may be in DIC (either due to systemic injuries, or directly related to severe head injury possibly because the brain is rich in thromboplastin). Operating on patients in DIC is usually disastrous. At the least, check a PT/INR/PTT if GCS >8 (which implies at least localizing)

1. if GCS >8 (which implies at least localizing)
   a) operative neurosurgical intervention is probably not required
   b) utilize good neuroanesthesia techniques (elevate head of bed, judicious administration of IV fluids, avoiding prophylactic hyperventilation…)
   c) obtain a head CT scan immediately post-op

2. if patient has focal neurologic deficit, an exploratory burr-hole should be placed in the O.R. simultaneously with the treatment of other injuries. Placement is guided by the pre-op deficit (p.836)

3. if there is severe head injury (GCS ≤8) without localizing signs, or if initial burr hole is negative, or if there is no pre-op neuro exam, then
   a) measure the ICP: insert a ventriculostomy catheter (if the lateral ventricle cannot be entered after 3 passes, it may be completely compressed or it may be displaced, and an intraparenchymal fiber-optic monitor or subarachnoid bolt should be used)
      • normal ICP: unlikely that a surgical lesion exists. Manage ICP medically and, if a IVC was inserted, with CSF drainage
      • elevated ICP (≥ 20 mm Hg): inject 3–4 cc of air into ventricles through IVC, then obtain portable intraoperative AP skull x-ray (intra-operative pneumoencephalogram) to determine if there is any midline shift. If there is mass effect with ≥ 5 mm of midline shift is explored with burr-hole(s) on the side opposite the direction of shift. If no mass effect, intracranial hypertension is managed medically and with CSF drainage
   b) routine use of exploratory burr holes for children with GCS=3 has been found not to be justified

54.7.2 Fat embolism syndrome

General information

Most often seen after a long bone fracture (usually femoral, but may include clavicular, tibial, and even isolated skull fracture). Although almost all patients have pulmonary fat emboli at autopsy, the syndrome is usually mild or subclinical, only 10–20% of cases are severe, and the fulminant form leading to multiple organ failure is rare. Clinical findings usually appear within 12–72 hrs of injury, and do not always include the complete classic clinical triad of:

• acute respiratory failure (including hypoxemia, tachypnea, dyspnea) with diffuse pulmonary infiltrates (usually seen as bilateral fluffy infiltrates). May be the only manifestation of fat emboli in up to 75% of cases

• global neurologic dysfunction: may include confusion (PaO_2 usually not low enough to account for these changes), lethargy, seizures

• petechial rash: seen ≈ 24–72 hrs after the fracture, usually over thorax

Other possible findings include:

• pyrexia

• retinal fat emboli

There is no specific test for fat embolism syndrome (FES). The following have been proposed, but have poor sensitivity and specificity: fat globules in the urine (positive in one-third) and serum, serum lipase activity. In cases of unexplained neurologic or pulmonary abnormalities, it may be possible to diagnose FES if on bronchoalveolar lavage 5% of cells in the washings staining for neutral fat with red oil. Nonspecific tests include ABG (findings: hypoxemia, hypocarbia from hyperventilation, respiratory alkalosis).

Treatment

Pulmonary support with oxygen, and mechanical ventilation if necessary including use of PEEP. The use of steroids is controversial. Ethyl alcohol (to decrease serum lipase activity) and heparin have not been shown to be of benefit. Early operative fixation of long bone fractures may reduce the incidence of FES.
Outcome
Usually related more to the underlying injuries. Although FES itself is usually compatible with good recovery, 10% mortality is usually quoted.

54.7.3 Indirect optic nerve injury
General information
≈ 5% of head trauma patients manifest an associated injury to some portion of the visual system. Approximately 0.5–1.5% of head trauma patients will sustain indirect injury (as opposed to penetrating trauma) to the optic nerve, most often from an ipsilateral blow to the head (usually frontal, occasionally temporal, rarely occipital). The optic nerve may be divided into 4 segments: intraocular (1 mm in length), intraorbital (25–30 mm), intracanalicular (10 mm), and intracranial (10 mm). The intracanalicular segment is the most common one damaged with closed head injuries. Funduscopic abnormalities visible on initial exam indicates anterior injuries (injury to the intraocular segment (optic disc) or the 10–15 mm of the intraorbital segment immediately behind the globe where the central retinal artery is contained within the optic nerve), whereas posterior injuries (occurring posterior to this but anterior to the chiasm) takes 4–8 weeks to show signs of disc pallor and loss of the retinal nerve fiber layer.

Treatment
See reference. No prospective study has been carried out. Optic nerve decompression has been advocated for indirect optic nerve injury, however, the results are not clearly better than expectant management with the exception that documented delayed visual loss appears to be a strong indication for surgery. Tranasethmoidal is the accepted route, and is usually done within 1–3 weeks from the trauma. The use of “megadose steroids” may be appropriate as an adjunct to diagnosis and treatment.

54.7.4 Post-traumatic hypopituitarism
Trauma is a rare cause of hypopituitarism. It may follow closed head injury (with or without basilar skull fracture) or penetrating trauma. In 20 cases in the literature all had deficient growth hormone and gonadotropin, 95% had corticotropin deficiency, 85% had reduced TSH, 63% had elevated PRL. Only 40% had transient or permanent DI.

54.8 Exploratory burr holes
54.8.1 General information
In a trauma patient, the clinical triad of altered mental status, unilateral pupillary dilatation with loss of light reflex, and contralateral hemiparesis is most often due to upper brainstem compression by uncal transtentorial herniation which, in the majority of trauma cases, is due to an extraaxial intracranial hematoma. Furthermore, the prognosis of patients with traumatic herniation is poor. Outcome may possibly be improved slightly by increasing the rapidity with which decompression is undertaken, however, an upper limit of salvageability is probably still only ≈ 20% satisfactory outcome.

Burr holes are primarily a diagnostic tool, as bleeding cannot be controlled and most acute hematomas are too congealed to be removed through a burr hole. However, if the burr hole is positive, it is possible that modest decompression may be performed, and then the definitive craniotomy can be undertaken incorporating the burr hole(s).

With widespread availability of quickly accessible CT scanning, exploratory burr holes are infrequently indicated.

54.8.2 Indications
1. clinical criteria: based on deteriorating neurologic exam. Indications in E/R (rare): patient dying of rapid transtentorial herniation (see below) or brainstem compression that does not improve or stabilize with mannitol and hyperventilation. The indicators of transtentorial herniation/brainstem compression:
   a) sudden drop in Glasgow Coma Scale (GCS) score
   b) one pupil fixes and dilates
paralysis or decerebration develops (usually contralateral to blown pupil)

b) recommended situations where criteria should be applied:
   - neurologically stable patient undergoes witnessed deterioration as described above
   - awake patient undergoes same process in transport, and changes are well documented by
     competent medical or paramedical personnel

2. other criteria
   a) some patients needing emergent surgery for systemic injuries (e.g. positive peritoneal lav-
      age + hemodynamic instability) where there is not time for a brain CT (p. 834)

54.8.3 Management

Controversial. The following should serve only as guidelines:

1. if patient fits the above criteria (emergent operation for systemic injuries or deterioration with
   failure to improve with mannitol and hyperventilation), and CT scan cannot be performed and
   interpreted immediately, then treatment should not wait for CT scan
   a) in general, if the O.R. can be immediately available, burr holes are preferably done there
      (equipped to handle craniotomy, better lighting and sterility, dedicated scrub nurse…) espe-
      cially in older patients (>30 yrs) not involved in MVAs (below). This may more rapidly diag-
      nose and treat extraaxial hematomas in herniating patients, although no difference in
      outcome has been proven
   b) if delay in getting to the O.R. is foreseen, emergency burr holes in the E/R should be
      performed

2. placement of burrhole(s) as outlined under Technique below

54.8.4 Technique

Position

Shoulder roll, head turned with side to be explored up. Three pin skull-fixation used if concern about
possible aneurysm or AVM (to allow for retractors and increased stability) or if additional stability is
desired (e.g. with unstable cervical fractures), otherwise a horse-shoe head-holder suffices and saves
time and makes it easier to turn the head to access to the other side if needed.

Choice of side for initial burr hole

Start with a temporal burr hole (see below) on the side:

1. ipsilateral to a blown pupil. This will be on the correct side in >85% of epidurals and other
   extra-axial mass lesions
2. if both pupils are dilated, use the side of the first dilating pupil (if known)
3. if pupils are equal, or it is not known which side dilated first, place on side of obvious external
   trauma
4. if no localizing clues, place hole on left side (to evaluate and decompress the dominant
   hemisphere)

Approach

Burr holes are placed along a path that can be connected to form a “trauma flap” if a craniotomy
becomes necessary (Fig. 54.2). The “trauma flap” is so-called because it provides wide access to
most of the cerebral convexity permitting complete evacuation of acute blood clot and control of
most bleeding.

First outline the trauma flap with a skin marker:

1. start at the zygomatic arch <1 cm anterior to the tragus (spares the branch of the facial nerve to
   the frontalis muscle and spares the anterior branch of the superficial temporal artery(STA))
2. proceed superiorly and then curve posteriorly at the level of top of the pinna
3. 4–6 cm behind the pinna it is taken superiorly
4. 1–2 cm ipsilateral to the midline (sagittal suture) curve anteriorly to end behind the hairline

Burr hole locations

1. first (temporal) burrhole: over middle cranial fossa (#1 in Fig. 54.2) just superior to the zygo-
   matic arch. Provides access to middle fossa (the most common site of epidural hematoma) and
   usually allows access to most convexity subdural hematomas, as well as proximity to middle me-
   ningeal artery in region of pterion
2. If no epidural hematoma, the dura is opened if it has bluish discoloration (suggests subdural hematoma (SDH)) or if there is a strong suspicion of a mass lesion on that side.
3. If completely negative, usually perform temporal burr hole on contralateral side.
4. If negative, further burr holes should be undertaken if a CT cannot now be done.
5. Proceed to ipsilateral frontal burr hole (#2 in Fig. 5.4.2).
6. Subsequent burr holes may be placed at parietal region (#3 in Fig. 5.4.2) and lastly in posterior fossa (#4 in Fig. 5.4.2).

**Literature**

In 100 trauma patients undergoing transtentorial herniation or brainstem compression as outlined above, exploratory burr holes (bilateral temporal, frontal and parietal, done in the O.R.) were positive in 56% lower rates in younger patients (<30 yrs) and those in MVAs (as opposed to falls or assaults). SDH was the most common extraaxial mass lesion (alone and unilateral in 70% bilateral in 11% and in combination with EDH or ICH in >9%).

When burr holes were positive, the first burr hole was on the correct side 86% of the time when placed as suggested above. Six patients had significant extraaxial hematomas missed with exploratory burr holes (mostly due to incomplete burr hole exploration). Only 3 patients had the above neurologic findings as a result of intraparenchymal hematomas.

**Outcome**

Mean follow-up: 11 mos (range: 1–37). 70 of the 100 patients died. No morbidity or mortality was directly attributable to the burr holes. Four patients with good outcome and 4 with moderate disability had positive burr holes.

55 Concussion, High Altitude Cerebral Edema, Cerebrovascular Injuries

55.1 Concussion

55.1.1 General information

Key concepts

- A traumatic biomechanically induced complex pathophysiological process affecting the brain with no identifiable structural abnormalities on imaging studies
- Concussion is a subset of mild TBI (mTBI) and is therefore not equivalent to mTBI
- Indicators of concussion: post-traumatic alterations in any of: orientation, balance, speed of reaction, and/or impaired verbal learning and memory in a patient with GCS 13–15\(^1\)
- Does not require loss of consciousness (LOC) or even a direct blow to the head
- Grading scales have been abandoned in favor of experienced assessment assisted by various “side-line” tools

Concussion occurs in a subset of patients with mild traumatic brain injury (mTBI; Fig. 54.1). It is considered “mild” because it is usually not life-threatening by itself. While most patients recover completely, effects of concussion can be serious, and in some instances, may be lifelong.

Much of the discussion in this chapter relates to concussion in sports which, is the largest source of data on the subject, and generalization to other types of trauma must be done circumspectly.

There has been a move away from grading scales for concussion, and the current recommendation is for the diagnosis to be determined in the judgement of an experienced examiner with the assistance of various assessment tools, ideally with the availability of pre-injury baseline metrics for comparison.

Concussion can occur without a direct blow to the head, e.g. with violent shaking of the torso and head. Concussion symptoms can present soon after an insult or in a delayed fashion.

The subject may not be aware that they have sustained a concussion.

55.1.2 Epidemiology

Incidence: 1.6–3.8 million concussions occur per year in the United States from sports and recreational activities. It is estimated that 50% of concussions go unreported.\(^2\)

55.1.3 Concussion genetics

There is no clear evidence to support a genetic predisposition to concussion. Apolipoprotein E4, Apo E G-219 T promoter and tau exon 6 have been studied in small retrospective and prospective trials without definitive association.\(^2,3\)

55.1.4 Concussion – definition

There is no universally accepted definition for concussion.\(^4\) Of the many contemporary definitions,\(^2,3,4,5,6,7\) most key elements are contained in the Concussion in Sport Group 2012 consensus definition\(^3\) summarized below. However, opinions differ e.g. whether there is any long-term effect of concussion or if that necessitates a different diagnosis.

Definition: Concussion is a complex pathophysiological process affecting the brain resulting in alteration of brain function, that is induced by nonpenetrating biomechanical forces, without identifiable abnormality in standard structural imaging.

The Concussion in Sport Group\(^5\) elaborates on this definition as follows:
- Results in a graded set of neurological symptoms that may or may not involve loss of consciousness (LOC).
- Symptom onset is usually rapid, short-lived and resolves spontaneously. Manifestations may include transient deficits in balance, coordination, memory/cognition, strength, or alertness.
• May result in neuropathological changes, but the acute clinical symptoms largely reflect a functional disturbance rather than a structural injury.
• Resolution of the clinical and cognitive features typically follows a sequential course.
• Typically associated with grossly normal standard structural neuroimaging studies.

55.1.5 Concussion versus mTBI
• Concussion and mTBI are not interchangeable. Concussion may be thought as a subclass of mTBI on the less severe end of the brain injury spectrum, though with similar clinical symptoms. A major difference between the two is that mTBI may demonstrate abnormal structural imaging (such as cerebral hemorrhage/contusion) and concussion, by definition, must have normal imaging studies. mTBI is part of an injury severity spectrum primarily based on GCS score. TBI is evaluated 6 hours after injury and differentiated into mild, moderate and severe; see Grading (p. 824). Concussion is evaluated directly after the insult and based on a clinical diagnosis aided by a multitude of standardized assessment tools. To include concussion under the full spectrum of traumatic brain injury then it must fall at the low end of mTBI and overlap with the subset of “minimal” injury. Most mTBIs with negative imaging can be considered concussions but the majority of sports concussions cannot be classified as mTBI.

55.1.6 Risk factors for concussion
• History of previous concussion increases risk for further concussion
• Being involved in an accident: bicyclist, pedestrian or motor vehicle collision
• Combat soldier
• Victim of physical abuse
• Falling (especially pediatrics or elderly)
• Males are diagnosed with sports-related concussion more than females (due to increased number of male participation in sports studied) but females have a higher risk overall when compared to males who play in the same sport. (i.e. soccer and basketball)
• Participating in sports with high risk of concussion:
  ○ American football
  ○ Australian rugby
  ○ Ice hockey
  ○ Boxing
  ○ *Soccer is the highest risk for females
• (For contrast, sports with the lowest risk of concussion: baseball, softball, volleyball & gymnastics)
• BMI > 27 kg/m² and less than 3 hours of training per week increase risk of sports-related concussion

55.1.7 Diagnosis

Triggers
Findings suggestive of concussion are listed in Table 55.1. The diagnosis of concussion should be considered when any of these findings occur following trauma. In pre-verbal children, findings may include those in Table 55.2.

General diagnostic information

Clinical evaluation
No physiologic measure has been identified that can detect the underlying changes that lead to the manifestations of concussion. Therefore the diagnosis relies on: self-reporting of abnormal function (symptoms), observed physiologic abnormalities (signs) including assessment of cognitive dysfunction, sometimes with the assistance of imaging tests to rule out a structural substrate.

A clinical diagnosis of concussion is made if there are abnormal findings in balance, coordination, memory/cognition, strength, reaction speed or alertness after a traumatic insult to the head. Findings include confusion, amnesia, headache, drowsiness or LOC (LOC is not a requirement for diagnosing concussion; patients themselves may be unaware whether or not they experienced LOC). Frequent neurobehavioral features of concussion are shown in Table 55.1. In children who may not be able to verbalize their symptoms, evidence of concussion may include findings in Table 55.2. Positive imaging findings would necessitate a more severe diagnosis such as cerebral contusion.
Approach

- Take a concussion specific symptom survey including inquiries about: H/A, N/V, light sensitivity, tinnitus, feeling like being in a fog, sleep disturbances
- History of diagnoses that might have an impact on the assessment or on a current concussion
  - History of prior concussions
  - H/A history
  - ADD/HD
  - Learning disabilities
  - Medications (prescribed and other) that might affect alertness or cognition
- Perform a good general neurological exam
- Include a concussion specific neuro exam
  - Check orientation
  - Assess for amnesia and impaired verbal memory
  - Balance: Romberg test (look for significant sway or breaking stance), single leg stance
  - Eye movements: optokinetic nystagmus (OKN), smooth pursuit
  - Simultaneous task performance: e.g. snap fingers while walking
- Include assessment aids (“sideline tools”) as appropriate (see below)

Assessment aids

- There is no single validated assessment tool for diagnosis of concussion. It is primarily a clinical diagnosis that is ideally made by certified healthcare providers who are familiar
with the patient based on a detailed history and physical examination and a continuum of evaluation from the sideline to the clinic (diagnosis is ideally within made within 24 hours of injury)\(^2,3,4,5,6,7\)

- Diagnosis may be aided by concussion assessment tools such as the SCAT3, ImPACT\(^\text{™}\).

  No test has shown high validity on independent testing, and no test should be used as the sole method of diagnosing concussion or for determining suitability for return to play. Athletes have also learned to “game” some baseline tests to avoid removal from play after possible concussion.

- SCAT3 (Sports Concussion Assessment Tool – 3rd Edition)\(^12\): Derived from the 2012 Zurich Conference.\(^3\) The SCAT has become the most commonly used standardized tool for sideline assessment of sport concussion. The sensitivity and specificity of concussion assessment tools change over the course of a concussion so a tool designed for sideline use (i.e. SCAT3) is not appropriate for office use.

  - SCAT3\(^\text{™}\) is a trademarked tool developed by the Concussion in Sports Group for use only by medical professionals for assessing sports-related concussion.
  - It can be found at [http://bjsm.bmj.com/content/47/5/259.full.pdf](http://bjsm.bmj.com/content/47/5/259.full.pdf).
  - To be used in athletes of 13 years or older (for 12 and younger, use Child SCAT3\(^13\))
  - It is a multimodal assessment tool with 8 sections that includes self-reported symptoms and evaluation of functional domains such as cognition, memory, balance, gait and motor skills
  - Takes 8–10 m to administer
  - A “normal” SCAT3 does not rule out concussion
  - It has not been validated

- Other types of sports concussion assessment tools (many can be viewed on YouTube):
  - Neurocognitive testing (may take up to 20 minutes to administer)
  - SAC (Standardized Assessment of Concussion)\(^14\): a neurocognitive test that includes tests of immediate memory, delayed recall, serial 7’s, digit span
  - ImPACT\(^\text{™}\) (Immediate Post-Concussion Assessment and Cognitive Testing): a widely used commercially produced computer test ([https://www.impacttest.com](https://www.impacttest.com)). Independent validation studies have yielded conflicting results and results can diverge from observations\(^15\)
  - PCSS (Post-Concussive Symptom Scale)
  - CSI (Concussion Symptom Inventory)
  - BESS (Balance Error Scoring System): the subject stands in each of various standardized positions for 20 seconds each, and the number of errors are recorded (breaking stance, opening eyes, taking hands off hip…).
  - SOT (Sensory Organization Test)
  - “Concussion Quick Check” app for mobile devices produced by the AAN
  - King-Devick eye movement testing: only takes 2–3 minutes to administer. On printed cards or tablet computer ([http://kingdevicktest.com](http://kingdevicktest.com)/for-concussions/).

- Formal neuropsychological testing: it is recommended that this be reserved for patients with prolonged cognitive symptoms

- Concussion serum biomarkers: no moiety has been identified that can reliably diagnose concussion on serum or saliva testing. Neuron-specific enolase, S100, and cleaved tau protein have been studied for prognostication after mTBI and concussion. S100 has demonstrated only a 33.3% sensitivity for postconcussive symptoms and 93% sensitivity for an Extended Glasgow Outcome Scale < 5 at 1 month. Another study involving pediatric patients with mTBI showed no difference in levels of neuron-specific enolase or S100B in asymptomatic and symptomatic children. A prospective study found no significant correlation between cleaved tau protein and postconcussive syndrome in patients with mTBI\(^16\)

**On-site/sideline evaluation**

Any individual suspected of having a concussion (displaying ANY findings in Table 55.1) should be removed from the activity (for athletes, stopped from playing) and assessed by a licensed healthcare provider trained in the evaluation and management of concussions with attention to excluding a cervical spine injury.\(^2,3\) If no provider is available, return to the activity is not permitted and urgent referral to a physician should be arranged.

After ruling out emergency issues, the provider should perform a concussion assessment (may employ standardized tools such as SCAT3\(^\text{™}\) or other methodologies).

The patient should not be left alone, and serial evaluations for signs of deterioration should be made over the following few hours.

For return to play guidelines, see below.
55.1.8 Indications for imaging or other diagnostic testing

Imaging in concussion is typically used to rule out more serious traumatic injuries. Indications for CT or MRI imaging:

- Adults with or without LOC or amnesia
  - Focal neurologic deficit
  - GCS < 15
  - Severe headache
  - Coagulopathy
  - Vomiting
  - Age > 65 years old
  - Seizures
- Peds
  - LOC > 60 secs
  - Evidence of skull fracture
  - Focal neurologic deficit

Other imaging studies:

- Diffusion Tensor Imaging (DTI): used to quantify white matter tract integrity throughout the brain with 4 types of analysis methods – voxel analysis, region of interest (ROI) analysis, histogram analysis, and tractography. There is no strong consensus regarding the best method for utilizing DTI for diagnosis or prognosis in the individual patient but multiple studies have shown group differences in DTI parameters between mTBI and control patients.  
- Functional MRI (fMRI): consists of 2 types (task-based fMRI and resting state fMRI) and is based on the blood oxygen level dependent (BOLD) effect, in which specialized MRI sequences measure/detect regions of increased oxygen rich blood flow to areas of upregulated neuronal activity. Both task-based and resting state fMRI modalities have shown group differences between mTBI and control patients (specifically in frontal lobe dysfunction) but further studies need to be completed on both a single time point and longitudinal basis before these techniques can be widely adopted for individual diagnosis and therapeutic guidance.
- Imaging studies that are currently used primarily in concussion research: positron emission tomography (PET), single photon emission CT (CT-SPECT), MR-spectroscopy (MRS).

Quantitative EEG (QEEG) is another research tool for concussion that assesses brain activity, patterns of cortical activation and neuronal networks. The concept is that post-concussion studies are compared to baseline. Currently undergoing proof of concept evaluation.

55.1.9 Acute pathophysiology

Biomechanical force results in unregulated ionic (K⁺ efflux, Na⁺/Ca²⁺ influx) flux and unrestricted hyperacute glutamate release from sublethal mechanoporation of lipid membranes at the cellular level. This triggers voltage/ligand gated ion channels causing a cortical spreading depression-like state that is thought to be the substrate behind immediate postconcussive symptoms. Subsequently, ATP-dependent ionic pumps are extensively upregulated to restore cellular homeostasis causing widespread intracellular energy reserve depletion and an increase in ADP. Cells then pass into a state of impaired metabolism (energy crisis) that can last up to 7–10 days and may be associated with alterations in CBF. This impaired metabolic state is associated with vulnerability to repeat injury as well as behavioral and spatial learning impairments. Cells also undergo cytoskeletal damage, axonal

dysfunction, and altered neurotransmission with the as yet unproven impression that each of these pathologic processes correlate with a separate symptomology.17

55.1.10 Post concussion syndrome (PCS)

Occurs in 10% -15% of concussed individuals. As with most concussion related pathologies, there are multiple definitions of PCS. An amalgam of some definitions is as follows: Patients having ≥3 symptoms including headache, fatigue, dizziness, irritability, difficulty concentrating, memory difficulty, insomnia, and intolerance to stress, emotion, or alcohol, and symptoms must begin within 4 weeks of injury and remain for ≥1 month after onset of symptoms.16,18 In one retrospective study, the following conclusions were reached18:

- >80% of PCS patients had at least 1 previous concussion
- average number of previous concussions was 3.4
- median duration of PCS was 6 months
- 50% of patients were <18 years of age
- LOC does not increase the risk for PCS

55.1.11 Prevention of concussion

- The AAN guidelines conclude that protective headgear in rugby is “highly probable” to decrease the incidence of concussion.7 However, the AMSSM (American Medical Society for Sports Medicine) hold that there is no clear evidence that soft or hard helmets reduce the severity or incidence of concussion (in football, lacrosse, hockey, soccer, and rugby).2,3 Biomechanical studies have shown helmets reduced impact forces on the brain but this has not translated into concussion prevention.3
- There is insufficient data to determine whether one type of football helmet protects better than another in preventing concussions3,7
- No significant evidence that a mouthpiece protects against concussion3,7

55.1.12 Management of concussion and post-concussion syndrome

Return to Play (RTP)

- No system of return to play (RTP) guidelines has been rigorously tested and proven to be scientifically sound
- After sustaining a concussion, athletes should not return to play the same day.2,3,4,5,6,7 Prohibited by some state laws.
- a symptomatic player should not return to competition.
- If there is any uncertainty: “When in doubt, sit them out”
- Evaluation should proceed in a stepwise fashion. A player needs to be completely asymptomatic both at rest and with provocative exercise before full clearance is given.3 There is no standardized RTP protocol. Each player’s progression should be individualized.2 Generally, the athlete’s level of activity should be gradually increased over 24 hour increments from light aerobic activity to full contact practice. The athlete is evaluated after each progression. If postconcussive symptoms occur then the player is dropped back to the previous asymptomatic level and then allowed another attempt at progression after a 24-hour rest period. 80–90% of concussions resolve within 7–10 days. This recovery time may be longer for children or adolescents.3
- The CDC endorses a graded 5-step return to play for student athletes19 as shown in Table 55.4. The athlete should move to the next step only if they have no new symptoms. If symptoms return or new ones develop, then medical attention should be sought and, after clearance the student can return to the previous step.

Contraindications for return to play are shown in Table 55.5.

Management of post-concussive syndrome

An extremely complicated topic, partly because of potential for litigation and the fact that symptoms are often vague and nonspecific and there may be no objective findings to corroborate subjective symptoms.

Most symptoms from concussion resolve within 7–10 days and do not require treatment. The most common exception to this is post-traumatic headache, the most common subtype being acute post-traumatic migraine.
Typical symptoms include: H/A, dizziness, insomnia, exercise intolerance, depression, irritability, anxiety, memory loss, difficulty concentrating, fatigue, light or noise hypersensitivity. Patients with protracted symptoms may require more directed treatment.

- Psychological and neuropsychological involvement is often employed.
- Pharmacologic treatment: there are no evidence-based studies of the utility of medications for post-concussive symptoms (aside from H/A).

Intractable headaches: occur in ≈15% of concussions

- Expert neurology consultation is usually required for difficult to control headaches
- The first line drugs are OTC medications
- Triptans are usually employed for nonresponders
- Third line drugs include Ketorolac or DHE-45 (dihydroergotamine)
- Steroids may be beneficial for some
- Avoid: narcotics, butalbital/caffeine preparations (Fioricet, Esgic…), beta blockers and calcium channel blockers

### 55.1.13 Second impact syndrome (SIS)

A rare condition described primarily in athletes who sustain a second head injury while still symptomatic from an earlier one. Classically, the athlete walks off the field under their own power after the second injury, only to deteriorate to coma within 1–5 minutes and then, due to vascular engorgement, develops malignant cerebral edema that is refractory to all treatment and progresses to herniation. Mortality: 50–100%.

A syndrome compatible with SIS was first described by Schneider\(^2^5\) in 1973, and was later dubbed the “second impact syndrome of catastrophic head injury” in 1984.\(^2^4\) Although it is contended that SIS is rare (if it exists at all) and may be overdiagnosed,\(^2^2\) its apparent predilection for teens and children still warrants extra precaution following concussion.

### 55.1.14 Chronic traumatic encephalopathy (CTE)

There is limited evidence-based research involving the pathophysiology and natural history of CTE. Thought to be a distinct neurodegenerative disease (taupathy) associated with repetitive brain trauma, not limited to athletes with reported concussions, and can only be diagnosed postmortem with a pathology-confirmed analysis. Small studies have shown that there is a variable age of onset with variable behavioral, mood, and cognitive deficits present at the time of death (92% symptomatic at time of death).\(^1^0,^1^6\)

See section about CTE (p. 924) for further details.
55.2 Other TBI definitions

55.2.1 Contusion

A contusion is a TBI with CT findings that may include:

- low attenuation areas: representing associated edema
- high attenuation areas (AKA “hemorrhagic contusions”): usually produce less mass effect than their apparent size. Most common in areas where sudden deceleration of the head causes the brain to impact on bony prominences (e.g., temporal, frontal and occipital poles). These areas may progress (or “blossom” in neuroradiological jargon) to frank parenchymal hemorrhages. Surgical decompression may sometimes be considered if herniation threatens (p.891).

55.2.2 Contrecoup injury

(French: “counter blow”) in addition to the potential injury to the brain directly under the point of impact, the force imparted to the head may cause the brain to be thrust against the skull directly opposite the blow. May result in contusions typically in locations described above.

55.2.3 Other definitions

Posttraumatic brain swelling

This term encompasses two distinct processes:

1. increased cerebral blood volume: may result from loss of cerebral vascular autoregulation (p.856). This hyperemia may sometimes occur with extreme rapidity, in which case it has sometimes been referred to as diffuse or “malignant cerebral edema”23 which carries close to 100% mortality and may be more common in children. Management consists of aggressive measures to maintain ICP <20 mm Hg and CPP >60 mm Hg.24 CPP ≥70 mm Hg is generally recommended, see ICP treatment threshold (p.866).

2. true cerebral edema: classically at autopsy these brains “weep fluid.”25 Both vasogenic and cytotoxic cerebral edema (p.90) can occur within hours of head injury25,26 and occasionally may be treated with decompressive craniectomy (p.891).

Diffuse axonal injury (DAI) (AKA diffuse axonal shearing)

A primary lesion of rotational acceleration/deceleration head injury.27 In its severe form, hemorrhagic foci occur in the corpus callosum and dorsolateral rostral brain stem with microscopic evidence of diffuse injury to axons (axonal retraction balls, microglial stars, and degeneration of white matter fiber tracts). Often cited as the cause of loss of consciousness in patients rendered immediately comatose following head injury in the absence of a space occupying lesion on CT (although DAI may also be present with subdural or epidural hematomas29).

May be diagnosed clinically when loss of consciousness (coma) lasts >6 hours in absence of evidence of intracranial mass or ischemia. May be graded as shown in Table 55.6.

55.3 High-altitude cerebral edema

Acute high-altitude sickness (AHAS) is a systemic disorder that affects individuals usually within 6–48 hrs after ascent to high altitudes. Acute mountain sickness (AMS) is the most common form of AHAS, with symptoms of nausea, headache, anorexia, dyspnea, insomnia and fatigue.31

<table>
<thead>
<tr>

</tbody>
</table>
and is often assessed using the Lake Louise system.\textsuperscript{32} The incidence is \( \approx 25\% \) at 7,000 feet, and \( \approx 50\% \) at 15,000 feet. Other symptoms of AHAS include edema of feet and hands, and pulmonary edema (HAPE=high altitude pulmonary edema). Ocular findings include retinal hemorrhages,\textsuperscript{33} nerve fiber layer infarction, papilledema and vitreous hemorrhage.\textsuperscript{34} Cerebral edema (HACE=high altitude cerebral edema), usually associated with pulmonary edema, may occur in severe cases of AHAS. Symptoms of HACE include: severe headache, mental dysfunction (hallucinations, inappropriate behavior, reduced mental status), and neurologic abnormalities (ataxia, paralysis, cerebellar findings).

The unproven “tight-fit” hypothesis postulated that individuals with less compliant CSF systems (smaller ventricles and CSF spaces) were more vulnerable to AMS.\textsuperscript{35} A small study of 10 volunteers\textsuperscript{36} analyzing CT scans before ascent and symptoms showed a trend that supports the hypothesis.

Prevention: gradual ascent, 2–4 day acclimatization at intermediate altitudes (especially to include sleeping at these levels), avoidance of alcohol or hypnotics.

Treatment of cerebral edema: immediate descent and oxygen (6–12 L/min by NC or face-mask) are recommended. Dexamethasone 8 mg PO or IV followed by 4 mg q 6 hrs may help temporize.

55.4 Traumatic cervical artery dissections
55.4.1 General information

Cervical arterial dissections are a subset of cervical cerebrovascular injuries as shown below.

Cervical cerebrovascular injuries:
\begin{itemize}
  \item penetrating injury (p.1017)
  \item traumatic dissection: the subject of this chapter
    \begin{itemize}
      \item due to blunt trauma
      \item due to stretching: e.g. from neck hyperextension or therapeutic spinal manipulation
      \item iatrogenic: dissection caused by intimal tear from angiography catheters
    \end{itemize}
  \item traumatic compression or occlusion
    \begin{itemize}
      \item kinking from malalignment: e.g. with cervical fracture-dislocation
      \item compression by bone fragments: e.g. by fractures through foramen transversarium
    \end{itemize}
\end{itemize}

This chapter deals with traumatic cervical artery dissections. There is significant overlap with spontaneous cerebrovascular arterial dissections (p.1322), however, features that are more pertinent to post-traumatic dissections are covered here.

Optimal screening, diagnostic and treatment methods are controversial. A 13% mortality rate is considered low. Nearly one-third of patients are not treatable.

55.4.2 Epidemiology

Incidence: 1–2% of blunt trauma patients\textsuperscript{37} (among those who stayed \( \geq 24 \) hrs in a trauma hospital the incidence was 2.4\%\textsuperscript{37}).

55.4.3 Risk factors

Traumatic risk factors for blunt cerebrovascular injury (BCVI) are shown in Table 55.7. Risk factors not directly related to the type of trauma include fibromuscular dysplasia, where dissections may follow minor injuries because of increased susceptibility. BCVI can occur even in the absence of identifiable risk factors.\textsuperscript{37}

55.4.4 Presentation

Signs and symptoms of BCVI are shown in Table 55.8.

55.4.5 Evaluation of patients with risk factors or signs/symptoms of BCVI

The following is an adaptation of the guidelines of the Western Trauma Association flow chart\textsuperscript{39} (including footnotes!) into an outline format. Their recommendations are based on observational studies and expert opinion (no Class I data was available).

NB: CTA on scanners with \( \geq 16 \) detectors (16-slice multidetector CT angiography, (16MD-CTA) have an accuracy near 99\%\textsuperscript{40} & equivalent predictive value to cerebral angiogram. MRA\textsuperscript{41,42} and
ultrasound are not considered adequate for BCVI screening. If unavailable, then catheter angiography should be employed.

1. 16MD-CTA should be obtained as follows:
   a) emergently in patients with signs/symptoms of BCVI (Table 55.8)
   b) asymptomatic patients with risk factors (Table 55.7) for BCVI:
      • if the presence of BCVI would alter therapy (e.g. no contraindication to heparin) then MDCTA should be done within 12 hours if possible
      • if heparin is contraindicated due to associated injuries, timing of MDCTA is determined by patient stability

2. if the MDCTA is equivocal, or if it is negative but clinical suspicion remains high: a catheter arteriogram should be done (otherwise, if negative: stop)
3. grading: if the MDCTA or the arteriogram shows positive findings (p.1324):
   a) the injury is graded using the scale shown in Table 55.9 (sometimes referred to as the “Denver grading scale”)
   b) proceed with grade-based management (see below)

55.4.6 Management of documented BCVI

Antiplatelet therapy is as effective in preventing stroke as anticoagulation for cerebrovascular dissection.

Grade specific therapy
• Grade I & II
  o Most resolve on their own
  o Even though there might be a slight benefit of heparin over aspirin for low grade injuries, due to the low overall risk the general trend is to treat these with aspirin
• Grade III
  o Anticoagulate with heparin. Rationale: heparin and aspirin are roughly equivalent for Grade III, however, most will need to be restudied in 7-10 days
  o Repeat angiogram or 16MD-CTA 7-10 days post-injury. See below for subsequent management
• Grade IV: endovascular occlusion to prevent embolization
• Grade V: highly lethal injury
  o accessible lesions should be considered for urgent surgical repair (anecdotal)
  o inaccessible lesions (the majority): incomplete transection may be amenable to endovascular stenting with concurrent antithrombotics; complete transections should be ligated (or occluded endovascularly)

Table 55.7 Traumatic risk factors for BCVI

- high energy transfer mechanism associated with:
  o displaced mid face fracture: LeFort fracture type II or III (p.887)
  o basilar skull fracture involving carotid canal
- TBI consistent with DAI and GCS<6
- cervical vertebral body or transverse foramen fracture, subluxation, or ligamentous injury at any level
- any fracture involving Cl–3
- near hanging with anoxic brain injury
- clothesline-type injury or seat belt abrasion with significant cervical swelling, pain, or mental status changes

Table 55.8 Signs & symptoms of BCVI

- arterial hemorrhage from neck/nose/mouth (? go to O.R.)
- cervical bruit in pt.<50 yrs old
- expanding cervical hematoma
- focal neurologic deficit: TIA, Horner's syndrome, hemiparesis, VBI
- neurologic deficit inconsistent with head CT
- stroke on CT or MRI
For Grade III repeat MDCTA or angiography 7–10 days post injury to assess healing. Results:
- lesion healed: discontinue anticoagulation
- non-healed lesions:
  - consider endovascular stenting “with caution” for severe luminal narrowing or expanding pseudoaneurysm (controversial: results have been mixed – favorable and unfavorable)
  - transition from heparin to aspirin (75–150 mg/d) alone
  - repeat MDCTA or angiography 3 months post injury (rationale: most heal with canalization in 6 wks). Results:
    - healed lesion: consider discontinuing aspirin
    - non-healed: optimal drug and duration is not known. Recommendation: lifelong antiplatelet therapy with either aspirin or clopidogrel. Dual therapy is used for acute coronary syndromes and following angioplasty (± stenting) but is not recommended in patients who have had a stroke or TIA.

Heparinization:
When anticoagulation is employed, perform a baseline PTT and then begin heparin drip 15 U/kg/hr IV. Repeat PTT after 6 hours, and titrate to PTT = 40–50 seconds.
Trauma contra-indications to anticoagulation: patients that are actively bleeding, have potential for bleeding, or in whom the consequences of bleeding are severe. Specific examples include: liver and spleen injuries, major pelvic fractures, and intracranial hemorrhage.
Dissection-related anticoagulation risks include: extension of the medial hemorrhage (with possible SAH), and intracerebral hemorrhage (conversion of pale infarct to hemorrhagic).

55.4.7 Carotid artery blunt injuries

General information
See general information related to cerebral arterial dissections and spontaneous dissections (p.1322). For evaluation and management, see above.
This section considers blunt (i.e. nonpenetrating) specifically related to ICA dissection. Neck hyperextension with lateral rotation is a common mechanism of injury, and is thought to stretch the ICA over the transverse processes of the upper cervical spine. In posttraumatic dissection, ischemic symptoms are the most common.

Etiologies:
1. following MVAs: the most common etiology
2. attempted strangulation
3. spinal manipulation therapy: VA dissections are more common than ICA

Most carotid dissections start ≈ 2 cm distal to the ICA origin.

Clinical
The risk of stroke with various ICA dissection grades is shown in Table 55.10. The risk of stroke increases with increasing grade for ICA injuries. This does not hold true for VA injuries.
Grade I injuries: 70% heal with or without heparin. 25% will persist. 4–12% will progress to more severe grade. Data suggests that anticoagulation reduces the risk of progression.
Grade II: ≈ 70% progress to more severe grade even with heparin therapy.
Grade III & IV: most persist.
Initially, there may be no neurologic sequelae, however, progressive thrombosis, intramural hemorrhage or embolic phenomenon may develop in a delayed fashion. The distribution of time delays following trauma to time of presentation are shown in Table 55.11 (the majority are evident within the 1st 24 hours).

Management
See Management of documented BCVI (p. 849).

Outcome
Natural history is not well known. Many patients with minor symptoms may not present and presumably do well. In one series, 75% of patients returned to normal, 16% had a minor deficit, and 8% had a major deficit or died.\(^5\)

55.4.8 Vertebral artery blunt injuries

General information
See anatomy of vertebral artery segments (p. 80).

Blunt vertebral artery injury (BVI) is very rare, being found in 0.5–0.7% of patients with blunt injuries with aggressive screening.\(^5\) It may produce vertebrobasilar insufficiency (VBI) or posterior circulation stroke. Fractures through the foramen transversarium, facet fracture-dislocation, or vertebral subluxation are frequently identified in patients with BVI\(^38,55,56\) (overall incidence increases to 6% in the presence of cervical fracture or ligamentous injury\(^54\)).

Etiologies
While motor vehicle accidents are the most common mechanism of injury, any trauma that can injure the C-spine can cause BVI (diving accidents, spinal manipulation...).

1. automobile accidents
2. spinal manipulation therapy (SMT): including chiropractic\(^37\) or similar, which comprise 11 of 15 case reports reviewed by Caplan et al.\(^35\) VA dissections were independently associated with SMT within 30 days in multivariate analysis (odds ratio = 6.62, 95%CI 1.4 to 30)\(^59\)
3. sudden head turning
4. direct blows to the back of the neck\(^38\)
Stroke from BVI

The Denver grade of the dissection in BVI does not correlate with risk of stroke or mortality (as it does with ICA dissection). Unlike with carotid injuries, there is rarely a premonitory “warning” TIA. Time from injury to stroke: mean 4 days (range: 8 hours -12 days).

Evaluation

When BVI is identified, it is critical to assess the status of the contralateral VA.

Practice guideline: Vertebral artery blunt injuries

Evaluation

Level I
- Patients meeting the “Denver Screening Criteria” (symptoms shown in Table 55.8 or risk factors shown in Table 55.7) should undergo 16MD-CTA to screen for BVI

Level II
- Catheter angiogram is recommended in select patients after blunt cervical trauma if 16MD-CTA is not available especially if concurrent endovascular intervention is a consideration.
- MRI is recommended for BVI after blunt cervical trauma in patients with incomplete SCI or vertebral subluxation injuries.

Treatment

Practice guideline: Vertebral artery blunt injuries

Treatment

Level II
- No specific guidelines were made among treatment options (anticoagulation, antiplatelet therapy, or no treatment)
- The role of endovascular therapy for BVI has not been defined

Strokes were more frequent in patients with BVI who were not treated initially with IV heparin despite an asymptomatic BVI. However, based on historical controls, it is not clear if either screening or treatment improves overall outcome. Recommendations: treat all BVI with aspirin. Restudy chronic occlusion in 3 months.

Treatment options include endovascular stenting when amenable. This can restore near-normal flow, but long-term results are lacking. Also, stenting requires ≥3 months of antiplatelet therapy which is contraindicated in some situations.

Outcome

Overall mortality with unilateral BVI ranges from 8-18% which is lower than with ICA dissections (17-40%). Bilateral VA dissection appears highly fatal.

References

56 Neuromonitoring

56.1 General information

This section considers neuromonitoring instrumentation that can be done primarily at the patient’s bedside, and therefore does not include CT perfusion studies, PET scans, etc. The bulk of neuromonitoring literature deals with intracranial pressure (ICP). Other parameters that can be monitored include: jugular venous oxygen monitoring (p.865), regional CBF (p.866), brain tissue oxygen tension (p.865), and brain metabolites (pyruvate, lactate, glucose…) (p.866).

The role of adjunctive monitoring is currently unknown. Unanswered questions include: should neuromonitoring be disease specific (e.g. is SAH different from TBI), which monitors provide additional unique information, what are the critical values of the monitored entity, and what interventions should be undertaken to correct abnormalities?

56.2 Intracranial pressure (ICP)

56.2.1 Background

Intracranial pressure (ICP) is discussed in this section on trauma because of the close relationship between elevated ICP and brain damage from head injury. However, factors involved in diagnosing and treating intracranial hypertension (IC-HTN) also may pertain (with modifications) to brain tumors, dural venous thrombosis, etc.

56.2.2 Cerebral perfusion pressure (CPP) and cerebral autoregulation

Secondary brain injury (i.e. following the initial trauma) is attributable in part to cerebral ischemia; see Secondary injury (p.824). The critical parameter for brain function and survival is not actually ICP, rather it is adequate cerebral blood flow (CBF) to meet CMRO$_2$ demands; see discussion of CBF & CMRO$_2$ (p.1264). CBF is difficult to quantitate, and can only be measured continuously at the bedside with specialized equipment and difficulty. However, CBF depends on cerebral perfusion pressure (CPP), which is related to ICP (which is more easily measured) as shown in Eq (56.1).

\[
CPP = \frac{MAP - ICP}{\text{f}_{\text{g}}} \quad \text{(Note: the actual pressure of interest is the mean carotid pressure (MCP) which may be approximated as the MAP with the transducer zeroed \(\approx\) at the level of the foramen of Monro.\text{f}_{\text{g}}\n
As ICP becomes elevated, CPP is reduced at any given MAP. Normal adult CPP is \(>50\) mm Hg. Cerebral autoregulation is a mechanism whereby over a wide range, large changes in systemic BP produce only small changes in CBF. Due to autoregulation, CPP would have to drop below \(40\) in a normal brain before CBF would be impaired.

In the head injured patient, older recommendations were to maintain CPP \(\geq70\) mm Hg due to increased cerebral vascular resistance. However, recent evidence suggests that elevated ICP (\(\geq20\) mm Hg) may be more detrimental than changes in CPP (as long as CPP is \(>60\) mm Hg\textsuperscript{4}) (higher levels of CPP were not protective against significant ICP elevations).

56.2.3 ICP principles

The following are approximations to help simplify understanding ICP (these are only models, and as such are not entirely accurate):

1. normal intracranial constituents (and approximate volumes):
   a) brain parenchyma (which also contains extracellular fluid): \(1400\) ml
   b) cerebral blood volume (CBV): \(150\) ml
   c) cerebrospinal fluid (CSF): \(150\) ml
2. these volumes are contained in an inelastic, completely closed container (the skull)
3. pressure is distributed evenly throughout the intracranial cavity (in reality, pressure gradients exist\(^6,7\))

4. the modified Monro-Kellie doctrine\(^8\) states that the sum of the intracranial volumes (CBV, brain, CSF, and other constituents (e.g., tumor, hematoma...)) is constant, and that an increase in any one of these must be offset by an equal decrease in another. The mechanism: there is a pressure equilibrium in the skull. If the pressure from one intracranial constituent increases (as when that component increases in volume), it causes the pressure inside the skull (ICP) to increase. When this increased ICP exceeds the pressure required to force one of the other constituents out through the foramen magnum (FM) (the only true effective opening in the intact skull) that other component will decrease in size via that route until a new equilibrium is established. The cranio-spinal axis can buffer small increases in volume with no change or only a slight increase in ICP. If the expansion continues, then the new equilibrium will be at a higher ICP. The result:

a) at pressures slightly above normal, if there is no obstruction to CSF flow (obstructive hydrocephalus), CSF can be displaced from the ventricles and subarachnoid spaces and exit the intracranial compartment via the FM

b) intravenous blood can also be displaced through the FM via the IJVs
c) as pressure continues to rise, arterial blood is displaced and CPP decreases, eventually producing diffuse cerebral ischemia. At pressures equal to mean arterial pressure, arterial blood will be unable to enter the skull through the FM, producing complete cessation of blood flow to the brain, with resultant massive infarction
d) increased brain edema, or an expanding mass (e.g., hematoma) can push brain parenchyma downward into the foramen magnum (cerebral herniation) although brain tissue cannot actually exit the skull

56.2.4 Normal ICP

The normal range of ICP varies with age. Values for pediatrics are not well established. Guidelines are shown in Table 56.1.

Table 56.1 Normal ICP

<table>
<thead>
<tr>
<th>Age group</th>
<th>Normal range (mm Hg)</th>
</tr>
</thead>
<tbody>
<tr>
<td>adults and older children(^a)</td>
<td>&lt;10–15</td>
</tr>
<tr>
<td>young children</td>
<td>3–7</td>
</tr>
<tr>
<td>term infants(^b)</td>
<td>1.5–6</td>
</tr>
</tbody>
</table>

\(^a\)the age of transition from “young” to “older” child is not precisely defined

\(^b\)may be subatmospheric in newborns
A secondary increase in ICP is sometimes observed 3–10 days following the trauma, and may be associated with a worse prognosis. Possible causes include:

1. delayed hematoma formation
   a) delayed epidural hematoma (p. 894)
   b) delayed acute subdural hematoma (p. 898)
   c) delayed traumatic intracerebral hemorrhage (or hemorrhagic contusions) with perilesional edema: usually in older patients, may cause sudden deterioration. May become severe enough to require evacuation (p. 892)
2. cerebral vasospasm
3. severe adult respiratory distress syndrome (ARDS) with hypoventilation
4. delayed edema formation: more common in pediatric patients
5. hyponatremia

Clinical presentation – Cushing’s triad

The classic clinical presentation of IC-HTN (regardless of cause) is Cushing's triad which is shown in Table 56.2. However, the full triad is only seen in ≈ 33% of cases of IC-HTN.

Patients with significant ICP elevation due to trauma, brain masses (tumor) or hydrocephalus (but paradoxically not with pseudotumor cerebri) will usually be obtunded.

CT scan and elevated ICP

Whereas CT findings may be correlated with a risk of IC-HTN, no combination of CT findings has been shown to allow accurate estimates of actual ICP. 60% of patients with closed head injury and an abnormal CT will have IC-HTN. (Note: “abnormal” CT: demonstrates hematomas (EDH, SDH or ICH), contusions, compression of basal cisterns (p. 921), herniation or swelling.)

Only 13% of patients with a normal CT scan will have IC-HTN. However, patients with a normal CT AND 2 or more risk factors identified in Table 56.3 will have ≈ 60% risk of IC-HTN. If only 1 or none are present, ICP will be increased in only 4%.

56.2.6 ICP monitoring

Indications for ICP monitoring

Practice guideline: Indications for ICP monitoring

For salvageable patients with severe traumatic brain injury (GCS ≤ 8 after cardiopulmonary resuscitation)

Level II: with an abnormal admitting brain CT (note: abnormal” CT: demonstrates hematomas (EDH, SDH or ICH), contusions, compression of basal cisterns (p. 921), herniation or swelling)

Level III: with a normal admitting brain CT, but with ≥ 2 of the risk factors for IC-HTN in Table 56.3

1. neurologic criteria: see Practice guideline: Indications for ICP monitoring (p. 858)
   a) some centers monitor patients who don’t follow commands. Rationale: patients who follow commands (GCS ≥ 9) are at low risk for IC-HTN, and one can follow sequential neurologic exams in these patients and institute further evaluation or treatment based on neurologic deterioration
   b) some centers monitor patients who don’t localize, and follow neuro exam on others

Table 56.2 Cushing’s triad with elevated ICP

1. hypertension
2. bradycardia
3. respiratory irregularity

Table 56.3 Risk factors for IC-HTN with a normal CT

- age > 40 yrs
- SBP < 90 mm Hg
- decerebrate or decorticate posturing on motor exam (unilateral or bilateral)
2. multiple systems injured with altered level of consciousness (especially where therapies for other injuries may have deleterious effects on ICP, e.g. high levels of PEEP or the need for large volumes of IV fluids or the need for heavy sedation)
3. with traumatic intracranial mass (EDH, SDH, depressed skull fracture…)
   a) a physician may choose to monitor ICP in some of these patients\textsuperscript{16,18}
   b) post-op, subsequent to removal of the mass
4. non-traumatic indications for ICP monitoring:
   a) some centers monitor ICP in patients with acute fulminant liver failure with an INR>1.5 and Grade III of IV coma. A recent study shows that a subarachnoid bolt may be inserted after administration of factor VII 40 mcg/kg IV over 1–2 minutes (the bolt is inserted as soon as possible (usually within 15 minutes and no more than 2 hours after administration)) without significant risk of hemorrhage. All patients were treated with hypothermia; other ICP treatment measures were used for refractory IC-HTN

Contraindications (relative)
1. “awake” patient: monitor usually not necessary, can follow neuro exam
2. coagulopathy (including DIC): frequently seen in severe head injury. If an ICP monitor is essential, take steps to correct coagulopathy (FFP, platelets…) and consider subarachnoid bolt or epidural monitor (an IVC or intraparenchymal monitor is contraindicated). See recommended range of PT or INR (p.157).

Duration of monitoring
D/C monitor when ICP normal \(\times 48–72\) hrs after withdrawal of ICP therapy. Caution: IC-HTN may have delayed onset (often starts on day 2–3, and day 9–11 is a common second peak especially in peds). Also see delayed deterioration (p.824). Avoid a false sense of security imparted by a normal early ICP.

Complications of ICP monitors
General information
Table 56.4 for a summary of complication rates for various types of monitors.\textsuperscript{3}
1. infection: see below
2. hemorrhage\textsuperscript{3}: overall incidence is 1.4% for all devices (see Table 56.4 for breakdown). The Angioma Alliance\textsuperscript{21} definition of hemorrhage: acute or subacute symptoms (any of: headache, seizure, impaired consciousness, or new/worsened focal neurological deficit referable to the anatomic location of the CM) accompanied by radiological, pathological, surgical, or rarely only cerebrospinal fluid evidence of recent extra- or intralesional hemorrhage. This definition does not include an increase in CM diameter without other evidence of recent hemorrhage, nor the presence of a hemosiderin halo. Risk of significant hematoma requiring surgical evacuation is \(\approx 0.5–2.5\%\textsuperscript{5,22,23}
3. malfunction or obstruction: with fluid coupled devices, higher rates of obstruction occur at ICPs > 50 mm Hg
4. malposition: 3% of IVCs require operative repositioning

<td>2.8%</td>
<td>9–40%</td>
</tr>
</tbody>
</table>

\textsuperscript{a}some studies report this as infection, but do not distinguish between clinically significant infection and colonization of ICP monitor
Infection with ICP monitors
Colonization of the monitoring device is much more common than clinically significant infection (ventriculitis or meningitis). See Table 56.4 for colonization rates. Fever, leukocytosis and CSF pleocytosis have low predictive value (CSF cultures are more helpful). Range of reported infection rates: 1–27% \(^{24}\)

Practice guideline: Infection prophylaxis with ICP monitors

Level III\(^{25}\): neither prophylactic antibiotics nor routine ventricular catheter exchange is recommended to reduce infection

Identified risk factors for infection include\(^{20,24,26,27}\):
1. intracerebral, subarachnoid or intraventricular hemorrhage
2. ICP > 20 mm Hg
3. duration of monitoring: contradictory results in literature. One prospective study in 1984 found an increased risk with monitor duration > 5 days (infection risk reaches 42% by day 11).\(^{22,26}\) Another found no correlation with monitoring duration.\(^{28}\) A retrospective analysis\(^{20}\) found a non-linear increase of risk during the first 10–12 days after which the rate diminished rapidly
4. neurosurgical operation: including operations for depressed skull fracture
5. irrigation of system
6. leakage around IVCs
7. open skull fractures (including basilar skull fractures with CSF leak)
8. other infections: septicemia, pneumonia

Factors not associated with increased incidence of infection:
1. insertion of IVC in neuro intensive care unit (instead of O.R.)
2. previous IVC
3. drainage of CSF
4. use of steroids

Treatment of infection
Removal of device if at all possible (if continued ICP monitoring is required consideration may be given to inserting a monitor at another site) and appropriate antibiotics.

Types of monitors
1. intraventricular catheter (IVC): AKA external ventricular drainage (EVD), connected to an external pressure transducer via fluid-filled tubing. The standard by which others are judged (also below; note: other options for IVCs utilize transducers tipped with fiberoptic or strain gauge devices which are located within the intraventricular catheter; in this discussion, “IVC” does not refer to this type)
   a) advantages:
   - most accurate (can be recalibrated to minimize measurement drift)\(^{29}\)
   - lower cost
   - in addition to measuring pressure, allows therapeutic CSF drainage (may help reduce ICP directly, and may drain particulate matter, e.g. blood breakdown products after SAH, that could occlude arachnoid granulations\(^{30}\))
   b) disadvantages
   - may be difficult to insert into compressed or displaced ventricles
   - obstruction of the fluid column (e.g. by blood clot, or by coaptation of the ependymal lining on the catheter as the ventricle collapses with drainage) may cause inaccuracy
   - some effort is required to check and maintain function, e.g. IVC problems (p. 862) and IVC trouble shooting (p. 863)
   - transducer must be consistently maintained at a fixed reference point relative to patient’s head (must be moved as HOB is raised/lowered)
2. intraparenchymal monitor (e.g. Camino labs or Honeywell/Phillips\(^{31,32}\)): similar to IVC but more expensive. Some are subject to measurement drift,\(^{33,34}\) others may not be\(^{35}\)
3. less accurate monitors
   a) subarachnoid screw (bolt): risk of infection 1% rises after 3 days. At high ICPs (often when needed most) surface of brain may occlude lumen → false readings (usually lower than actual, may still show ≈ normal waveform)
b) subdural: may utilize a fluid coupled catheter (e.g. Cordis Cup catheter), fiberoptic tipped catheter, or strain gauge tipped catheter

c) epidural: may utilize a fluid coupled catheter, or fiberoptic tipped catheter (e.g. Ladd fiberoptic). Accuracy is questionable

d) in infants, one can utilizing an open anterior fontanelle (AF):

- fontanometry\(^{16}\): probably not very accurate
- applanation principle: may be used in suitable circumstances (viz.: if the fontanelle is concave with the infant upright, and convex when flat or head down) to estimate the ICP within 1 cm H\(_2\)O. The infant is placed supine, and the AF is visualized and palpated while the head is raised and lowered. When the AF is flat, the ICP equals atmospheric pressure, and ICP can be estimated in cm H\(_2\)O as the distance from the AF to the point where the venous pressure is 0 (for a recumbent infant, the midpoint of the clavicle usually suffices). If the AF is not concave with the infant erect, then this method cannot be used because either the ICP exceeds the distance from the AF to the venous zero point, or the scalp may be too thick

Conversion factors: between \(\text{mm Hg}\) and cm H\(_2\)O are shown in Eq (56.2) and Eq (56.3) (the density of mercury is 13.6 times that of water, and CSF is fairly close to water).

\[
1 \text{ mm Hg} = 1/36 \text{ cm H}_2\text{O} \tag{56.2}
\]

\[
1 \text{ cm H}_2\text{O} = 0.735 \text{ mmHg} \tag{56.3}
\]

Intraventricular catheter (IVC)

Insertion technique

For technique to place catheter in frontal horn, see Kocher’s point (p.1512). The right side is usually used unless specific reasons to use the left are present (e.g. blood clot in right lateral ventricle which might occlude IVC).

Set-up

Fig. 56.1 shows a typical external ventricular drainage (EVD) system/ ventriculostomy ICP monitor. Not every system will have the same components (some may have less and some may have more). Note that the effect of having an opening on the top of the drip chamber (through an air-filter) is the same as having the drip nozzle open to air, and therefore as long as this filter is not wet or plugged the pressure in the IVC is regulated by the height of the nozzle (as read on the pressure scale; note that the “0” is level with the nozzle).

The external auditory canal (EAC) is often used as a convenient external landmark for “0” (approximates the level of the foramen of Monro). In Fig. 56.1 the drip chamber is illustrated at 8 cm above the EAC.

Normal functioning of the IVC system

The system should be checked for proper functioning at least every 2–4 hours, and any time there is a change in: ICP (increase or decrease), neuro exam, or CSF output (for systems open to drainage).

1. check for presence of good waveform with respiratory variations and transmitted pulse pressures
2. IVCs: to check for patency, open the system to drain and lower the drip chamber below level of head and observe for 2–3 drops of CSF (normally do not allow more than this to drain)
3. for systems open to drainage:
   a) volume of CSF in drip chamber should be indicated every hour with a mark on a piece of tape on the drip chamber, and the volume should increase with time unless ICP is less than the height of the drip chamber (in practice, under these circumstances the system would usually not be left open to drainage).
   NB: the maximum expected output from a ventriculostomy would be \(\approx 450–700\) ml per day in a situation where none of the produced CSF is absorbed by the patient. This is not commonly encountered. A typical amount of drainage would be \(\approx 75\) ml every 8 hrs
   b) drip chamber should be emptied into drainage bag regularly (e.g. q 4 or 8 hours) and any time the chamber begins to get full (record volume)
in cases where there is a question whether the monitor is actually reflecting ICP, lowering the HOB towards 0° should increase ICP. Gentle pressure on both jugular veins simultaneously should also cause a gradual rise in ICP over 5–15 seconds that should drop back down to baseline when the pressure is released

IVC problems
The following represents some of the error or pitfalls that commonly occur with external ventricular drainage. Some also apply to ICP monitoring in general.

1. air filter on drip chamber gets wet (prevents air from passing through filter)
   a) result: fluid cannot drain freely into drip chamber (the pressure is no longer regulated by the height of the drip nozzle)
   - if the outflow from the drip chamber is clamped, then no flow at all is possible
   - if the clamp on the drip chamber outlet is open, then the pressure is actually regulated by the height of the nozzle in the collection bag and not the nozzle in the drip chamber
   b) solution: if a fresh filter is available, then replace the wet one. Otherwise one must improvise (with the risk of exposing the system to contamination): e.g. replace the wet filter with a filter from an IV set, or with a sterile gauze taped over the opening

2. air filter on collection bag gets wet: this will make it difficult to empty the drip chamber into the bag
a) this is not usually an urgent problem unless the drip chamber is full and the collection bag is distended tensely with air
b) the filter will dry out with time and will usually start to work again
c) if it is necessary to empty the drip chamber before the filter is dry, then using sterile technique insert a needle into the bag drainage port and decompress the bag of fluid and air

3. improper connections: a pressurized irrigation bag with or without heparinized solution should never be connected to an ICP monitor
4. changing position of head of bed: must move drip chamber up or down to keep it level with the same external landmarks (e.g. level of auditory canal):
   a) when open to drainage, this will assure the correct pressure will be maintained
   b) when opened to pressure transducer, will maintain correct zero
5. when open to drain, pressure reading from transducer is not meaningful: the pressure cannot exceed the height of the drip chamber in this situation (because at that point, fluid will drain off), and the opening to the “atmosphere” in the drip chamber will dampen the waveform
6. drip chamber falls to floor:
   a) overdrainage, possible seizures and/or subdural hematoma formation
   b) solution: securely tape chamber to pole, bed-rail..., check position regularly

IVC troubleshooting
See also IVC problems above.

IVC no longer works:
1. manifestation of problem:
   a) dampening or loss of normal waveform
   b) no fluid drains into drip chamber (applies only when catheter has been opened to drain)
2. possible causes:
   a) occlusion of catheter proximal to transducer
      • slide clamp closed or stopcock closed
      • catheter occluded by brain particles, blood cells, protein
   b) IVC pulled out of ventricle
      • test: temporarily lower drip nozzle and watch for 2–3 drops CSF
      • solution:
   c) verify all clamps are open
d) flush no more than 1.5 ml of non-bacteriostatic saline (AKA preservative-free saline) with very gentle pressure into ventricular catheter (NB: in elevated ICP the compliance of the brain is abnormally low and small volumes can cause large pressure changes)
   • if no return then brain or clot is probably plugging catheter. If it is known that the ventricles are ≈ completely collapsed then the IVC may be OK and CSF should still drain over time. Otherwise this is a non-functioning catheter, and if a monitor/drain is still indicated then a new catheter may need to be inserted (CT may be considered first if the status of the ventricles is not known). If catheter is clogged by intraventricular hemorrhage, rt-PA may sometimes be used (p.1344)

ICP waveform dampened:
1. possible causes:
   a) occlusion of catheter proximal to transducer: see above
   b) IVC pulled out of ventricle: no fluid will drain
   c) air in system:
      • solution: allow CSF to drain and expel air
      • caution: do not allow excessive amount of CSF to drain (may allow obstruction of catheter, subdural formation...). Do not inject fluid to flush air into brain
d) following decompressive craniectomy: due to the fact that the monitor is no longer in a closed space, this is a normal finding in this setting

Types of ICP waveforms
Normal waveforms
The normal ICP waveform (as occurs with normal blood pressure and in the absence of IC-HTN) as illustrated in Fig. 56.2 is rarely seen since ICP is usually monitored only when it is elevated. The origin of the variations seen in the normal tracing is somewhat in dispute. One explanation describes these two types of waveforms.
1. small pulsations transmitted from the systemic blood pressure to the intracranial cavity
   a) large (1–2 mm Hg) peak corresponding to the arterial systolic pressure wave, with a small
dicrotic notch
   b) this peak is followed by smaller and less distinct peaks
   c) followed by a peak corresponding to the central venous “A” wave from the right atrium
2. blood pressure pulsations are superimposed on slower respiratory variations. During expiration,
   the pressure in the superior vena cava increases which reduces venous outflow from the cranium
   causing an elevation in ICP. This may be reversed in a mechanically ventilated patients, and is
   opposite to that in the lumbar subarachnoid space which follows the pressure in the inferior vena
cava

Pathological waveforms
As ICP rises and cerebral compliance decreases, the venous components disappear and the arterial
pulses become more pronounced. In right atrial cardiac insufficiency, the CVP rises and the ICP
waveform takes on a more “venous” or rounded appearance and the venous “A” wave begins to
predominate.
A number of “pressure waves” that are more or less pathologic have been described. Currently,
this classification is not considered to be of great clinical utility, with more emphasis being placed
on recognizing and successfully treating elevations of ICP. Plateau waves will rarely be seen because
they are usually aborted at the onset by instituting treatments outlined herein (p.866). A brief
description of some of these waveforms is included here for general information:
1. Lundberg A waves AKA plateau waves (of Lundberg, Fig. 56.3): ICP elevations ≥ 50 mm Hg for 5–
   20 minutes. Usually accompanied by a simultaneous increase in MAP (it is debated whether the
   latter is cause or effect)
2. Lundberg B waves AKA pressure pulses: amplitude of 10–20 mm Hg is lower than A waves. Vari-
   ation with types of periodic breathing. Last 30 secs – 2 mins
3. Lundberg C waves: frequency of 4–8/min. Low amplitude C waves (AKA Traube-Hering waves)
   may sometimes be seen in the normal ICP waveform. High amplitude C-waves may be pre-termi-
   nal, and may sometimes be seen on top of plateau waves
56.3 Adjuncts to ICP monitoring

56.3.1 Jugular venous oxygen monitoring

Indications for SjVO₂ or pBtO₂ monitoring include the need for augmented hyperventilation (PCO₂ = 20-25) to control ICP. Parameters related to oxygen content of the blood in the jugular veins are global in nature and are insensitive to focal pathology. Requires retrograde placement of catheter near to the origin of the internal jugular vein at the base of the skull. Parameters that can be measured:

1. jugular venous oxygen saturation (SjVO₂): measured continuously with special fiberoptic catheter. Normal SjVO₂ ≥ 60% Desaturations to <50% suggest ischemia. Multiple desaturations (<50%), or sustained (≥ 10 minutes) or profound desaturation episodes are associated with poor outcome.

Sustained desaturations should prompt an evaluation for correctable etiologies: kinking of jugular vein, anemia, increased ICP, poor catheter position, CPP < 60 mm Hg, vasospasm, surgical lesion, PaCO₂ <28 mm Hg. High SjVO₂ >75% may indicate hyperemia or infarcted tissue and is also associated with poor outcome.

2. jugular vein oxygen content (CVO₂). Requires intermittent sampling of blood

3. arterial-jugular venous oxygen content difference (AVdO₂): AVdO₂ > 9 ml/dl (vol%) probably indicates global cerebral ischemia, while values < 4 ml/dl indicate cerebral hyperemia (“luxury perfusion” in excess of the brain’s metabolic requirement)

56.3.2 Brain tissue oxygen tension monitoring (pBtO₂)

Indications for SjVO₂ or pBtO₂ monitoring include the need for augmented hyperventilation (PCO₂ = 20-25) to control ICP. Monitored e.g. with Licox® probe. The likelihood of death increases with longer times of brain tissue oxygen tension (pBtO₂) <15 mm Hg or even a brief drop of pBtO₂ <6. Initial pBtO₂ <10 mm Hg for > 30 minutes correlates with increased risk of death or bad outcome. Also, see Practice guideline: Brain oxygen monitoring (p.867).

Probe placement:

1. TBI: assumed to be a diffuse process, often placed on least injured side

2. SAH: placed in vascular distributions at greatest risk of vasospasm
   a) ACA (with ACA or a-comm aneurysm): standard frontal placement (≈ 2–3 cm off midline on appropriate side)
   b) MCA (with ICA or MCA aneurysm): 4.5–5.5 cm off midline
   c) ACA-MCA watershed area: 3 cm lateral to midline

3. ICH: usually placed near the site of the hemorrhage

Effect of pBtO₂ monitoring/intervention on outcome: no randomized studies

1. in TBI: goal was to maintain pBtO₂ >25 mm Hg. Adding pBtO₂ monitoring resulted in improved outcome. May have been result of increased attentiveness (“Hawthorne effect”)

2. in SAH: a moving correlation coefficient (ORx) between CPP and pBtO₂ was used to label high ORxs as disturbed autoregulation, and this value on post SAH days 5 & 6 had predictive value for delayed infarction

Management suggestions for pBtO₂ <15–20 mm Hg:

1. consider jugular venous O₂ saturation monitor or lactate microdialysis monitor for confirmation
2. consider CBF study to determine generalizability of pBtO2 monitor reading
3. treatment: proceed to each tier as needed
   a) tier 1
      • keep body temperature <37.5 C
      • increase CPP to >60 mmHg (use fluids preferentially to pressors until CVP >8 cm H2O, then use pressors)
   b) tier 2
      • increase FiO2 to 60%
      • increase paco2 to 45–50 mmHg
      • transfuse PRBCs until Hgb >10 g/dl
   c) tier 3
      • increase FiO2 to 100%
      • consider increasing PEEP to increase PaO2 if FiO2 is at 100%
      • decrease ICP to <10 mmHg (drain CSF, mannitol, sedation…)

56.3.3 Bedside monitoring of regional CBF (rCBF)

Thermal diffusion flowmetry permits continuous rCBF monitoring by assessing thermal convection due to tissue blood flow. The probe tip is inserted into the white matter of the brain. Commercially available systems include Hemedex® monitoring system (Codman) utilizing the QFLOW 500® probe which is not MRI compatible.

Probe placement: issues similar to those discussed for pBtO2 (see above).

Readout:
1. K value (thermal conduction): range for white matter is 4.9–5.8 mW/cm-°C (the monitor suppresses CBF readings if the K value is outside this range)
   a) K<4.9: the probe tip is probably out of the brain tissue or white matter – the probe should be advanced 1–2 mm
   b) K>5.8 the tip is probably too deep, near a blood vessel, or in the ventricle or epidural or subdural space – the probe should be retracted 1–2 mm
2. CBF
   a) normal white matter: 18–25 ml/100g-min
   • white matter CBF<15: may indicate vasospasm or ischemia
   • white matter CBF<10: may indicate infarction
   b) normal gray matter: 67–80 ml/100g-min

Observational data: in a small study of SAH (n=5) and TBI (n=3)51 there was good correlation between rCBF and pBtO2 91% of the time. Monitoring was not possible 36% of the time due to patient fever (wherein the system prevents monitoring).

56.3.4 Cerebral microdialysis

Compounds assayed include: lactate, pyruvate, lactate/pyruvate ratio, glucose, glutamate, urea and electrolytes including K+ & calcium. Some observational data:
1. lactate levels increase during episodes of SjVO2 desaturation52
2. decreased extracellular glucose was associated with increased mortality53

56.4 Treatment measures for elevated ICP

56.4.1 General information

This section presents a general protocol for treating documented (or sometimes clinically suspected) intracranial hypertension (IC-HTN). Guidelines promulgated by the Brain Trauma Foundation3,54,55,56 are generally followed. Unless otherwise stated, guidelines are for adult patients (≥18 years age).

56.4.2 Treatment thresholds

Intracranial pressure treatment thresholds

The optimal ICP at which to begin treatment is not known. Various cutoff values are used at different centers above which treatment measures for intracranial hypertension (IC-HTN) are initiated.
Although 15, 20 and 25 have been quoted, the Brain Trauma Foundation guideline is ICP > 20 mm Hg as shown in Practice guideline: ICP treatment threshold (p.867). Caution: patients can herniate even at ICP < 20 (depends on location of intracranial mass).

Rationale: There is high mortality and worse outcome among patients with ICP persistently > 20 compared to 20% in those where ICP could be kept < 20. Better control may be possible by treating early rather than waiting and trying to control higher ICPs or when plateau waves occur.

Practice guideline: ICP treatment threshold

- Level II*: treatment for IC-HTN should be initiated for ICP > 20 mm Hg
- Level III*: the need for treatment should be based on ICP in combination with clinical examination & brain CT findings

Cerebral perfusion pressure (CPP)

The optimal value for CPP has yet to be determined. The threshold for ischemia is in the range of CPP < 50–60 mm Hg. Because of deleterious systemic effects, paradigms of maintaining CPP > 70 mm Hg have been superseded. Practice guideline: Cerebral perfusion pressure issues (p.867) outlines current recommendations regarding CPP.

Practice guideline: Cerebral perfusion pressure issues

- Level II*: avoid aggressive use of fluids and pressors to maintain CPP > 70 mm Hg (because of risk of adult respiratory distress syndrome (ARDS))
- Level II*: avoid CPP < 50 mm Hg
- Level III*: ancillary monitoring of CBF, oxygenation or metabolism assists CPP management

Brain oxygenation parameters

Suggestions for treatment thresholds are shown in Practice guideline: Brain oxygen monitoring (p.867). It remains to be determined which interventions are useful to achieve this, and whether this improves outcome.

Practice guideline: Brain oxygen monitoring

- Level II*: jugular venous O₂ saturation < 50% or brain tissue oxygen tension (pBtO₂) < 15 mm Hg are treatment thresholds

56.4.3 ICP management protocol: Quick reference summary

Table 56.5 summarizes a protocol for control of IC-HTN (below for details). Dosages are given for an average adult, unless specified as mg/kg. Treatment may be initiated prior to insertion of a monitor if there is acute neurologic deterioration or clinical signs of IC-HTN, but continued treatment requires documentation of persistent IC-HTN.

For persistent IC-HTN consider “second tier” therapies (p.871).

Temporary measures which may be used to quickly treat an acute ICP crisis are shown in Table 56.6.
Table 56.5 Summary of measures to control IC-HTN

Goals: keep ICP < 20 mm Hg, and CPP ≥ 50 mm Hg

<table>
<thead>
<tr>
<th>Step</th>
<th>Rationale/Remedy</th>
</tr>
</thead>
<tbody>
<tr>
<td>GENERAL MEASURES (should be utilized routinely)</td>
<td></td>
</tr>
<tr>
<td>elevate HOB to 30–45°</td>
<td>↓ ICP by enhancing venous outflow, but also reduces mean carotid pressure → no net change in CBF</td>
</tr>
<tr>
<td>keep neck straight, avoid neck constrictions (tight trach tape, tight cervical collar...)</td>
<td>constriction of jugular venous outflow causes ↑ ICP</td>
</tr>
</tbody>
</table>
| avoid arterial hypotension (SBP < 90 mm Hg) | • Hypotension reduces CBF  
• : normalize intravascular volume, use pressors if needed |
| control hypertension if present | • : nicardipine if not tachycardic  
• : beta-blocker if tachycardic (labetalol, esmolol...)  
• : avoid overtreatment → hypotension |
| avoid hypoxia (PaO₂ < 60 mm Hg or O₂ sat < 90%) | hypoxia may cause further ischemic brain injury  
: maintain airway and adequate oxygenation |
| ventilate to normocarbia (PaCO₂ = 35–40 mm Hg) | avoid prophylactic hyperventilation (p. 872) |
| light sedation: e.g. codeine 30–60 mg IM q 4 hrs PRN | (same as heavy sedation, see below) |
| controversial: prophylactic hypothermia. If used, hold at target temp > 48 hrs | Hypothermia → ↓ CMRO₂ – efficacy not rigorously proven (p. 872) |
| unenhanced head CT scan for ICP problems | rule out surgical condition |

SPECIFIC MEASURES FOR IC-HTN

proceed to successive steps if documented IC-HTN persists – each step is ADDED to the previous measure)

<table>
<thead>
<tr>
<th>Step</th>
<th>Rationale/Remedy</th>
</tr>
</thead>
<tbody>
<tr>
<td>heavy sedation (e.g. fentanyl 1–2 ml or MSO4 2–4 mg IV q 1 hr) and/or paralysis (e.g. vecuronium 8–10 mg IV)</td>
<td>reduces elevated sympathetic tone and HTN induced by movement, tensing abdominal musculature...</td>
</tr>
<tr>
<td>drain 3–5 ml CSF if IVC present</td>
<td>reduces intracranial volume</td>
</tr>
</tbody>
</table>
| hyperventilate to PaCO₂ = 30–35 mm Hg ("blows off" CO₂) | CO₂ is a potent vasodilator  
Hyperventilation → ↓ PaCO₂ → ↓ CBV → ↓ ICP  
hyperventilation also → ↓ CBF |
| mannitol 0.25–1 gm/kg, then 0.25 mg/kg q 6 hrs, increase dose if IC-HTN persists & serum osmol < 320 (NB: skip this step if hypovolemia or hypotension) | Mannitol → initially↑ plasma volume & ↑ serum toxicity which draws fluid out of brain → ↓ intracranial volume, may also improve rheologic properties of blood.  
Mannitol is an osmotic diuretic, and eventually → ↓ plasma volume |
| if there is “osmotic room” (i.e. serum osmol < 320) bolus with 10–20 ml of 23.4% hypertonic saline (HS) | some patients refractory to mannitol will respond to HS |
| Augmented hyperventilation to ↓ PaCO₂ to 25–30 mm Hg | Due to risk of cerebral ischemia from ↓ CBF, monitor SjVO₂ (p. 865) or CBF if possible |

If IC-HTN persists, consider unenhanced head CT & EEG. Proceed to “second tier” therapy (p. 871)

*a see text for details (p. 870). As IC-HTN subsides, carefully withdraw treatment  
b if IC-HTN persists, and especially for a sudden unexplained rise in ICP or loss of previously controlled ICP, give strong consideration to repeating cranial CT to rule out a surgical condition, i.e. “clot” (SDH, EDH, or ICH) or hydrocephalus  
*EEG to rule-out subclinical status epilepticus which is a rare cause of sustained IC-HTN
56.4.4 ICP management protocol details

Goals of therapy

1. keep ICP ≤20 mm Hg (prevents “plateau waves” from compromising cerebral blood-flow (CBF) and causing cerebral ischemia and/or brain death)\(^{10}\)

2. keep CPP ≥50 mm Hg.\(^{61}\) The primary goal is to control ICP, simultaneously, CPP should be supported by maintaining adequate MAP\(^6^3\) (no study shows any deleterious effect on ICP, morbidity or mortality as a result of normalizing intravascular volume or inducing systemic hypertension to achieve the desired CPP).

Surgical treatment

1. Traumatic Intracranial masses should be treated as indicated. See surgical indications for subdural (p.895), epidural (p.893) or intraparenchymal (p.891) hematoma or posterior fossa mass lesions (p.905)

2. patients with hemorrhagic contusions (“pulped brain”) showing progressive deterioration may benefit from surgical excision of portions of the contused brain tissue especially if not eloquent brain (p.871)

3. decompressive craniectomy may be considered for IC-HTN that cannot be controlled medically

General care

Major goals

1. avoid hypoxia (pO\(_2\) < 60 mm Hg)

2. avoid hypotension (SBP ≤ 90 mm Hg): 67% positive-predictive value (PPV) for poor outcome (79% PPV when combined with hypoxia)\(^6^4\)

Details of general treatment measures

1. prophylaxis against steroid ulcers (if steroids are used) and Cushing’s (stress) ulcers (seen in severe head injury and in increased ICP, accompanied by hypergastrinemia)\(^{65,66,67,68,69}\) for all patients including ped’s; see Prophylaxis for stress ulcers (p.129).

   a) elevating gastric pH: titrated antacid and/or H2 antagonist (e.g. ranitidine 50 mg IV q 8 hrs) or proton pump inhibitor. See discussion of potential increased mortality as a result of increased gastric pH (p.129)

   b) sucralfate

---

### Table 56.6 Measures to treat an acute ICP crisis

<table>
<thead>
<tr>
<th>Step</th>
<th>Rationale</th>
</tr>
</thead>
<tbody>
<tr>
<td>Verify basics: check airway, neck position…(see general measures in Table 56.5). For resistant or sudden IC-HTN, consider STAT unenhanced head CT</td>
<td></td>
</tr>
<tr>
<td>be sure patient is sedated and paralyzed (Table 56.5)</td>
<td>↓ intracranial volume</td>
</tr>
<tr>
<td>drain 3–5 ml CSF if IVC present</td>
<td>↑ plasma volume → ↑ CBF → ↓ ICP, also ↑ serum osmolality → ↓ extracellular brain water</td>
</tr>
<tr>
<td>mannitol(^6^1) 1 gm/kg IV bolus or 10–20 ml of 23.4% saline</td>
<td>“blow off” (reduce) PaCO(_2) → ↓ CBV → ↓ ICP, CAUTION: due to reduced CBF, use for no more than several minutes (p.872)</td>
</tr>
<tr>
<td>hyperventilate with Ambu® bag (do not reduce PaCO(_2) &lt; 25 mm Hg)</td>
<td></td>
</tr>
<tr>
<td>pentobarbital(^a) 100 mg slow IV or thiopental 2.5 mg/kg IV over 10 minutes</td>
<td>sedates, ↓ ICP, treats seizures, may be neuroprotective also myocardial depressant → ↓ MAP</td>
</tr>
</tbody>
</table>

\(^a\)for measures to treat ICP that is trending up over a longer period, see Table 56.5 or information starting \(^b\)skip this step and go to hyperventilation if hypotensive, volume depleted, or if serum osmolality >320 mOsm/L \(^c\)the availability of pentobarbital in the U.S. has been reduced, and other sedatives may need to be substituted (p.876)
2. aggressive control of fever (fever is a potent stimulus to increase CBF, and may also increase plateau waves)\textsuperscript{10}
3. arterial line for BP monitoring and frequent ABGs
4. CVP or PA line if high doses of mannitol are needed (goal: keep patient euvoletic)
5. IV fluids
   a) choice of fluids:
      • isolated head injury: IVF of choice is isotonic (e.g. NS + 20 mEq KCl/L)
      • avoid hypotonic solutions (e.g. lactated ringers) which may impair cerebral compliance\textsuperscript{70}
   b) fluid volume:
      • provide adequate fluid resuscitation to avoid hypotension
      • normalization of intravascular fluid volume is not detrimental to ICP
      • although fluid restriction reduces the amount of mannitol needed to control ICP,\textsuperscript{71} the concept of “running patients dry” is obsolete\textsuperscript{72}
      • if mannitol is required, patient should be maintained at euvoletic
      • also exercise caution in restricting fluids following SAH; see Cerebral salt wasting (p. 118)
      • if injuries to other systems are present (e.g. perforated viscus), they may dictate fluid management
   c) pressors (e.g. dopamine) are preferable to IV fluid boluses in head injury

**Measures to lower ICP**

**General measures that should be routine**

1. positioning:
   a) elevate HOB 30–45° (see below)
   b) keep head midline (to prevent kinking jugular veins)
2. light sedation: codeine 30–60 mg IM q 4 hrs PRN, or lorazepam (Ativan\textsuperscript{®}) 1–2 mg IV q 4–6 hrs PRN
3. avoid hypotension (SBP < 90 mm Hg): normalize intravascular volume, support with pressors if needed
4. control HTN; in ICH, aim for patient’s baseline, see Initial management of ICH (p. 1339)
5. prevent hyperglycemia: (aggravates cerebral edema) usually present in head injury,\textsuperscript{73,74} may be exacerbated by steroids
6. intubation: for GCS ≤ 8 or respiratory distress. Give IV lidocaine first (below) and antibiotics (p. 827)
7. avoid hyperventilation: keep PaCO\textsubscript{2} at the low end of eucapnia (35 mm Hg)
8. prophylactic hypothermia: non-statistically significant trend suggests reduced mortality.\textsuperscript{75} Maintain target temperature for > 48 hours

**Measures to use for documented IC-HTN**

First, check General measures that should be routine. Proceed to each step if IC-HTN persists.

1. heavy sedation and/or paralysis when necessary (also assists treatment of HTN) e.g. when patient is agitated, or to blunt the elevation of ICP that occurs with certain maneuvers such as moving the patient to CT table. Caution: with heavy sedation or paralysis, the ability to follow the neurologic exam is lost (follow ICPs)
   a) for heavy sedation (intubation recommended to avoid respiratory depression → elevation of PaCO\textsubscript{2} → ↑ ICP): e.g. one of the following:
      • MSO\textsubscript{4}: 2–4 mg/hr IV drip
      • fentanyl: 1–2 mIV q 1 hr (or 2–5 mcg/kg/hr IV drip)
      • sufentanil: 10–30 mcg test dose, then 0.05–2 mcg/kg/hr IV drip
      • midazolam (Versed\textsuperscript{®}): 2 mg test dose, then 2–4 mg/hr IV drip
      • propofol drip (p. 106): 0.5 mg/kg test dose, then 20–75 mcg/kg/min IV drip avoid high-dose propofol (do not exceed 83 mcg/kg/min)
      • “low dose” pentobarbital (adult: 100 mg IV q 4 hrs; ped: 2–5 mg/kg IV q 4 hrs)
   b) paralysis (intubation mandatory): e.g. vecuronium 8–10 mg IV q 2–3 hrs
2. CSF drainage (when IVC is being utilized to measure ICP): 3–5 ml of CSF should be drained with the drip chamber at ≤ 10 cm above EAC. Works immediately by removal of CSF (reducing intracranial volume) and possibly by allowing edema fluid to drain into ventricles\textsuperscript{76} (latter point is controversial)
3. “osmotic therapy” when there is evidence of IC-HTN:
   a) mannitol (also see below) 0.25–1 gm/kg bolus (over < 20 mins) followed by 0.25 gm/kg IV (over 20 min) q 6 hrs PRN ICP > 20. Recent literature suggests that 1.4 gm/kg initial dose is more effective. May “alternate” with:
furosemide (Lasix®) (also see below): adult 10–20 mg IV q 6 hrs PRN ICP >20. Peds: 1 mg/kg, 6 mg max IV q 6 hrs PRN ICP >20

b) keep patient euvoletic to slightly hypervolemic
c) if IC-HTN persists and serum osmolarity is < 320 mOsm/L, increase mannitol up to 1 gm/kg, and shorten the dosing interval
d) if ICP remains refractory to mannitol, consider hypertonic saline, either continuous 3% saline infusion or as bolus of 10–20 ml of 23.4% saline
(D/Cafter ≈ 72 hours to avoid rebound edema)
e) hold osmotic therapy if serum osmolarity is ≥ 320 mOsm/L (higher tonicity may have no advantage and risks renal dysfunction; see below) or SBP < 100

4. hyperventilation (HPV) to PaCO₂ = 30–35 mm Hg (for details, see below)
   a) do not use prophylactically
   b) avoid aggressive HPV (PaCO₂ ≤ 25 mm Hg) at all times
   c) use only for
      • short periods for acute neurologic deterioration
      • or chronically for documented IC-HTN unresponsive to sedation, paralytics, CSF drainage and osmotic therapy
d) avoid HPV during the first 24 hrs after injury if possible

5. steroids: the routine use of glucocorticoids is not recommended for treatment of patients with head injuries (see below)

“Second tier” therapy for persistent IC-HTN
If IC-HTN remains refractory to the above measures, and especially if there is loss of previously controlled ICP, strong consideration should be given to repeating a head CT to rule out a surgical condition before proceeding with “second tier” therapies which are either effective but with significant risks (e.g. high-dose barbiturates), or are unproven in terms of benefit on outcome. Also consider an EEG to rule-out subclinical status epilepticus (seizures that are not clinically evident); see treatment measures for status epilepticus (p.471); some medications are effective for both seizures and IC-HTN, e.g. pentobarbital, propofol...

1. high dose barbiturate therapy (p.875): initiate if ICP remains >20–25 mm Hg
2. hyperventilate to PaCO₂ = 25–30 mm Hg. Monitoring SjV O₂, AVdO₂, and/or CBF is recommended (see below)
3. hypothermia: patients must be monitored for a drop in cardiac index, thrombocytopenia, elevated creatinine clearance, and pancreatitis. Avoid shivering which raises ICP
4. decompressive surgery:
   a) decompressive craniectomy removal of portion of calvaria. Controversial (may enhance cerebral edema formation). Cranietectomy decreased ICP to <20 mm Hg in 85% regardless of pupillary response to light, timing of craniectomy, brain shift and age. Outcomes were improved when IC-HTN responded. Further randomized trials are indicated. Early decompressive craniectomy may be considered in patients undergoing emergent surgery (for fracture, EDH, SDH...). Flap must be at least 12 cm in diameter, and duraplasty is mandatory. Also, see Hemicraniectomy for malignant MCA territory infarction (p.1303)
   b) removal of large areas of contused hemorrhagic brain (makes room immediately; removes region of disrupted BBB). If contused, consider temporal tip lobectomy (no more than 4–5 cm on dominant side, 6–7 cm on non-dominant) (total temporal lobectomy is probably too aggressive) or frontal lobectomy. Has not shown great therapeutic promise
5. lumbar drainage: showing some promise. Watch for “cerebral sag”
6. hypertensive therapy

Adjunctive measures
1. lidocaine: 1.5 mg/kg IVP (watch for hypotension, reduce dose if necessary) at least one minute before endotracheal intubation or suctioning. Blunts the rise in ICP as well as tachycardia and systemic HTN (based on patients with brain tumors undergoing intubation under light barbiturate-nitrous oxide anesthesia; extrapolation to trauma patients is unproven)
2. high frequency (jet) ventilation: consider if high levels of positive end-expiratory pressure (PEEP) are required (NB: patients with reduced lung compliance, e.g. pulmonary edema, transmit more of PEEP through lungs to thoracic vessels and may raise ICP). PEEP ≤ 10 cm H₂O does not cause clinically significant increases in ICP. Higher levels of PEEP > 15–20 are not recommended. Also, rapid elimination of PEEP may cause a sudden increase in circulating blood volume which may exacerbate cerebral edema and also elevate ICP
Details of some measures employed in treating increased ICP

Elevating head of bed (HOB)
Seemingly simple, but there is still some controversy. Early data obtained from dog studies indicated that keeping the HOB at 30–45° optimized the trade-off between the following two factors as the HOB is elevated: reducing ICP (by enhancing venous outflow and by promoting displacement of CSF from the intracranial compartment to the spinal compartment) and reducing the arterial pressure (and thus CPP) at the level of the carotid arteries. Some studies showed a deleterious effect from elevating the HOB and were used to justify nursing these patients with HOB flat. Recent data indicate that although mean carotid pressure (MCP) is reduced, the ICP is also reduced and the CBF is unaffected by elevating the HOB to 30°. The onset of action of raising the HOB is immediate.

Prophylactic hypothermia

Practice guideline: Prophylactic hypothermia

Level III: prophylactic hypothermia:
• improves the chances of having a moderate to good outcome – 4–5 on the Glasgow Outcome Score Table 88.5 – at the end of the follow-up period when target temperatures of 32–35°C (91.4–95°F) were used (note: no clear relationship was found for cooling duration or rewarming rate)
• showed a non-significant trend suggesting that it lowers mortality when the target temperature is maintained for >48 hrs (note: the actual target temperature and rewarming rate did not influence mortality)

Hyperventilation

Intraarterial carbon dioxide (PaCO₂) is the most potent cerebrovascular vasodilator, the effect of which is probably mediated by changes in pH caused by the rapid diffusion of CO₂ across the BBB. Hyperventilation (HPV) lowers ICP by reducing PaCO₂ which causes cerebral vasoconstriction, thus reducing the cerebral (intracranial) blood volume (CBV). Of concern, vasoconstriction also lowers cerebral blood flow (CBF) which could produce focal ischemia in areas with preserved cerebral autoregulation as a result of shunting. However, ischemia does not necessarily follow as the O₂ extraction fraction (OEF) may also increase, up to a point.

Practice guideline: Hyperventilation for ICP management

Level I: in the absence of IC-HTN, chronic prolonged hyperventilation (HPV) (PaCO₂ ≤ 25 mm Hg) should be avoided
Level II: prophylactic hyperventilation (PaCO₂ ≤ 25 mm Hg) is not recommended
Level III
• HPV may be necessary for brief periods when there is acute neurologic deterioration, or for longer periods if there is IC-HTN refractory to sedation, paralysis, CSF drainage and osmotic diuretics
• HPV should be avoided ≤ 24 hrs after head injury
• if HPV is used, jugular venous oxygen saturation (SjVO₂) (p. 865) or PbrO₂ (p. 865) should be measured to monitor brain O₂ delivery

*See also Practice guideline: Early/prophylactic hyperventilation (p. 827).
the use of HPV to PaCO$_2 = 30$ mm Hg within 8–14 hrs of severe head injury did not impair global cerebral metabolism, but focal changes were not studied. Hyperventilation to PaCO$_2 < 30$ mm Hg further reduces CBF, but does not consistently reduce ICP and may cause loss of cerebral autoregulation. If carefully monitored, there may be occasion to use this. There are no studies showing any improvement in outcome with aggressive HPV (PaCO$_2 \leq 25$ mm Hg) which can cause diffuse cerebral ischemia.

A summary of the ranges of PaCO$_2$ and the recommendations is shown in Table 56.7.

Reducing PaCO$_2$ from 35 to 29 mm Hg lowers ICP 25–30% in most patients. Onset of action: ≤30 seconds. Peak effect at ≈8 mins. Duration of effect is occasionally as short as 15–20 mins. Effect may be blunted by 1 hour (based on patients with intracranial tumors), after which it is difficult to return to normocarbia without rebound elevation of ICP. Thus, HPV must be weaned slowly.

Indications for hyperventilation (HPV)

1. HPV for brief periods (minutes) at the following times
   a) prior to insertion of ICP monitor: if there are clinical signs of IC-HTN (Table 54.2)
   b) after insertion of a monitor: if there is a sudden increase in ICP and/or acute neurologic deterioration, HPV may be used while evaluating patient for a treatable condition (e.g. delayed intracranial hematoma)

2. HPV for longer periods: when there is documented IC-HTN unresponsive to sedation, paralytics, CSF drainage (when available) and osmotic diuretics

3. HPV may be appropriate for IC-HTN resulting primarily from hyperemia (p.901)

Caveats for hyperventilation

1. avoid during the first 5 days after head injury if possible (especially first 24 hrs)
2. do not use prophylactically (i.e. without appropriate indications, see above)
3. if documented IC-HTN is unresponsive to other measures, hyperventilate only to PaCO$_2 = 30–35$ mm Hg
4. if prolonged HPV to PaCO$_2$ of 25–30 mm Hg is deemed necessary, consider monitoring SjVO$_2$, AVdO$_2$, or CBF to rule-out cerebral ischemia (p.865)
5. do not reduce PaCO$_2 < 25$ mm Hg (except for very brief periods of a few minutes)

Mannitol

Practice guideline: Mannitol in severe traumatic brain injury

**Level II**

Mannitol is effective for control of IC-HTN after severe TBI (note: current information did not allow recommendations regarding hypertonic saline to be made)

- intermittent boluses may be more effective than continuous infusion
- effective doses range from 0.25–1 gm/kg body weight
- avoid hypotension (SBP < 90 mm Hg) which may result from the diuretic effect of mannitol which can lead to ↓ circulating fluid volume
Lev e l III

- indications: signs of transtentorial herniation or progressive neurological deterioration not attributable to systemic pathology
- euvo lem ia should be maintained (hypovolemia should be avoided) by fluid replacement. An indwel ling urinary catheter is essential
- serum osmolarity should be kept <320 mOsm when there is concern about renal failure

No controlled clinical trial has been conducted to show the benefits of mannitol over placebo. The exact mechanism(s) by which mannitol provides its beneficial effects is still controversial, but probably includes some combination of the following

1. lowering ICP
   - immediate plasma expansion: reduces the hematocrit and blood viscosity (improved rheology) which increases CBF and O2 delivery. This reduces ICP within a few minutes, and is most marked in patients with CPP < 70 mm Hg
   - osmotic effect: increased serum tonicity draws edema fluid from cerebral parenchyma. Takes 15–30 minutes until gradients are established. Effect lasts 1.5–6 hrs, depending on the clinical condition
2. supports the microcirculation by improving blood rheology (see above)
3. possible free radical scavenging

With bolus administration, onset of ICP lowering effect occurs in 1–5 minutes; peaks at 20–60 minutes. When urgent reduction of ICP is needed, an initial dose of 1 gm/kg should be given over 30 minutes.

Cautions with mannitol

1. man nit ol opens the BBB, and mannitol that has crossed the BBB may draw fluid into the CNS (this may be minimized by repeated bolus administration vs. continuous infusion which can aggravate vasogenic cerebral edema). Thus, when it is time to D/C mannitol, it should be tapered to prevent ICP rebound
2. caution: corticosteroids + phenytoin + mannitol may cause hyperosmolar nonketotic state with high mortality
3. excessively vigorous bolus administration may → HTN and if autoregulation is defective → increased CBF which may promote herniation rather than prevent it
4. high doses of mannitol carries the risk of acute renal failure (acute tubular necrosis), especially in the following: serum osmolarity > 320 mOsm/L; use of other potentially nephrotoxic drugs, sepsis, pre-existing renal disease
5. large doses prevents diagnosing DI by use of urinary osmols or SG
6. because it may further increase CBF, the use of mannitol may be deleterious when IC-HTN is due to hyperemia

Furosemide

The use of furosemide (Lasix®) has been advocated, but little data exists to support this. Loop acting diuretics may reduce ICP by reducing cerebral edema (possibly by increasing serum tonicity), and may also slow the production of CSF. They also act synergistically with mannitol (above).

- 10–20 mg IV q 6 hrs, may be alternated with mannitol such that the patient receives one or the other q 3 hrs. Hold if serum osmolarity > 320 mOsm/L

Hypertonic saline (HS)

May reduce ICP in patients refractory to mannitol, although no improvement in outcome over mannitol has been demonstrated. Potentially deleterious effect on stroke penumbra in animal studies. Studies are not adequate to make recommendations regarding use.
Continuous infusion: 3% saline at 25–50 ml/hr may be given through a peripheral IV. Bolus: 10–20 ml of 7.5–23.4% saline must be given through a central line. HS should be discontinued after \( \approx 72 \) hours to avoid rebound edema.\(^{124}\) Hold if serum osmolality > 320 mOsm/L.

**Steroids**

**Practice guideline: Glucocorticoids in severe head injury**

**Level I\(^{128}\):** the use of glucocorticoids (steroids) is not recommended for improving outcome or reducing ICP in patients with severe TBI (except in patients with known depletion of endogenous adrenal hormones\(^{129,130}\)). High-dose methylprednisolone is associated with increased mortality and is contraindicated\(^{128}\).

Although glucocorticoids reduce vasogenic cerebral edema (e.g. surrounding brain tumors) and may be effective in lowering ICP in pseudotumor cerebri, they have little effect on cytotoxic cerebral edema which is the more prevalent derangement following trauma; see Cerebral edema (p. 90).

Significant side effects may occur with steroids\(^ {131}\) including coagulopathies, hyperglycemia\(^ {132}\) with its undesirable effect on cerebral edema – see Possible deleterious side effects of steroids (p. 594) – and increased incidence of infection (due to immunosuppression). High-dose methylprednisolone is associated with increased mortality.\(^ {133}\)

Non-glucocorticoid steroids (e.g. 21-aminosteroids, AKA lazaroids, including tirilazad\(^ {134,135}\)) and the synthetic glucocorticoid triamcinolone\(^ {136}\) have also failed to show overall benefit.

**High-dose barbiturate therapy**

**Practice guideline: Barbiturates in severe head injury**

**Level II\(^ {137}\):** prophylactic use of barbiturates for burst suppression EEG is not recommended

**Level II\(^ {137}\):** high-dose barbiturates are recommended for IC-HTN refractory to maximal medical and surgical ICP lowering therapy. Patients should be hemodynamically stable before and during treatment

Theoretical benefits of barbiturates in head injury derive from vasoconstriction in normal areas (shunting blood to ischemic brain tissue), decreased metabolic demand for \( O_2 \) (CMRO\(_2\)) with accompanying reduction of CBF, free radical scavenging, reduced intracellular calcium, and lysosomal stabilization.\(^ {138}\) There is little question that barbiturates lower ICP, even when other treatments have failed;\(^ {139}\) but regarding outcome, studies have shown both benefits\(^ {140,141}\) and lack of same.\(^ {142,143}\) A subgroup of patients with preserved vasoreactivity may benefit from the use of barbiturates\(^ {144}\); and when reserved for use in patients who failed to respond sufficiently to other measures, barbiturates have been shown to lower ICP.\(^ {145}\) Patients that do respond have a lower mortality (33%) than those in whom ICP control could not be accomplished (75%).\(^ {141}\)

The limiting factor for therapy is usually hypotension due to barbiturate induced reduction of sympathetic tone\(^ {146,150}\) (causing peripheral vasodilation) and direct mild myocardial depression. Hypotension occurs in \( \approx 50\)% of patients in spite of adequate blood volume and use of dopamine.\(^ {147}\)

NB: the ability to follow the neurologic exam is lost with high-dose barbiturates, and one must follow ICP.

“Barbiturate coma” vs. high-dose therapy: If barbiturates are given until there is burst suppression on EEG, this is considered true “barbiturate coma.” This results in near maximal reductions in CMRO\(_2\) and CBF.\(^ {3}\) However, most regimens should technically be called “high dose intravenous therapy” since they simply try to establish target serum barbiturate levels (e.g. 3–4 mg\( /L\) for pentobarbital), even though there is poor correlation between serum level, therapeutic benefit, and systemic complications.\(^ {3}\)

Adjunctive measures to administration of high-dose barbiturates:

1. consider a Swan-Ganz (PA) catheter placed during the first hour of loading dose
2. high-dose barbiturates often causes paralytic ileus: therefore NG tube to suction & IV hyperalimentation are usually needed
Indications
The use of barbiturates should be reserved for situations where the ICP cannot be controlled by the previously outlined measures, as there is evidence that prophylactic barbiturates do not favorably alter outcome, and are associated with significant side effects, mostly hypotension, that can cause neurologic deterioration.

Choice of agents
A number of agents have been studied, however, there is inadequate data to recommend one drug over another. The most information is available on pentobarbital (see below). Alternative agents which have not been as well studied: thiopental (see below), phenobarbital (p.451) & propofol (p.877).

Drug info: Pentobarbital (Nembutal®)
Pentobarbital has a fast onset (full effects within ≈ 15 minutes), short duration of action (3–4 hrs), and a half-life of 15–48 hrs.

Protocols for pentobarbital therapy in adults
There are many protocols. A simple one from a randomized clinical trial:

1. **Loading dose:**
   a) pentobarbital 10 mg/kg I.V. over 30 minutes
   b) then 5 mg/kg q 1 hr × 3 doses
2. **Maintenance:** 1 mg/kg/hr

A more elaborate protocol:

1. **Loading dose:** pentobarbital 10 mg/kg/hr I.V. over 4 hrs as follows:
   a) **FIRST HOUR:** 2.5 mg/kg slow IVP q 15 min × 4 doses (total: 10 mg/kg in first hr), follow BP closely
   b) next 3 hours: 10 mg/kg/hr continuous infusion (put 2500 mg in 250 ml of appropriate I.V. run at K ml/hr × 3 hrs (K = patient’s weight in kg))
2. **Maintenance:** 1.5 mg/kg/hr infusion (put 250 mg in 250 ml I.V. and run at 1.5 × Kml/hr)
3. **Check serum pentobarbital level 1 hr after loading dose completed; usually 3.5–5.0 mg%**
4. **Check serum pentobarbital level q day thereafter**
5. **If level ever > 5 mg% and ICP acceptable, reduce dose**
6. **Baseline brain stem auditory evoked response (BAER) early in treatment. May be omitted on clinical grounds. Repeat BAER if pentobarbital level ever > 6 mg% Reduce dose if BAER deteriorates (NB: hemotympanum may interfere with BAER)**
7. **Goal: ICP < 24 mm Hg and pentobarbital level 3–5 mg% Consider discontinuing pentobarbital due to ineffectiveness if ICP still > 24 with adequate drug levels × 24 hrs**
8. **If ICP < 20 mm Hg, continue treatment × 48 hrs, then taper dose. Backtrack if ICP rises**

Neuro function takes ≈ 2 days off pentobarbital to return. If desired to perform a brain death exam, the pentobarbital level needs to be ≤ 10 mcg/ml before the exam is valid.

</tr>
</tbody>
</table>

*Levels reported are for intolerant patients; there is significant variability between patients and tolerant patients may not be sedated even at levels as high as 100 mcg/ml*
Drug info: Thiopental (Pentothal®)

May be useful when a rapidly acting barbiturate is needed (e.g. intra-op) or when large doses of pentobarbital are not available. One of many protocols follows (note: thiopental has not been as well studied for this indication, but is theoretically similar to pentobarbital[148,149]):

1. loading dose: thiopental 5 mg/kg (range: 3–5) IV over 10 minutes — transient burst suppression (<10 minutes) and blood thiopental levels of 10–30 mcg/ml. Higher doses (~35 mg/kg) have been used in the absence of hypothermia to produce longer duration burst suppression for cardiopulmonary bypass.
2. follow with continuous infusion of 5 mg/kg/hr (range: 3–5) for 24 hours
3. may need to rebolus with 2.5 mg/kg as needed for ICP control
4. after 24 hours, fat stores become saturated, reduce infusion to 2.5 mg/kg/hr
5. titrate to control ICP or use EEG to monitor for electrocerebral silence
6. "therapeutic" serum level: 6–8.5 mg/dl

Drug info: Propofol (Diprivan®)

Level II[137]: propofol may control ICP after several hours of dosing, but it does not improve mortality or 6 month outcome. Caution: high-dose propofol (total dose >100 mg/kg for >48 hrs) can cause significant morbidity (see propofol infusion syndrome).

- 0.5 mg/kg test dose, then 20–75 mcg/kg/min infusion. Increase by 5–10 mcg/kg/min q 5–10 minutes PRN ICP control (do not exceed 83 mcg/kg/min = 5 mg/kg/hr).

Side effects: include Propofol Infusion Syndrome (p. 133). Use with caution at doses >5 mg/kg/hr or at any dose for >48 hrs.

57 Skull Fractures

57.1 General information
Classified as either closed (simple fracture) or open (compound fracture).
Diastatic fractures extend into and separate sutures. More common in young children.¹

57.2 Linear skull fractures over the convexity
90% of pediatric skull fractures are linear and involve the calvaria.
Table 57.1 shows some differentiating features to distinguish linear skull fractures. See also Indications for CT and admission criteria for TBI (p. 830).
By themselves, linear skull fractures over the convexity rarely require surgical intervention.

57.3 Depressed skull fractures
For special considerations in pediatrics, see Depressed skull fractures (p. 915) in pediatrics section.

57.3.1 Indications for surgery
See Practice guideline: Surgical management of depressed skull fractures (p. 882). Some additional observations regarding surgery to elevate a depressed skull fracture in an adult:
1. consider surgery for depressed skull fractures with deficit referable to underlying brain
2. more conservative treatment is recommended for fractures overlying a major dural venous sinus (note: exception: depressed fractures overlying and depressing one of the dural sinuses may be dangerous to elevate, and if the patient is neurologically intact, and no indication for operation (e.g. CSF leak mandates surgery) may be best managed conservatively).

Practice guideline: Surgical management of depressed skull fractures

Indications for surgery
Level III:
1. open (compound) fractures
   a) surgery for fractures depressed > thickness of calvaria and those not meeting criteria for nonsurgical management listed below
   b) nonsurgical management may be considered if
      • there is no evidence (clinical or CT) of dural penetration (CSF leak, intradural pneumocephalus on CT...)
      • and no significant intracranial hematoma
      • and depression is <1 cm
      • and no frontal sinus involvement
      • and no wound infection or gross contamination
      • and no gross cosmetic deformity
2. closed (simple) depressed fractures: may be managed surgically or nonsurgically

Timing of surgery
Level III: early surgery to reduce risk of infection

Surgical methods
Level III:
1. elevation and debridement are recommended
2. option: if there is no evidence of wound infection, primary bone replacement
3. antibiotics should be used for all compound depressed fractures
There is no evidence that elevating a depressed skull fracture will reduce the subsequent development of posttraumatic seizures,\(^3\) which are probably more related to the initial brain injury.

57.3.2 Surgical treatment for depressed skull fractures

General information

</tr>
</tbody>
</table>

### Technical considerations of surgery

Surgical goals (modified\(^4\))

1. debridement of skin edges
2. elevation of bone fragments
3. repair of dural laceration
4. debridement of devitalized brain
5. reconstruction of the skull
6. skin closure

**Techniques**

1. with open (compound) contaminated fractures, it may be necessary to excise depressed bone. In these cases or when air sinuses are involved, to minimize the risk of infecting the flap, some surgeons follow the patient for 6–12 months to rule out infection before performing a cosmetic cranioplasty. There has been no documented increase in infection with replacement of bone fragments; soaking the fragments in povidone-iodine has been recommended\(^4\)
2. elevating the bone may be facilitated by drilling burr holes around the periphery and either using rongeurs or craniotome to excise the depressed portion
3. in cases where laceration of a major dural sinus is suspected and surgery is mandated, adequate preparation must be made for dural sinus repair\(^5\); NB: the SSS is often to the right of the sagittal suture (p. 61)

<table>

</table>
a) prepare for massive blood loss
b) have small Fogarty catheter ready to temporarily occlude sinus
c) have dural shunt ready (Kapp-Gielchinsky shunt, if available, has an inflatable balloon at both ends)
d) prep out saphenous vein area for vein graft
e) bone fragments that may have lacerated sinus should be removed last

57.4 Basal skull fractures

57.4.1 General information

Most basal (AKA basilar) skull fractures (BSF) are extensions of fractures through the cranial vault. Severe basilar skull fractures may produce shearing injuries to the pituitary gland. BSF, especially those involving the clivus, may be associated with traumatic aneurysms. This rarely occurs in pediatrics.

57.4.2 Some specific fracture types

Temporal bone fractures

General information

Although often mixed, there are two basic types of temporal bone fractures:

- longitudinal fracture: more common (70–90%). Usually through petro-squamosal suture, parallel to and through EAC. Can often be diagnosed on otoscopic inspection of the EAC. Usually passes between cochlea and semicircular canals (SCC) sparing the VII and VIII nerves, but may disrupt the ossicular chain
- transverse fracture: perpendicular to EAC. Often passes through cochlea and may place stretch on geniculate ganglion, resulting in VIII and VII nerve deficits respectively

Posttraumatic facial palsy

Posttraumatic unilateral peripheral facial nerve palsy may be associated with transverse petrous bone fractures as noted above.

Management

Management is often complicated by multiplicity of injuries (including head injury requiring endotracheal intubation) making it difficult to determine the time of onset of facial palsy. Guidelines:

1. regardless of time of onset:
   a) steroids (glucocorticoids) are often utilized (efficacy unproven)
   b) consultation with ENT physician is usually indicated
2. immediate onset of unilateral peripheral facial palsy: facial EMG (AKA electroneuronography or ENOG) takes at least 72 hrs to become abnormal. These cases are often followed and are possible candidates for surgical VII nerve decompression if no improvement occurs with steroids (timing of surgery is controversial, but is usually not done emergently)
3. delayed onset of unilateral peripheral facial palsy: follow serial ENOGs, if continued nerve deterioration occurs while on steroids, and activity on ENOG drops to less than 10% of the contralateral side, surgical decompression may be considered (controversial, thought to improve recovery from ≈40% to ≈75% of cases)

Clival fractures

See reference.

3 categories (75% are longitudinal or transverse):

1. longitudinal: may be associated with injuries of vertebrobasilar vessels including:
   a) dissection or occlusion: may cause brain stem infarction
   b) traumatic aneurysms
2. transverse: may be associated with injuries to the anterior circulation
3. oblique

Clival fractures are highly lethal. May be associated with:

1. cranial nerve deficits: especially III through VI; bitemporal hemianopsia
2. CSF leak
3. diabetes insipidus
4. delayed development of traumatic aneurysms

Occipital condyle fractures
These are considered in the section on Spine fractures (p. 966).

57.4.3 Radiographic diagnosis
BSF appear as linear lucencies through the skull base. A CT scan with multiplanar projections is the most sensitive means for directly demonstrating BSF. Plain skull x-rays and clinical criteria (see below) may also be able to make the diagnosis. Indirect radiographic findings (on CT or plain films) that suggest BSF include: pneumocephalus (diagnostic of BSF in the absence of an open fracture of the cranial vault), air/fluid level within or opacification of air sinus with fluid (suggestive).

57.4.4 Clinical diagnosis
Some of these signs may take several hours to develop. Signs include:
1. CSF otorrhea or rhinorrhea
2. hemotympanum or laceration of external auditory canal
3. postauricular ecchymoses (Battle’s sign)
4. periorbital ecchymoses (raccoon’s eyes) in the absence of direct orbital trauma, especially if bilateral
5. cranial nerve injury:
   a) VII and/or VIII: usually associated with temporal bone fracture
   b) olfactory nerve (Cr. N. I) injury: often occurs with anterior fossa BSF and results in anosmia, this fracture may extend to the optic canal and cause injury to the optic nerve (Cr. N. II)
   c) VI injury: can occur with fractures through the clivus (see below)

57.4.5 Management
NG tubes
Caution: cases have been reported with BSF where an NG tube has been passed intracranially through the fracture and is associated with fatal outcome in 64% of cases. Possible mechanisms include: a cribriform plate that is thin (congenitally or due to chronic sinusitis) or fractured (due to a frontal basal skull fracture or a comminuted fracture through the skull base). Suggested contraindications to blind placement of an NG tube include: trauma with possible basal skull fracture, ongoing or history of previous CSF rhinorrhea, meningitis with chronic sinusitis.

Prophylactic antibiotics
The routine use of prophylactic antibiotics is controversial. This remains true even in the presence of a CSF fistula; see CSF fistula (cranial) (p. 384). However, most ENT physicians recommend treating fractures through the nasal sinuses as open contaminated fractures, and they use broad spectrum antibiotics (e.g. ciprofloxacin) for 7–10 days.

Treatment of the BSF
Most do not require treatment by themselves. However, conditions that may be associated with BSF which may require specific management include:
1. “traumatic aneurysms” (p. 1227)
2. postransverse carotid-cavernous fistula (p. 1256)
3. CSF fistula: operative treatment may be required for persistent CSF rhinorrhea; see CSF fistula (cranial) (p. 384)
4. meningitis or cerebral abscess: may occur with BSF into air sinuses (frontal or mastoid) even in the absence of an identifiable CSF leak. May even occur many years after the BSF was sustained; see Post craniospinal trauma meningitis / post-traumatic meningitis (p. 318)
5. cosmetic deformities
6. postransverse facial palsy (below)
57.5 Craniofacial fractures

57.5.1 Frontal sinus fractures

General information

Frontal sinus fractures account for 5–15% of facial fractures.

In the presence of a frontal sinus fracture, intracranial air (pneumocephalus) on CT even without a clinically evident CSF leak, must be presumed to be due to dural laceration (although it could also be due to a basal skull fracture, below).

Anesthesia of the forehead may occur due to supratrochlear and/or supraorbital nerve involvement.

The risks of posterior wall fractures are not immediate, but may be delayed (some even by months or years) and include:

1. brain abscess
2. CSF leak with risk of meningitis
3. cyst or mucocele formation: injured frontal sinus mucosa has a higher predilection for mucocele formation than other sinuses. Mucoceles may also develop as a result of frontonasal duct obstruction due to fracture or chronic inflammation. Mucoceles are prone to infection (mucopyocele) which can erode bone and expose dura with risk of infection

Anatomic considerations of the frontal sinus

The frontal sinus begins to appear around age 2 yrs, and becomes radiographically visible by age 8 as it extends above the superior orbital rim. The sinus is lined with respiratory epithelium, the mucous secretion of which drains through the frontonasal duct medially and inferiorly into the middle nasal meatus.

Surgical considerations

Indications

Linear fractures of the anterior wall of the frontal sinus are treated expectantly.

Indications for exploration of posterior wall fractures is controversial. Some argue that a few mm of displacement, or that CSF fistula that resolves may not require exploration. Others vehemently disagree.

Technique

In the presence of a traumatic forehead laceration, the frontal sinus may be exposed through judicious incorporation of the laceration in a forehead incision. Without such a laceration, either a bicornonal (souttar) skin incision or a butterfly incision (through the lower part of the eyebrows, crossing the midline near the glabella) is used.

In the presence of pneumocephalus, if no obvious dural laceration is found the dural undersurface of the frontal lobes should be checked for leaks. Extradural inspection and repair is rarely indicated; the act of lifting the dura off the floor of the frontal fossa in the region of the ethmoid sinuses often creates lacerations. Intradural repair is accomplished using a graft (fascia lata is most desirable; pericranium is thinner but is often acceptable) which is held in place with sutures and must extend all the way back to the ridge of the sphenoid wing (fibrin glue may be a helpful adjunct).

A pericranial flap is placed across the floor of the frontal fossa to help isolate the dura from the frontal sinus and to prevent CSF fistula.

Dealing with frontal sinus

Simple packing of the sinus (with bone wax, Gelfoam®, muscle or fat) increases the possibility of infection or mucocele formation.

The rear wall of the sinus is removed (so-called cranialization of the frontal sinus). The sinus is then exenterated (mucosa is stripped from sinus wall down to the nasofrontal duct, the mucosa is inverted over itself in the region of the duct and is packed down into the duct, temporalis muscle plugs are then packed into the frontonasal ducts), then the bony wall of the sinus is drilled with a diamond burr to remove tiny remnants of mucosa found in the surface of bone that may proliferate and form a mucocele. If there is any remnant of sinus, it may then be packed with abdominal fat that fills all corners of the cavity. Post-op risks related to frontal sinus injury include: infection, mucocele formation and CSF leak.
57.5.2 LeFort fractures
Complex fractures through inherently weak “cleavage planes” resulting in an unstable segment ("floating face"). Shown in Fig. 57.1 (usually occur as variants of this basic scheme).
- LeFort I: transverse AKA transmaxillary fracture. Fracture line crosses pterygoid plate and maxilla just above the apices of the upper teeth. May enter maxillary sinus(es)
- LeFort II: pyramidal. Fracture extends upward across inferior orbital rim and orbital floor to medial orbital wall, then across nasofrontal suture. Often from downward blow to the nasal area
- LeFort III: craniofacial dislocation. Involves zygomatic arches, zygomaticofrontal suture, nasofrontal suture, pterygoid plates, and orbital floors (separating maxilla from cranium). Requires significant force, therefore often associated with other injuries, including brain injuries

57.6 Pneumocephalus
57.6.1 General information
AKA (intra)cranial aerocele, AKA pneumatocele, is defined as the presence of intracranial gas. It is critical to distinguish this from tension pneumocephalus which is gas under pressure (see below). The gas may be located in any of the following compartments: epidural, subdural, subarachnoid, intraparenchymal, intraventricular.

57.6.2 Etiologies of pneumocephalus
Anything that can cause a CSF leak can produce associated pneumocephalus (p.386).
1. skull defects
   a) post neurosurgical procedure
      • craniotomy: risk is higher when patient is operated with surgery in the sitting position
      • shunt insertion
      • burr-hole drainage of chronic subdural hematoma: incidence is probably <2.5% although higher rates have been reported
   b) posttraumatic
      • fracture through air sinus (frontal, ethmoid…): including basal skull fracture
      • open fracture over convexity (usually with dural laceration)
   c) congenital skull defects: including defect in tegmen tympani
   d) neoplasm (osteoma, epidermoid, pituitary tumor): usually caused by tumor erosion through floor of sella into sphenoid sinus
2. infection
   a) with gas-producing organisms
   b) mastoiditis

Fig. 57.1 LeFort fractures
3. post invasive procedure:
   a) lumbar puncture
   b) ventriculostomy
   c) spinal anesthesia

4. spinal trauma (LP could be included here as well)

5. barotrauma: e.g. with scuba diving (possibly through a defect in the tegmen tympani)

6. may be potentiated by a CSF drainage device in the presence of a CSF leak

57.6.3 Presentation

H/A in 38% N/V, seizures, dizziness, and obtundation. An intracranial succussion splash is a rare (occurring in ≈ 7%) but pathognomonic finding. Tension pneumocephalus may additionally cause signs and symptoms just as any mass (may cause focal deficit or increased ICP).

57.6.4 Differential diagnosis (things that can mimic pneumocephalus)

Although intracranial low-density on CT may be associated with epidermoid, lipoma, or CSF, nothing is as intensely black as air. This can often be better appreciated on bone-windows than on soft-tissue windows.

57.6.5 Tension pneumocephalus

Intracranial gas can develop elevated pressure in the following settings:

1. when nitrous oxide anesthesia is not discontinued prior to closure of the dura; see nitrous oxide, N₂O (p. 105)

2. when a “ball-valve” effect occurs due to an opening to the intracranial compartment with soft tissue (e.g. brain) that may permit air to enter but prevent exit of air or CSF

3. when trapped room temperature air expands with warming to body temperature: a modest increase of only ≈ 4% results from this effect

4. in the presence of continued production by gas-producing organisms

57.6.6 Diagnosis

Pneumocephalus is most easily diagnosed on CT which can detect quantities of air as low as 0.5 ml. Air appears dark black (darker than CSF) and has a Hounsfield coefficient of −1000. One characteristic finding with bilateral pneumocephalus is the Mt. Fuji sign in which the two frontal poles appear peaked and are surrounded by and separated by air, resembling the silhouette of the twin peaks of Mt. Fuji (see Fig. 57.2). Intracranial gas may also be evident on plain skull x-rays.

Fig. 57.2 Mt. Fuji sign with bilateral pneumocephalus. Axial noncontrast CT scan
Since simple pneumocephalus usually does not require treatment, it is critical to differentiate it from tension pneumocephalus, which may need to be evacuated if symptomatic. It may be quite difficult to distinguish the two; brain that has been compressed e.g. by a chronic subdural hematoma may not expand immediately post-op and the “gas gap” may mimic the appearance of gas under pressure.

57.6.7 Treatment

When pneumocephalus is due to gas-producing organisms, treatment of the primary infection is initiated and the pneumocephalus is usually followed.

Treatment of non-infectious simple pneumocephalus depends on the whether or not the presence of a CSF leak is suspected. If there is no leak the gas will be resorbed with time, and if the mass effect is not severe it may simply be followed. If a CSF leak is suspected, management is as with any CSF fistula, see CSF fistula (cranial) (p. 384).

Treatment of significant or symptomatic post-op pneumocephalus by breathing 100% O₂ via a nonrebreather mask increases the rate of resorption (100% FiO₂ can be tolerated for 24–48 hours without serious pulmonary toxicity). Tension pneumocephalus producing significant symptoms must be evacuated. The urgency is similar to that of an intracranial hematoma. Dramatic and rapid improvement may occur with the release of gas under pressure. Options include placement of new twist drill or burr holes, or insertion of a spinal needle through a pre-existing burr hole (e.g. following a craniotomy).

References

58 Traumatic Hemorrhagic Conditions

58.1 Posttraumatic parenchymal injuries

58.1.1 Cerebral edema

Surgical decompression is occasionally an option; see Practice guideline: Posttraumatic cerebral edema (p.891).

**Practice guideline: Posttraumatic cerebral edema**

Indications and timing for surgery

Level III: bifrontal decompressive craniectomy within 48 hrs of injury is a treatment option for patients with diffuse, medically refractory posttraumatic cerebral edema and associated IC-HTN.

58.1.2 Diffuse injuries

Patients with severe diffuse injuries occasionally may be considered for decompressive craniectomy; see Practice guideline: Diffuse injuries (p.891).

**Practice guideline: Diffuse injuries**

Indications for surgery

Level III: decompressive craniectomy is an option for patients with refractory IC-HTN and diffuse parenchymal injury with clinical and radiographic evidence for impending transtentorial herniation.

58.2 Hemorrhagic contusion

58.2.1 General information

AKA traumatic intracerebral hemorrhage (TICH). The definition is not uniformly agreed upon. Often considered as high density areas on CT (some exclude areas < 1 cm diameter³). TICH usually produce much less mass effect than their apparent size. Most commonly occur in areas where sudden deceleration of the head causes the brain to impact on bony prominences (e.g. temporal, frontal and occipital poles) in coup or contrecoup fashion.

TICH often enlarge and/or coalesce with time as seen on serial CTs. They also may appear in a delayed fashion (below). Surrounding low density may represent associated cerebral edema. CT scans months later often show surprisingly minimal or no encephalomalacia.

58.2.2 Treatment

**Practice guideline: Surgical management of TICH**

- Level III: Indications for surgical evacuation for TICH:
  - progressive neurological deterioration referable to the TICH, medically refractory IC-HTN, or signs of mass effect on CT
  - or TICH volume >50 cm³ cc or ml
  - or GCS 6–8 with frontal or temporal TICH volume >20 cm³ with midline shift (MLS) ≥ 5 mm (p. 921) and/or compressed basal cisterns on CT (p. 921)
  - nonoperative management with intensive monitoring and serial imaging: may be used for TICH without neurologic compromise and no significant mass effect on CT and controlled ICP
58.2.3 Delayed traumatic intracerebral hemorrhage (DTICH)

DTICH demonstrated in patients on imaging that was not evident on initial admitting CT scan.

Incidence of DTICH in patients with GCS $\leq 8$: $\approx 10\%$ (reported incidence varies with resolution of CT scanner, timing of scan, and definition). Most DTICH occur within 72 hrs of the trauma. Some patients seem to be doing well and then present with an apoplectic event (although DTICH accounted only for $12\%$ of patients who “talk and deteriorate”).

Factors that contribute to formation of DTICH include local or systemic coagulopathy, hemorrhage into an area of necrotic brain softening, coalescence of extravasated microhematomas.

Treatment is the same as for TICH (see above).

Outcome for patients with DTICH described in the literature is generally poor, with a mortality ranging from 50–75\%.

58.3 Epidural hematoma

58.3.1 General information

Incidence of epidural hematoma (EDH): 1\% of head trauma admissions (which is $\approx 50\%$ the incidence of acute subdurs). Ratio of male:female = 4:1. Usually occurs in young adults, and is rare before age 2 yrs or after age 60 (perhaps because the dura is more adherent to the inner table in these groups).

Dogma was that a temporoparietal skull fracture disrupts the middle meningeal artery as it exits its bony groove to enter the skull at the pterion, causing arterial bleeding that gradually dissects the dura from the inner table resulting in a delayed deterioration. Alternate hypothesis: dissection of the dura from the inner table occurs first, followed by bleeding into the space thus created.

Source of bleeding: 85\% = arterial bleeding (the middle meningeal artery is the most common source of middle fossa EDHs). Many of the remainder of cases are due to bleeding from middle meningeal vein or dural sinus.

70\% occur laterally over the hemispheres with their epicenter at the pterion, the rest occur in the frontal, occipital, and posterior fossa (5–10\% each).

58.3.2 Presentation with EDH

“Textbook” presentation ($<10\%$–27\% have this classic presentation):

- brief posttraumatic loss of consciousness (LOC): from initial impact
- followed by a “lucid interval” for several hours
- then, obtundation, contralateral hemiparesis, ipsilateral pupillary dilatation as a result of mass effect from hematoma

Deterioration usually occurs over a few hours, but may take days and rarely, weeks (longer intervals may be associated with venous bleeding).

Other presenting findings: H/A, vomiting, seizure (may be unilateral), hemi-hyperreflexia + unilateral Babinski sign, and elevated CSF pressure (LP is seldom used any longer). Bradycardia is usually a late finding. In peds, EDH should be suspected if there is a 10\% drop in hematocrit after admission.

Contralateral hemiparesis is not uniformly seen, especially with EDH in locations other than laterally over the hemisphere. Shift of the brain stem away from the mass may produce compression of the opposite cerebral peduncle on tentorial notch which can produce ipsilateral hemiparesis (so called Kernohan’s phenomenon or Kernohan’s notch phenomenon), a false localizing sign.

60\% of patients with EDH have a dilated pupil, 85\% of which are ipsilateral.

No initial loss of consciousness occurs in 60\% No lucid interval in 20\% NB: a lucid interval may also be seen in other conditions (including subdural hematoma).

58.3.3 Differential diagnosis

- subdural hematoma
- a posttraumatic disorder described by Denny-Brown consisting of a “lucid interval” followed by bradycardia, brief periods of restlessness and vomiting, without intracranial hypertension or mass. Children especially may have H/A, and may become drowsy and confused. Theory: a form of vagal syncope. CT must be done to rule-out EDH.
58.3.4 Evaluation

Plain skull x-rays

Usually not helpful. No fracture is identified in 40% of EDH. In these cases the patient’s age was almost always <30 yrs.

CT scan in EDH

“Classic” CT appearance occurs in 84% of cases: high density biconvex (lenticular) shape adjacent to the skull. In 11% the side against the skull is convex and that along the brain is straight, and in 5% it is crescent shaped (resembling subdural hematoma). An EDH may cross the falx (distinct from SDH which is limited to one side of the falx) but is usually limited by skull sutures. EDH usually has uniformly density, sharply defined edges on multiple cuts, high attenuation (undiluted blood), contiguous with inner table, usually confined to small segment of calvaria. Mass effect is frequent. Occasionally, an epidural may be isodense with brain and may not show up unless IV contrast is given.

Mottling of density has been described as a finding in hyperacute EDH.

58.3.5 Mortality with EDH

Overall: 20–55% (higher rates in older series). Optimal diagnosis and treatment within few hours results in 5–10% estimated mortality (12% in a recent CT era series). Mortality without lucid interval double that with. Bilateral Babinski’s or decerebration pre-op → worse prognosis. Death is usually due to respiratory arrest from uncal herniation causing injury to the midbrain.

20% of patients with EDH on CT also have ASDH at autopsy or operation. Mortality with both lesions concurrently is higher, reported range: 25–90%.

58.3.6 Treatment of EDH

Medical

CT may detect small EDHs and can be used to follow them. However, in most cases, EDH is a surgical condition (below).

Nonsurgical management may be attempted in the following:

Small (≤1 cm maximal thickness) subacute or chronic EDH, with minimal neurological signs/symptoms (e.g., slight lethargy, H/A) and no evidence of herniation. Although medical management of p-fossa EDHs has been reported, these are more dangerous and surgery is recommended.

In 50% of cases there will be a slight transient increase in size between days 5–16, and some patients required emergency craniotomy when signs of herniation occurred.

Management

Management includes: admit, observe (in monitored bed if possible). Optional: steroids for several days, then taper. Follow-up CT: in 1 wk if clinically stable. Repeat in 1–3 mos if patient becomes asymptomatic (to document resolution). Prompt surgery if signs of local mass effect, signs of herniation (increasing drowsiness, pupil changes, hemiparesis…) or cardiorespiratory abnormalities.

Surgical

Surgical indications and timing

See also more details (p. 893). EDH in pediatric patients is riskier than adults since there is less room for clot. The threshold for surgery in pediatrics should be very low.

Practice guideline: Surgical management of EDH

Indications for surgery

Level III:

1. EDH volume >30 cm\(^3\) should be evacuated regardless of GCS
2. EDH with the all of the following characteristics can be managed nonsurgically with serial CT scans and close neurological observation in a neurosurgical center:
   a) volume <30 cm\(^3\)
   b) and thickness <15 mm
c) and with midline shift (MLS) < 5 mm (p. 921)
d) and GCS > 8
e) and no focal neurologic deficit

Timing of surgery
Level III: it is strongly recommended that patients with an acute EDH and GCS < 9 and anisocoria undergo surgical evacuation ASAP.

(Note: Volume of a lens = 1.6 to 2 \times r^2 \times 0.4 to 0.5 \times d^2 \approx (A \times B \times T)/2 as in an ellipsoid, 1/2 the products of the height times the AP diameter and the thickness T. For a 1.5 cm thick EDH to be < 30 cc it would have to have a diameter (not radius) < 6.3 – 7 cm. For a 1 cm thick EDH to be < 30 cc, it would have to have a diameter < 7.7 – 8.6 cm.)

Bookmark the case: Craniotomy for acute EDH/SDH

Also see defaults & disclaimers (p. 27).

1. position: (depends on location of bleed, usually supine)
2. blood: type & screen (for severe SDH: T & C 2 U PR B C)
3. post-op: ICU
4. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery through the skull to remove blood clot, stop any bleeding identified, possible placement of intracranial pressure monitor
   b) alternatives: nonsurgical management
   c) complications: usual craniotomy complications (p. 28) plus further bleeding which may cause problems (especially in patients taking blood thinners, antiplatelet drugs including aspirin, or those with coagulopathy abnormalities or previous bleeds) and may require further surgery, any permanent brain injury that has already occurred is not likely to recover, hydrocephalus

Surgical technical issues
Evacuation is performed in the O.R. unless the patient herniates in E/R and access to OR is not within acceptable timeframe. Objectives:
1. clot removal: lowers ICP and eliminates focal mass effect. Blood is usually thick coagulum, thus exposure must provide access to most of clot. Craniotomy permits more complete evacuation of hematoma than e.g. burr holes
2. hemostasis: coagulate bleeding soft tissue (dural veins & arteries). Apply bone wax to intra-diploic bleeders (e.g. middle meningeal artery). Also requires large exposure
3. prevent reaccumulation: (some bleeding may recur, and dura is now detached from inner table) place dural tack-up sutures to edges of craniotomy and use central “tenting” suture

58.3.7 Special cases of epidural hematoma

Delayed epidural hematoma (DEDH)
Definition: an EDH that is not present on the initial CT scan, but is found on subsequent CT. Comprise 9-10% of all EDHs in several series.

Theoretical risk factors for DEDH include the following (NB: many of these risk factors may be incurred after the patient is admitted following a negative initial CT):
1. lowering ICP either medically (e.g. osmotic diuretics) and/or surgically (e.g. evacuating contralateral hematoma) which reduces tamponading effect
2. rapidly correcting shock (hemodynamic “surge” may cause DEDH)
3. coagulopathies

Observation agrees with what one would predict based on the above in that DEDH tend to occur in patients with severe head injury and associated systemic injuries. However, DEDH have been reported in mild head injury (GCS > 12) infrequently. Presence of a skull fracture has been identified as a common feature of DEDH.

Key to diagnosis: high index of suspicion. Avoid a false sense of security imparted by an initial “nonsurgical” CT. 6 of 7 patients in one series improved or remained unchanged neurologically.
despite enlarging EDH (most eventually deteriorate). 1 of 5 with an ICP monitor did not have a heralding increase in ICP. May develop once an intracranial lesion is surgically treated, as occurred in 5 of 7 patients within 24 hrs of evacuation of another EDH. 6 of 7 patients had known skull fractures in the region where the delayed EDH developed, but none of 3 had a skull fracture in another report.

**Posterior fossa epidural hematoma**

Comprise ≈ 5% of EDH. More common in 1st two decades of life. Although as many as 84% have occipital skull fractures, only ≈ 3% of children with occipital skull fractures develop p-fossa EDH. The source of bleeding is usually not found, but there is a high incidence of tears of the dural sinuses. Cerebellar signs are surprisingly lacking or subtle in most. See surgical indications (p. 905). Overall mortality is ≈ 26% (mortality was higher in patients with an associated intracranial lesion).

**58.4 Acute subdural hematoma**

**58.4.1 General information**

The magnitude of impact damage, as opposed to secondary damage (p. 824), is usually much higher in acute subdural hematoma (ASDH) than in epidural hematomas, which generally makes this lesion much more lethal. There is often associated underlying brain injury, which may be less common with EDH. Symptoms may be due to compression of the underlying brain with midline shift, in addition to parenchymal brain injury and possibly cerebral edema.

Two common causes of traumatic ASDH:

1. accumulation around parenchymal laceration (usually frontal or temporal lobe). There is usually severe underlying primary brain injury. Often no “lucid interval.” Focal signs usually occur later and are less prominent than with EDH
2. surface or bridging vessel torn from cerebral acceleration-deceleration during violent head motion. With this etiology, primary brain damage may be less severe, a lucid interval may occur with later rapid deterioration

ASDH may also occur in patients receiving anticoagulation therapy, usually with, but sometimes without, a history of trauma (the trauma may be minor). Receiving anticoagulation therapy increases the risk of ASDH 7-fold in males and 26-fold in females.

**58.4.2 CT scan in ASDH**

Crescentic mass of increased density adjacent to inner table. Edema is often present.

Locations:
- Usually over convexity
- Interhemispheric
- Layering on tentorium
- in p-fossa

Changes with time on CT (see Table 58.1): isodense after ≈ 2 wks, only clues may be obliteration of sulci and lateralizing shift, the latter may be absent if bilateral. Subsequently becomes hypodense to brain (p. 898). Membrane formation begins by about 4 days after injury.

Traumatic Hemorrhagic Conditions 895

58
Differences from EDH: SDH is more diffuse, less uniform, usually concave over brain surface, often less dense (from mixing with CSF), and bridging subdural veins (from brain surface to the skull) may be seen (cortical vein sign).

58.4.3 Treatment

Indications for surgery

Level III surgical indications are shown in Practice guideline: Surgical management of ASDH (p.896). Other factors that should be considered:

1. presence of anticoagulants or platelet inhibitors: patients in good neurologic condition may be better served by reversing these agents prior to operating (to increase the safety of surgery)
2. location of hematoma: in general, a SDH high over the convexity is less threatening than a temporal/parietal SDH of the same volume that also has MLS
3. patient’s baseline level of function, DNR status...
4. while the guidelines suggest evacuating SDH <10 mm thick in some circumstances, clots that are smaller than this may not be causing problems but may simply be an epiphenomenon

**Practice guideline: Surgical management of ASDH**

**Indications for surgery**

*Level III*:

1. ASDH with thickness >10 mm or midline shift (MLS) >5 mm (on CT) should be evacuated regardless of GCS
2. ASDH with thickness <10 mm and MLS <5 mm (see text regarding the evacuation of ASDH <10 mm thick) should undergo surgical evacuation if:
   - GCS drops by ≥ 2 points from injury to admission
   - and/or the pupils are asymmetric or fixed and dilated
   - and/or ICP is >20 mm Hg
3. monitor ICP in all patients with ASDH and GCS <9

**Timing of surgery**

*Level III*:

ASDH meeting surgical criteria should be evacuated ASAP (for issues regarding timing of surgery, see text)

**Surgical methods**

*Level III*:

ASDH meeting the above criteria for surgery should be evacuated via craniotomy with or without bone flap removal and duraplasty (a large craniotomy flap is often required to evacuate the thick coagulum and to gain access to possible bleeding sites).

**Timing of surgery**

Timing of surgery for ASDH is a matter of controversy. As a general principle, when surgery for ASDH is indicated it should be done as soon as possible.

“Four hour rule”

This “rule” was based on a 1981 series of 82 patients with ASDH, which held that:

1. patients operated within 4 hrs of injury had 30% mortality, compared to 90% mortality if surgery was delayed >4 hrs
2. functional survival (Glasgow Outcome Scale ≥4, see Table 88.5) rate of 65% could be achieved with surgery within 4 hrs
3. other factors related to outcome in this series included:
   - post-op ICP: 79% of patients with functional recovery had post-op ICPs that didn’t exceed 20 mm Hg, whereas only 30% of patients who died had ICP <20 mm Hg
   - initial neuro exam
   - age was not a factor in this study (ASDH tend to occur in older patients than EDH)
However, a subsequent study of 101 patients with ASDH found a delay to surgery (delays > 4 hours from the injury) showed a nonstatistically-significant trend where mortality increased from 59% to 69% and functional survival decreased (Glasgow Outcome Scale ≤ 4, see Table 88.5) from 26% to 16%.29

### Booking the case: Acute subdural hematoma

Same as for acute epidural hematoma (p. 894).

### Technical considerations

One may start with a small linear dural opening to effect clot removal and enlarge it as needed and only if brain swelling seems controllable. The actual bleeding site is often not identified at the time of surgery.

### 58.4.4 Morbidity and mortality with ASDH

Mortality Range: 50–90% (a significant percentage of this mortality is from the underlying brain injury, and not the ASDH itself).

- Mortality is traditionally thought to be higher in aged patients (60%), and is 90–100% in patients on anticoagulants.25
- In a series of 101 patients with ASDH, functional recovery was 19%29 Postoperative seizures occurred in 9% and did not correlate with outcome. The following variables were identified as strongly influencing outcome:
  - mechanism of injury: the worst outcome was with motorcycle accidents, with 100% mortality in unhelmeted patients, 33% in helmeted
  - age: correlated with outcome only > 65 yrs age, with 82% mortality and 5% functional survival in this group (other series had similar results30)
  - neurologic condition on admission: the ratio of mortality to functional survival rate related to the admission Glasgow Coma Scale (GCS) is shown in Table 58.2
  - postoperative ICP: patients with peak ICPs < 20 mm Hg had 40% mortality, and no patient with ICP > 45 had a functional survival

Of all the above factors, only the time to surgery and postoperative ICP can be directly influenced by the treating neurosurgeon.

### 58.4.5 Special cases of acute subdural hematoma

#### Interhemispheric subdural hematoma

**General information**

Subdural hematoma along the falx between the two cerebral hemispheres (older term: interhemispheric scissure).

- May occur in children,31 possibly associated with child abuse.32
- In adults, a consequence of: head trauma in 79–91% ruptured aneurysm33 in ≈ 12% surgery in the vicinity of the corpus callosum, and rarely spontaneously.34
- Incidence is unknown. Spontaneous cases should be investigated for possible underlying aneurysm. Occasionally may be bilateral, sometimes may be delayed (see below)

Table 58.2 Outcome as related to admission GCS
Most often are asymptomatic, or may present with the so-called “falx syndrome” – paresis or focal seizures contralateral to the hematoma. Other presentations: gait ataxia, dementia, language disturbance, oculomotor palsies.

Treatment
Controversial. Small asymptomatic cases may be managed expectantly. Surgery should be considered for progressive neurological deterioration with larger lesions. Approached through a parasagittal craniotomy. Surgery for these lesions can be treacherous – there is risk of venous infarction and one often finds they are dealing with a superior sagittal sinus injury.

Outcome
Reported mortality: 25–42%. Mortality is higher in the presence of altered levels of consciousness. Mortality rate may actually be lower (24%) than with all-comers. This is significantly lower than SDH in other sites (see above).

Delayed acute subdural hematoma (DASDH)
DASDHs have received less attention than delayed epidural or intraparenchymal hematomas. Incidence is ≈ 0.5% of operatively treated ASDHs.

Definition: ASDH not present on an initial CT (or MRI) that shows up on a subsequent study. Indications for treatment are the same as for ASDH. Neurologically stable patients with a small DASDH and medically controllable ICP are managed expectantly.

Infantile acute subdural hematoma
General information
Infantile acute subdural hematoma (IASDH) is often considered as a special case of SDH. Roughly defined as an acute SDH in an infant due to minor head trauma without initial loss of consciousness or cerebral contusion, possibly due to rupture of a bridging vein. The most common trauma is a fall backwards from sitting or standing. The infants will often cry immediately and then (usually within minutes to 1 hour) develop a generalized seizure. Patients are usually <2 yrs old (most are 6–12 mos, the age when they first begin to pull themselves up or walk).

These clots are rarely pure blood, and are often mixed with fluid. 75% are bilateral or have contralateral subdural fluid collections. It is speculated that IASDH may represent acute bleeding into a preexisting fluid collection.

Skull fractures are rare. In one series, retinal and preretinal hemorrhages were seen in all 26 patients.

Treatment
Guided by clinical condition and size of hematoma. Minimally symptomatic cases (vomiting, irritability, no altered level of consciousness and no motor disturbance) with liquefied hematoma may be treated with percutaneous subdural tap, which may be repeated several times as needed. Chronically persistent cases may require a subduroperitoneal shunt.

More symptomatic cases with high density clot on CT require craniotomy. A subdural membrane similar to those seen in adult chronic SDH is not unusual. Caution: these patients are at risk of developing intraoperative hypovolemic shock.

Outcome
8% morbidity and mortality rate in one series. Much better prognosis than ASDH of all ages probably because of the absence of cerebral contusion in IASDH.

58.5 Chronic subdural hematoma
58.5.1 General information
Originally termed “pachymeningitis hemorrhagica interna” by Virchow in 1857. Chronic subdural hematomas (CSDH) generally occur in the elderly, with the average age being ≈ 63 yrs; exception: subdural collections of infancy (p.903). Head trauma is identified in <50% (sometimes rather trivial trauma can produce these lesions). Other risk factors: alcohol abuse, seizures, CSF shunts,
coagulopathies (including therapeutic anticoagulation\textsuperscript{25}), and patients at risk for falls (e.g. with hemiplegia from previous stroke). CSDHs are bilateral in \approx 20–25\% of cases.\textsuperscript{38,39} 

Hematoma thickness tends to be larger in older patients due to a decrease in brain weight and increase in subdural space with age.\textsuperscript{40} 

Classically CSDHs contains dark “motor oil” fluid which does not clot.\textsuperscript{41} When the subdural fluid is clear (CSF), the collection is termed a subdural hygroma (p. 902).

58.5.2 Pathophysiology

Many CSDH probably start out as acute subdurals. Blood within the subdural space evokes an inflammatory response. Within days, fibroblasts invade the clot, and form neomembranes on the inner (cortical) and outer (dural) surface. This is followed by ingrowth of neocapillaries, enzymatic fibrinolysis, and liquefaction of blood clot. Fibrin degradation products are reincorporated into new clots and inhibit hemostasis. The course of CSDH is determined by the balance of plasma effusion and/or rebleeding from the neomembranes on the one hand and reabsorption of fluid on the other.\textsuperscript{42,43}

58.5.3 Presentation

Patients may present with minor symptoms of headache, confusion, language difficulties (e.g. word-finding difficulties or speech arrest, usually with dominant hemisphere lesions), or TIA-like symptoms (p. 1398). Or, they may develop varying degrees of coma, hemiplegia, or seizures (focal, or less often generalized). Often, the diagnosis may be unexpected prior to imaging.

58.5.4 Treatment

Overall management

1. seizure prophylaxis: used by some. It may be safe to discontinue after a week or so if there are no seizure. If late seizure occurs with or without prior use of AEDs, longer-term therapy is required
2. coagulopathies (including iatrogenic anticoagulation) should be reversed
3. surgical evacuation of hematoma indications as follows
   a) symptomatic lesions: including focal deficit, mental status changes...
   b) or subdurals with maximum thickness greater than \approx 1\text{ cm}
   c) or progressive increase in size on serial imaging (CT or MRI scans)

Surgical considerations

**Booking the case: Craniotomy: for chronic subdural**

Also see defaults & disclaimers (p. 27).

1. position: (usually supine), horseshoe headrest
2. post-op: ICU
3. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery through the skull to remove blood clot, stop any bleeding identified, placement a drainage tube to allow further fluid to drain after surgery for a day or so
   b) alternatives: nonsurgical management
   c) complications: usual craniotomy complications (p. 28) plus further bleeding which may cause problems (especially in patients taking blood thinners, antiplatelet drugs including aspirin, or those with coagulation abnormalities or previous bleeds) and may require further surgery, hydrocephalus

Surgical options

There is not uniform agreement on the best method to treat CSDHs. For details of techniques (burr holes, whether or not to use subdural drain...) see below.

1. placing two Burr holes, and irrigating through and through with tepid saline until the fluid runs clear
2. single “large” Burr hole with irrigation and aspiration: see below
3. single burr hole drainage with placement of a subdural drain, maintained for 24–48 hrs (removed when output becomes negligible)
4. twist drill craniostomy: see below (note that small “twist drill” drainage without subdural drain has higher recurrence rate than e.g. burr holes)
5. formal craniotomy with excision of subdural membrane (may be necessary in cases which persistently recur after above procedures, possibly due to seepage from the subdural membrane). Still a safe and valid technique.44 No attempt should be made to remove the deep membrane adherent to the surface of brain.

Techniques that promote continued drainage after the immediate procedure and that may thus reduce residual fluid and prevent reaccumulation:
1. use of a subdural drain: (see below)
2. using a generous burr hole under the temporalis muscle: (see below)
3. bed-rest restriction with the head of the bed flat (1 pillow is permitted) with mild overhydration for 24–48 hours post-op (or if a drain is used, until 24–48 hours after it is removed). May promote expansion of the brain and expulsion of residual subdural fluid. Allowing patients to sit up to 30–40° immediately post-op was associated with higher radiographic recurrence rate (2.3% for those kept flat, vs. 19% for those who sat up) but usually did not require reoperation.45
4. some advocate continuous lumbar subarachnoid infusion when the brain fails to expand, however there are possible complications.46

Twist drill craniostomy for chronic subdural hemorrhages
This method is thought to decompress the brain more slowly and avoids the presumed rapid pressure shifts that occurs following other methods, which may be associated with complications such as intraparenchymal (intracerebral) hemorrhage. May even be performed at the bedside under local anesthesia.

A 0.5 cm incision is made in the scalp in the rostral portion of the hematoma, and then a twist drill hole is placed at a 45° angle to the skull, aimed in the direction of the longitudinal axis of the collection. If the drill does not penetrate the dura, this is done with an 18 Ga. spinal needle. A ventricular catheter is inserted into the subdural space, and is drained to a standard ventriculostomy drainage bag maintained 20 cm below the level of the craniostomy site.47,48,49 The patient is kept flat in bed (see above). Serial CTs assess the adequacy of drainage. The catheter is removed when at least ≈ 20% of the collection is drained and when the patient shows signs of improvement, which occurs within a range of 1–7 days (mean of 2.1 days). Some include a low pressure shunt valve in the system to prevent reflux of fluid or air.

Burr holes for chronic subdural hematomas
To prevent recurrence, the use of small burr holes (without a subdural drain) is not recommended. A generous (>2.5 cm diameter – it is recommended that one actually measure this) subtemporal craniectomy should be performed, and bipolar coagulation is used to shrink the edges of the dura and subdural membrane back to the full width of the bony opening (do not try to separate these two layers as this may promote bleeding). This allows continued drainage of fluid into the temporalis muscle where it may be resorbed. A piece of Gelfoam® may be placed over the opening to help prevent fresh blood from oozing into the opening.

Subdural drain
Use of a subdural drain is associated with a decrease in need for repeat surgery from 19% to 10%.50 If a subdural drain is used, a closed drainage system is recommended. Difficulties may occur with ventriculostomy catheters because the holes are small and are restricted to the tip region (so-designed to keep choroid plexus from plugging the catheter when inserted into the ventricles when used as intended as a CSF shunt), especially with thick “oily” fluid (on the positive side, slow drainage may be desirable). The drainage bag is maintained ≈ 50–80 cm below the level of the head.49,51 An alternative is a small Jackson-Pratt® drain using “thumb-print” indentation of the suction bulb which provides good drainage with a self-contained one-way valve (however, there may be a risk of excessive negative pressure with overcompression of the bulb).

Post-op, the patient is kept flat (see above). Prophylactic antibiotics may be given until ≈ 24–48 hrs following removal of the drain, at which time the HOB is gradually elevated. CT scan prior to removal of the drain (or shortly after removal) may be helpful to establish a baseline for later comparison in the event of deterioration.
There is a case report of administration of urokinase through a subdural drain to treat reaccumulation of clot following evacuation.52

58.5.5 Outcome

General information

There is clinical improvement when the subdural pressure is reduced to close to zero, which usually occurs after ≈ 20% of the collection is removed.59

Patients who have high subdural fluid pressure tend to have more rapid brain expansion and clinical improvement than patients with low pressures.51

Residual subdural fluid collections after treatment are common, but clinical improvement does not require complete resolution of the fluid collection on CT. CTs showed persistent fluid in 78% of cases on post-op day 10, and in 15% after 40 days,51 and may take up to 6 months for complete resolution. Recommendation: do not treat persistent fluid collections evident on CT (especially before ≈ 20 days post-op) unless it increases in size on CT or if the patient shows no recovery or deteriorates.76% of 114 patients were successfully treated with a single drainage procedure using a twist drill craniostomy with subdural ventricular catheter, and 90% with one or two procedures.57 These statistics are slightly better than twist drill craniostomy with aspiration alone (i.e. no drain).

Complications of surgical treatment

Although these collections often appear innocuous, severe complications may occur, including:

1. seizures (including intractable status epilepticus)
2. intracerebral hemorrhage (ICH): occurs in 0.7–5%53 Very devastating in this setting: one–third of these patients die and one third are severely disabled (also, see below)
3. failure of the brain to re-expand and/or reaccumulation of the subdural fluid
4. tension pneumocephalus
5. subdural empyema: may also occur with untreated subdurals54

In 60% of patients ≥ age 75 yrs (and in no patients <75 yrs), rapid decompression is associated with hyperemia in the cortex immediately beneath the hematoma, which may be related to the complications of ICH or seizures.53 All complications are more common in elderly or debilitated patients.

Overall mortality with surgical treatment for CSDH is 0–8%.53 In a series of 104 patients treated mostly with craniostomy,56 mortality was ≈ 4% all of which occurred in patients >60 yrs old and were due to accompanying disease. Another large personal series reported 0.5% mortality.56 Worsening of neurologic status following drainage occurs in ≈ 4%.55

58.6 Spontaneous subdural hematoma

58.6.1 General information

Occasionally patients with no identifiable trauma will present with severe H/A with or without associated findings (nausea, seizures, lethargy, focal findings including possible ipsilateral hemiparesis57...) and CT or MRI discloses a subdural hematoma that may be acute, subacute or chronic in appearance. The onset of symptoms is often sudden.57

58.6.2 Risk factors

Risk factors identified in a review of 21 cases in the literature58 include:

1. hypertension: present in 7 cases
2. vascular abnormalities: arteriovenous malformation (AVM), aneurysm59
3. neoplasm
4. infection: including meningitis, tuberculosis
5. substance abuse: alcoholism, cocaine60
6. hypovitaminosis: especially vitamin C deficiency17
7. coagulopathies, including:
   a) iatrogenic (antiagulation e.g. with warfarin)
   b) Ginkgo biloba (GB) extract: EGB761 and LJ1379. Contains ginkgolides (especially Type B) which are inhibitors of platelet activating factor (PAF) at high concentrations,61 also cause
vasodilation and decreased blood viscosity. There have been case reports showing temporal relationship of hemorrhage to intake of GB, especially at higher doses over long periods of time. However, no consistent alteration was demonstrable in 29 measurable coagulation/clotting variables after 7 days (bleeding time was mildly prolonged in some case reports). Some individuals may possibly be more susceptible to the supplement, and there may be as-yet uncharacterized interactions with other entities (such as alcohol, aspirin...) but studies so far have been unrevealing.

c) factor XIII deficiency (protransglutaminase).

58.6 Etiology

The bleeding site was determined in 14 of the 21 cases, and was arterial in each, typically involving a cortical branch of the MCA in the area of the sylvian fissure where there is a large number of branches to a wide cortical area.

Possible mechanisms for arterial rupture in idiopathic acute subdural hematoma (ASDH) include tears occur secondary to sudden head movements or trivial head trauma of the following:

1. small artery at perpendicular branch point off a cortical artery
2. small artery connecting the dura and cortex
3. adhesions between cortical artery and dura

58.6.4 Treatment

As for traumatic SDH. If symptomatic and/or >= 1 cm thick, surgical evacuation is the treatment of choice. For subacute to chronic subdurals, burr-hole evacuation is usually adequate (see above). For acute SDH, a craniotomy is usually required, and should expose the sylvian fissure to identify bleeding point(s). Microsurgical repair of arterial wall has been described.

58.7 Traumatic subdural hygroma

58.7.1 General information

From the Greek hygos meaning wet. AKA traumatic subdural effusion, AKA hydroma. Excess fluid in the subdural space (may be clear, blood tinged, or xanthochromic and under variable pressure) is almost always associated with head trauma, especially alcohol-related falls or assaults. Skull fractures were found in 39% of cases. Distinct from chronic subdural hematoma, which is usually associated with underlying cerebral contusion, and usually contains darker clots or brownish fluid (“motor oil” fluid), and may show membrane formation adjacent to inner surface of dura (hygromas lack membranes).

“Simple hygroma” refers to a hygroma without significant accompanying conditions. “Complex hygroma” refers to hygromas with associated significant subdural hematoma, epidural hematoma, or intracerebral hemorrhage.

58.7.2 Pathogenesis

Mechanism of formation of hygroma is probably a tear in the arachnoid membrane with resultant CSF leakage into the subdural compartment. Hygroma fluid contains pre-albumin, which is also found in subdural hematomas. The most likely locations of arachnoid tears are in the sylvian fissure or the chiasmatic cistern. Another possible mechanism is post-meningitis effusion (especially influenza meningitis).

May be under high pressure. May increase in size (possibly due to a flap-valve mechanism) and exert mass effect, with the possibility of significant morbidity. Cerebral atrophy was present in 19% of patients with simple hygromas.

58.7.3 Presentation

Table 58.3 shows clinical findings of subdural hygromas. Many present without focal findings. Complex hygromas usually present more acutely and require more urgent treatment.
58.7.4 Imaging

On CT, the density of the fluid is similar to that of CSF. Signal characteristics on MRI follow those of CSF.

58.7.5 Treatment

Asymptomatic hygromas do not require treatment. Recurrence following simple burr-hole drainage is common. Many surgeons maintain a subdural drain for 24–48 hrs post-op. Recurrent cases may require either a craniotomy to locate the site of CSF leak (may be very difficult), or a subdural-peritoneal shunt may be placed.

58.7.6 Outcome

Outcome may be more related to accompanying injuries than to the hygroma itself.

5 of 9 patients with complex hygromas and subdural hematoma died. For simple hygromas, morbidity was 20% (12% for decreased mental status without focal findings, 32% if hemiparesis/plegia was present).

58.8 Extraaxial fluid collections in children

58.8.1 Differential diagnosis

1. benign subdural collection in infants (see below)
2. chronic symptomatic extraaxial fluid collections or effusions (see below)
3. cerebral atrophy: should not contain xanthochromic fluid with elevated protein
4. “external hydrocephalus”: ventricles often enlarged, fluid is CSF (p.400)
5. normal variant of enlarged subarachnoid spaces and interhemispheric fissure
6. acute subdural hematoma: high density (fresh blood) on CT (occasionally these will appear as low density collections in children with low hematocrits). Will usually be unilateral (the others above are usually bilateral). These lesions may occur as birth injuries, and typically present with seizures, pallor, tense fontanelle, poor respirations, hypotension, and retinal hemorrhages
7. “craniocerebral disproportion” (head too large for the brain): extracerebral spaces enlarged up to 1.5 cm in thickness and filled with CSF-like fluid (possibly CSF), ventricles at upper limits of normal, deep sulci, widened interhemispheric fissure, normal intracranial pressure. Patients are developmentally normal. May be the same as benign extra-axial fluid of infancy (see below). Making this diagnosis with certainty is difficult in first few months of life.

58.8.2 Benign subdural collections of infancy

General information

Benign subdural collections (or effusions) of infancy\(^{74,75}\) are perhaps better characterized by the term benign extra-axial fluid collections of infancy, since it is difficult to distinguish whether they are subdural or subarachnoid.\(^ {76}\) They appear on CT as peripheral hypodensities over the frontal lobes in infants. Imaging may also show dilatation of the interhemispheric fissure, cortical sulci,\(^ {77}\) and sylvian fissure. Ventricles are usually normal or slightly enlarged, with no evidence of transependymal absorption. Brain size is normal. Transillumination is increased over both frontal regions. The fluid is usually clear yellow (xanthochromic) with high protein content. The etiology of these is unclear, some cases may be due to perinatal trauma. They are more common in term infants than preemies. Must be differentiated from external hydrocephalus (p.400).

Presentation

Mean age of presentation is \(\approx 4\) months.\(^ {76}\)

May show: signs of elevated intracranial pressure (tense or large fontanelle, accelerated head growth crossing percentile curves), developmental delay usually as a result of poor head control due to the large size (Carolan et al. feel that developmental delay without macrocrania runs counter to the concept of “benign” collections\(^ {76}\)), frontal bossing, jitteriness. The poor head control may lead to positional flattening. Other symptoms, such as seizures (possibly focal) are indicative of symptomatic collections (see below). Large collections in the absence of macrocrania are more suggestive of cerebral atrophy.

Treatment

Most cases gradually resolve spontaneously, often within 8–9 months. A single subdural tap (p.1504) for diagnostic purposes (to differentiate from cortical atrophy and to rule out infection) may be done, and may accelerate the rate of disappearance. Repeat physical exams with OFC measurements should be done at \(\approx 3–6\) month intervals. Head growth usually parallels or approaches normal curves by \(\approx 1–2\) yrs age, and by 30–36 months orbital-frontal head circumference (OFC) approaches normal percentiles for height and weight. They usually catch up developmentally as OFCs normalize.

58.8.3 Symptomatic chronic extraaxial fluid collections in children

General information

Variously classified as hematomas (chronic subdural hematoma), effusions, or hygromas, with differing definitions associated with each. Since the appearance on imaging and the treatment is similar, Litofsky et al. proposed that they all be classified as extraaxial fluid collections.\(^ {78}\) The difference between these lesions and “benign” subdural effusions (see above) may simply be the degree of clinical manifestation.

Etiologies

The following etiologies were listed in a series of 103 cases:\(^ {78}\):

1. 36% were thought to be the result of trauma (22 were victims of child abuse)
2. 22% followed bacterial meningitis (post-infectious)
3. 19 occurred after placement or revision of a shunt (p.425)
4. no cause could be identified in 17 patients

Other causes include:\(^ {73}\):

1. tumors: extracerebral or intracerebral
2. post-asphyxia with hypoxic brain damage and cerebral atrophy
3. defects of hemostasis: vitamin K deficiency...

Signs and symptoms

Symptoms include: seizure (26%), large head (22%), vomiting (20%), irritability (13%), lethargy (13%), headache (older children), poor feeding, respiratory arrest...
Signs include: full fontanelle (30%), macrocrania (25%), fever (17%), lethargy (13%), hemiparesis (12%), retinal hemorrhages, coma, papilledema, developmental delay...

Evaluation
CT/MRI usually shows ventricular compression and obliteration of the cerebral sulci, unlike with benign subdural collections. The “cortical vein sign” (p.401) helps distinguish this from external hydrocephalus.

Treatment
Options include:
1. observation: follow-up with serial OFC measurements, ultrasound and CT/MRI
2. serial percutaneous subdural taps (p.1504): some patients require as many as 16 taps. Some series show good results and others show low success rate
3. burr hole drainage: may include long-term external drainage. Simple burr hole drainage may not be effective with severe craniocephalic disproportion as the brain will not expand to obliterate the extra-axial space
4. subdural-peritoneal shunt: unilateral shunt is usually adequate even for bilateral effusions (recent recommendations: no study is required to demonstrate communication between the 2 sides). An extremely low pressure system should be utilized. The general practice is to remove the shunt after 2–3 months of drainage (once the collections are obliterated) to reduce the risk of associated mineralization of the dura and arachnoid and possible risk of seizures (these shunts are easily removed at this time, but may be more difficult to remove at a later date)

Other recommendations:
At least one percutaneous tap should be performed to rule-out infection. Many authors recommend observation for the patient with no symptoms or with only enlarging head and developmental delay.

58.9 Traumatic posterior fossa mass lesions
Less than 3% of head injuries involve traumatic mass lesions of the posterior fossa. Epidural hematomas constitute the majority of these (p.894). Other entities (subdural hematoma, intraparenchymal hematoma) comprise the small remainder. See Practice guideline: Surgical management of traumatic posterior fossa mass lesions (p.905) for surgical management recommendations. Any of these can cause hydrocephalus.

Practice guideline: Surgical management of traumatic posterior fossa mass lesions

Indications for surgery
Level III*: symptomatic posterior fossa mass lesions or those with mass effect on CT should be surgically removed. Note: mass effect on CT: defined as dislocation, compression or obliteration of the 4th ventricle; compression or loss of basal cisterns (p. 921) or the presence of obstructive hydrocephalus
- asymptomatic lesions without mass effect on CT may be managed with close observation and serial imaging

Timing of surgery
Level III*: p-fossa mass lesions meeting surgical criteria should be evacuated ASAP due to the potential for rapid deterioration

Surgical methods
Level III*: suboccipital craniectomy is the recommended procedure

Most parenchymal hemorrhages managed nonsurgically were <3 cm diameter.

59 Gunshot Wounds and Non-Missile Penetrating Brain Injuries

59.1 Gunshot wounds to the head

59.1.1 General information

Gunshot wounds to the head (GSWH) account for the majority of penetrating brain injuries, and comprise ≈ 35% of deaths from brain injury in persons <45 yrs old. GSWH are the most lethal type of head injury, ≈ two-thirds die at the scene, and GSWH ultimately are the proximal cause of death in > 90% of victims.  

59.1.2 Primary injury

Primary injury from GSWH results from a number of factors including:
1. injury to soft tissue
   a) direct scalp and/or facial injuries
   b) soft tissue and bacteria may be dragged intracranially, the devitalized tissue may also then support growth of the bacteria
   c) pressure waves of gas combustion may cause injury if the weapon is close
2. comminuted fracture of bone: may injure subjacent vascular and/or cortical tissue (depressed skull fracture). May act as secondary missiles
3. cerebral injuries from missile
   a) direct injury to brain tissue in path of bullet, exacerbated by
      • fragmentation of bullet
      • ricochet off bone
      • deviations of the bullet from a straight path as it travels: tumbling (forward rotation – pitch), yaw (rotation about vertical axis), rotation (spin), nutation
      • deformation of bullet at impact: e.g. mushrooming
   b) injury to tissue by shock waves, cavitation
4. coup + contrecoup injury from missile impact on head (may cause injuries distant from bullet path)

Because of the complexities of ballistics (some of which are described above) there is often more damage distally than at the entry site even though the bullet slows (losing kinetic energy). Extent of primary injury is related to impact velocity:
- impact velocity >100 m/s: causes explosive intracranial injury that is uniformly fatal (NB: impact velocity is less than muzzle velocity)
- non-bullet missiles (e.g. grenade fragments) are considered low velocity
- low muzzle velocity bullets (≤250 m/s): as with most handguns. Tissue injury is caused primarily by laceration and maceration along a path slightly wider than missile diameter
- high muzzle velocity bullets (≈600–750 m/s): from military weapons and hunting rifles. Causes additional damage by shock waves and temporary cavitation (tissue pushed away from the missile causes a conical cavity of injury that may exceed bullet diameter many-fold, and causes low-pressure region which may draw surface debris into the wound)

59.1.3 Secondary injury

Cerebral edema occurs similar to closed head injury. ICP may rise rapidly within minutes (higher ICPs result from higher impact velocities). Cardiac output may also fall initially. Together, ↑ ICP and ↓ MAP adversely affect cerebral perfusion pressure. Other common complicating factors include: DIC, intracranial hemorrhage from lacerated blood vessels.

59.1.4 Late complications

Late complications include:
1. cerebral abscess: migration of bullet may be a tip-off (see below). Usually associated with retained contaminated material (bullet, bone, skin...) but may also result from persistent communication with nasal sinuses
2. traumatic aneurysm
3. seizures
4. fragment migration
   a) migration of a bullet: often indicates abscess or, less commonly, a hematoma cavity. May also migrate within the ventricles
   b) intraventricular fragments may migrate and cause obstructive hydrocephalus
5. lead toxicity: more of an issue with bullet in disc space (p.1017)

59.1.5 Evaluation

Physical exam
Exam should describe visible entrance and exit wounds. In through-and-through missile wounds of the skull, the entrance wound is typically smaller than the exit wound due to bullet mushrooming. Entrance wounds may be especially small with direct contact of the muzzle to the head. At surgery or autopsy, the entrance wound will typically show beveling of the inner table, whereas exit wounds have a beveled outer table.

Imaging
AP and lateral skull x-rays
This is one situation where skull x-rays still may provide useful information, as they are less susceptible to artifact from the bullet than the CT scan. Helps to localize metal and bone fragments, and to help identify entrance/exit sites (omit if time not available)

Head CT scan without contrast
The main assessment tool. Demonstrates location of bone and metal. Delineates bullet trajectory: assesses if bullet passed through ventricles and how many quadrants of the hemisphere have been traversed. Shows amount of blood in brain and assesses intracranial hematomas (epidural, subdural or intraparenchymal).

Angiography in GSWH
Rarely performed emergently. When done, usually performed on ≈ day 2–3.
   Indications for angiography:
   ● unexpected delayed hemorrhage
   ● a trajectory that would likely involve named vessels in a salvageable patient
   ● large intraparenchymal hemorrhages in a salvageable patient

59.1.6 Management

Initial management
General measures
1. CPR as required; endotracheal intubation if stuporous or airway compromised
2. additional injuries (e.g. chest wounds) identified and treated appropriately
3. usual precautions taken for spine injury
4. fluids as needed to replace estimated blood loss which may be variable: exercise restraint to avoid excessive hydration (to minimize cerebral edema)
5. pressors to support MAP during and after fluid resuscitation

Treatment specific to the injury
Neurological assessment as rapidly as possible and as thoroughly as time permits.
   The Glasgow Coma Scale is still the most widely used grading system and allows better comparison between series than specialized scales for GSWHs.
Decision by experienced neurosurgeon regarding the ultimate treatment of the patient will determine appropriate steps to be taken. Patients with little CNS function (in the absence of shock) are unlikely to benefit from craniotomy. Supportive measures are indicated in most cases (for possibility of organ donation, opportunity for family to adjust to situation, and requirements for observation period to determine actual brain death).
In patients considered for further treatment, rapid deterioration at any point with signs of herniation requires immediate surgical intervention. As time permits, the following should be undertaken:
1. initial steps
   a) control bleeding from scalp and associated wounds (hemostats on scalp vessels)
   b) shave scalp to identify entrance/exit sites, and to save time in the O.R.

2. medical treatment (similar to closed head injury)
   a) assume ICP is elevated:
      • elevate HOB 30–45° with head midline (avoids kinking jugular veins)
      • mannitol (1 gm/kg bolus) as blood pressure tolerates
      • hyperventilate to PaCO$_2$ = 30–35 mm Hg if indications are met (p. 873)
      • steroids: (unproven efficacy) 10 mg dexamethasone IVP
   b) prophylaxis against GI ulcers: H2 antagonist (e.g. ranitidine 50 mg IVP q 8 hrs) or proton pump inhibitor, NG tube to suction
   c) begin anticonvulsants (does not reduce incidence of late seizures)
   d) antibiotics: generally used although no controlled study demonstrates efficacy in preventing meningitis or abscess. Most organisms are sensitive to penicillinase resistant agents, e.g. nafcillin, recommended for ≈ 5 days
   e) tetanus toxoid administration

Surgical treatment

Indications for surgery are controversial. Some authors suggest that better outcome might occur with more aggressive management, and that poor outcome may be a self-fulfilling prophecy. Patients with minimal neurologic function, e.g. fixed pupils, decorticate or decerebrate posturing... (when not in shock and with good oxygenation) should not be operated upon, because the chance of meaningful recovery is close to zero. Patients with less severe injuries should be considered for urgent operation.

Goals of surgery
1. debridement of devitalized tissue: less tissue is injured in civilian GSWH, but elevated ICP post-op may imply more vigorous debridement was needed, especially of non-eloquent brain (e.g. temporal tips)
2. evacuation of hematomas: subdural, intraparenchymal...
3. removal of accessible bone fragments
4. retrieval of bullet fragment for forensic purposes (note: everyone who handles the fragments may be subpoenaed to testify as to the “chain of evidence”). Large intact fragments should be sought as they tend to migrate (note: risk of infection and seizures due to retained bullet fragments is not high in civilian GSWH, therefore only accessible fragments should be sought and removed)
5. obtaining hemostasis
6. watertight dural closure (usually requires graft)
7. separation of intracranial compartment from air sinuses traversed by bullet
8. identification of entry and exit wounds for forensic purposes; see Evaluation (p. 909)

Surgical technique

Some key points of surgical technique$^7$ (p. 2098–104):
- positioning and draping should make both entry and exit wounds accessible
- devitalized tissue around the entry & exit wounds should be excised
- fractured bone should be excised by a circumferential craniectomy (craniotomy may be used in some civilian GSWH, the entry site within the craniotomy should be rongeured or drilled back to clean bone)
- air sinuses that are traversed should have the mucosa exenterated, and are then packed with muscle, and covered with a graft (e.g. periosteum or fascia lata) to separate them from intracranial compartment
- the dura is opened in a stellate fashion
- pulped brain is removed from within using suction and bipolar in an enlarging cone until healthy tissue is encountered (further injury to deep midline structures should be avoided, here, stay within bullet tract)
- contralateral fragments with no exit wound should only be removed if accessible
- intraventricular fragments can present significant risk. Ventriculoscopy (if available) may be well suited for removing these
- dural closure should be watertight; grafts of pericranium, temporalis fascia, or fascia lata grafts may be used; avoid dura substitutes
- cranioplasty should be delayed 6–12 months to reduce risk of infection
- a post-op CSF fistula that persists >2 weeks should be repaired

ICP monitoring
ICP is often elevated after surgical debridement and monitoring may be warranted.

Outcome
Prognostic factors:
1. level of consciousness is the most important prognostic factor: ≈ 94% of patients who are comatose with inappropriate or absent response to noxious stimulus on admission die, and half the survivors are severely disabled.
2. as initially espoused by Cushing, the path of the bullet is also an important prognosticator. Especially poor prognosis is associated with:
   a) bullets that cross the midline
   b) bullets that pass through the geographic center of the brain
   c) bullets that enter or traverse the ventricles
   d) the more lobes traversed by the bullet
3. hematomas seen on CT are poor prognostic findings
4. suicide attempts are more likely to be fatal

59.2 Non-missile penetrating trauma

59.2.1 General information
This section deals with penetrating injuries to the brain (and to some extent to the spinal cord) excluding missile injuries, i.e. gunshot wounds (p.908). Includes trauma from: knives, arrows, lawn darts… Injury to neural tissue tends to be more limited than with missiles because many of the associated injurious aspects of the missile are absent (p.908).

59.2.2 Arrow injuries
As a result of the lower velocity (e.g. 58 m/s) compared to firearms and the sharp tip, injury is usually limited to tissue directly incised by the arrowhead.

59.2.3 Cases with foreign body still embedded
In penetrating trauma, it is usually not appropriate to remove any protruding part of the foreign body until the patient is in the operating room, unless it cannot be avoided. If possible, it is helpful to have another identical object for comparison in planning extrication of the embedded object. To minimize extending the trauma to the CNS, the protruding object should be stabilized in some way during transportation and evaluation. Intraoperatively, devices such as the Greenberg retractor may be used to stabilize the object during preparation and the initial approach.

59.2.4 Indications for pre-op angiography
1. object passes in region of large named artery
2. object passes near dural sinuses
3. visible evidence of arterial bleeding: angiography is not appropriate if hemorrhage cannot be controlled

59.2.5 Surgical techniques
It is impossible to give details to cover every situation. Some guidelines:
1. empiric antibiotic coverage is appropriate; see Meningitis post craniospinal trauma (p.318). Take cultures from the wound and the foreign body to guide later antibiotic therapy
2. optimal control can usually be gained by performing a craniotomy up to and if possible around the object, such that removing the bone flap will not disturb the object. The last remnants of bone may then be removed with a rongeur
3. If at all possible open the dura before removing the object, since removal with the dura closed does not allow adequate control of any bleeding from the brain.

4. Removal of the object ideally should follow the entry trajectory if possible.

5. Although gunshot wounds are not sterile as once thought, they are probably less contaminated than penetrating wounds. One should debride any easily accessible impacted bone and other extracranial tissue and material along the track.

59.2.6 Post-op care

1. A course of antibiotics are usually appropriate since infection is common.

2. Consider a post-op arteriogram to rule-out traumatic aneurysm.

References

60 Pediatric Head Injury

60.1 General information

75% of children hospitalized for trauma have a head injury. Although most pediatric head injuries are mild and involve only evaluation or brief hospital stays, CNS injuries are the most common cause of pediatric traumatic death. The overall mortality for all pediatric head injuries requiring hospitalization has been reported between 10–13% whereas the mortality associated with severe pediatric head injury presenting with decerebrate posturing has been reported as high as 71%.

Differences between adult and pediatric head injury:
1. epidemiology:
   a) children often have milder injuries than adults
   b) lower chance of a surgical lesion in a comatose child than in an adult
2. types of injury: injuries peculiar to pediatrics
   a) birth injuries: skull fractures, cephalhematoma (see below), subdural or epidural hematomas, brachial plexus injuries (p.550)
   b) perambulator/walker injuries
   c) child abuse (see below): shaken baby syndrome...
   d) injuries from skateboarding, scooters...
   e) lawn darts
   f) cephalhematoma: see below
   g) leptomeningeal cysts, AKA “growing skull fractures” (p.915)
3. response to injury
   a) responses to head injury of older adolescent are very similar to adults
   b) “malignant cerebral edema”: acute onset of severe cerebral swelling (probably due to hyperemia) following some head injuries, especially in young children (may not be as common as previously thought)
   c) posttraumatic seizures: more likely to occur within the 1st 24 hrs in children than in adults (p.462)

60.2 Management

60.2.1 Imaging studies

Indications for CT are shown below.

When not contraindicated, rapid sequence MRI may be used (avoids additional radiation in the growing child), especially for follow-up imaging.

Practice guideline: Imaging in minor pediatric head injury

- Recommendations: CT scan for children with neurologic or cognitive dysfunction, or suspicion of a depressed or basilar skull fracture.
- Recommendations: when a CT scan is not done in a child ≤ 1 year age meeting the above criteria (e.g. because of sedation concerns), a skull film may be considered.

Based mostly on prospective trials (not randomized) or large case series.

Definitions: pediatrics = ages 1 month – 17 years of age. Minor head injury: GCS ≥ 13 (excludes: suspicion or proof of child abuse, patients requiring hospitalization for other reasons).

≈ 22% of those with a history of loss of consciousness (LOC) > 5 mins have a brain injury, whereas 92% without LOC > 5 mins will have no brain injury.
60.2.2 Home observation

Practice guideline: Home observation in minor pediatric head injury

Recommendations\(^9\): a child with GCS=14–15 and normal CT scan can be considered for home observation if neurologically stable (these patients are at near zero risk of having an occult brain injury). Based mostly on prospective trials (not randomized) or large case series. Definitions: pediatrics = ages 1 month – 17 years of age. Minor head injury: GCS\(\geq\)13 (excludes: suspicion or proof of child abuse, patients requiring hospitalization for other reasons).

60.3 Outcome

As a group, children fare better than adults with head injury.\(^{10}\) However, very young children do not do as well as the school-age child.\(^{11}\)

All aspects of neuropsychological dysfunction following head injury may not always be related to the trauma, as children who get injured may have pre-existing problems that increase their propensity to get hurt (this is controversial).\(^{12}\)

60.4 Cephalhematoma

60.4.1 General information

Accumulation of blood under the scalp. Occurs almost exclusively in children.

Two types:
1. subgaleal hematoma: may occur without bony trauma, or may be associated with linear nondisplaced skull fracture (especially in age <1 yr). Bleeding into loose connective tissue separates galea from periosteum. May cross sutures. Usually starts as a small localized hematoma, and may become huge (with significant loss of circulating blood volume in age <1 year, transfusion may be necessary). Inexperienced clinicians may suspect CSF collection under the scalp which does not occur. Usually presents as a soft, fluctuant mass. These do not calcify
2. subperiosteal hematoma (some refer to this as cephalhematoma): most commonly seen in the newborn (associated with parturition, may also be associated with neonatal scalp monitor\(^{14,15}\)). Bleeding elevates periosteum, extent is limited by sutures. Firmer and less ballotable than subgaleal hematoma\(^{16}\) (p 312); scalp moves freely over the mass. 80% reabsorb, usually within 2–3 weeks. Occasionally may calcify

Infants may develop jaundice (hyperbilirubinemia) as blood is resorbed, occasionally as late as 10 days after onset.

60.4.2 Treatment

Treatment beyond analgesics is almost never required, and most usually resolve within 2–4 weeks. Avoid the temptation of percutaneously aspirating these as the risk of infection exceeds the risk of following them expectantly, and in the newborn removal of the blood may make them anemic. Follow serial hemoglobin and hematocrit in large lesions. If a subperiosteal hematoma persists >6 weeks, obtain a skull film. If the lesion is calcified, surgical removal may be indicated for cosmetic reasons (although with most of these the skull will return to normal contour in 3–6 months.\(^{16}\) (p 315)

60.5 Skull fractures in pediatric patients

60.5.1 General information

This section deals with some special concerns of skull fractures in pediatrics. Also see Child abuse (p.916).
60.5.2 Posttraumatic leptomeningeal cysts (growing skull fractures)

General information

Posttraumatic leptomeningeal cysts (PTLM C) (sometimes just traumatic leptomeningeal cysts) AKA growing skull fractures are not to be confused with arachnoid cysts (AKA leptomeningeal cysts, which are not posttraumatic). PTLM C consists of a fracture line that widens with time. Although usually asymptomatic, the cyst may cause mass effect with neurologic deficit.

PTLM C were first described in 1816,17 and are very rare, occurring in 0.05–0.6% of skull fractures.18,19 Usually requires both a widely separated fracture AND a dural tear. Mean age at injury: <1 year, over 90% occur before age 3 years20 (formation may require the presence of a rapidly growing brain)21 although rare adult cases have been described22,23,17 (a total of 5 cases in the literature as of 199817). PTLM C rarely occur >6 mos out from the injury. Some children may develop a skull fracture that seems to grow during the initial few weeks, that is not accompanied by a subgaleal mass, and that heal spontaneously within several months; the term “pseudogrowing fracture” has been suggested for these.24

Presentation

Most often presents as scalp mass (usually subgaleal), although there are reports of presentation with head pain alone.22

Diagnosis

Radiographic findings: progressive widening of fracture and scalloping (or saucerizing) of edges.

Screening for development of PTLM C

If early growth of a fracture line with no subgaleal mass is noted, repeat skull films in 1–2 months before operating (to rule-out pseudogrowing fracture). In young patients with separated skull fractures (the width of the initial fracture is rarely mentioned), consider obtaining follow-up skull film 6–12 mos post-trauma. However, since most PTLM C are brought to medical attention when the palpable mass is noticed, routine follow-up x-rays may not be cost-effective.

Treatment

Treatment of true PTLM C is surgical, with dural closure mandatory. Since the dural defect is usually larger than the bony defect, it may be advantageous to perform a craniotomy around the fracture site, repair the dural defect, and replace the bone.23 Pseudogrowing fractures should be followed with x-rays and operated only if expansion persists beyond several months or if a subgaleal mass is present.

60.5.3 Depressed skull fractures in pediatrics

See reference.25

General information

Most common in frontal and parietal bones. One third are closed, and these tend to occur in younger children (3.4 ± 4.2 yrs, vs. 8.0 ± 4.5 yrs for compound fractures) as a result of the thinner, more deformable skull. Open fractures tended to occur with MVAs, closed fractures tended to follow accidents at home. Dural lacerations are more common in compound fractures.

Simple depressed skull fractures

There was no difference in outcome (seizures, neurologic dysfunction or cosmetic appearance) in surgical vs. nonsurgical treatment in 111 patients <16 yrs age. In the younger child, remodelling of the skull as a result of brain growth tends to smooth out the deformity.

Indications for surgery for pediatric simple depressed skull fracture:
1. definite evidence of dural penetration
2. persistent cosmetic defect in the older child after the swelling has subsided
3. ± focal neurologic deficit related to the fracture (this group has a higher incidence of dural laceration, although it is usually trivial)
“Ping-pong ball” fractures

See reference.26

A green-stick type of fracture → caving in of a focal area of the skull as in a crushed area of a ping-pong ball. Usually seen only in the newborn due to the plasticity of the skull.

Indications for surgery

No treatment is necessary when these occur in the temporoparietal region in the absence of underlying brain injury as the deformity will usually correct as the skull grows.

- radiographic evidence of intraparenchymal bone fragments
- associated neurologic deficit (rare)
- signs of increased intracranial pressure
- signs of CSF leak deep to the galea
- situations where the patient will have difficulty getting long-term follow-up

Technique

Frontally located lesions may be corrected for cosmesis by a small linear incision behind the hairline, opening the cranium adjacent to the depression, and pushing it back out e.g. with a Penfield #3 dissector.

60.6  Nonaccidental trauma (NAT)

60.6.1 General information

AKA Child abuse. At least 10% of children <10 yrs age that are brought to E/R with alleged accidents are victims of child abuse.27 The incidence of accidental head trauma of significant consequence below age 3 is low, whereas this is the age group in which battering is highest.28

There are no findings that are pathognomonic for child abuse. Factors which raise the index of suspicion include:

1. retinal hemorrhage (see below)
2. bilateral chronic subdural hematomas in a child <2 yrs age (p.904)
3. skull fractures that are multiple (see below) or those that associated with intracranial injury
4. significant neurological injury with minimal signs of external trauma

60.6.2 Shaken baby syndrome

Vigorous shaking of a child produces violent whiplash-like angular acceleration-decelerations of the head (the infant head is relatively large in proportion to the body, and the neck muscles are comparatively weak)29 which may lead to significant brain injury. Some researchers believe that shaking alone may be inadequate to produce the severe injuries seen, and that impact is often also involved.30

Characteristic findings include retinal hemorrhages (see below), subdural hematomas (bilateral in 80% and/or subarachnoid hemorrhage (SAH). There are usually few or no external signs of trauma (including cases with impact, although findings may be apparent at autopsy). In some cases there may be finger marks on the chest, multiple rib fractures and/or pulmonary compression ± parenchymal lung hemorrhage. Deaths in these cases are almost all due to uncontrollable intracranial hypertension. There may also be injury to the cervicomedullary junction.31

60.6.3 Retinal hemorrhage (RH) in child abuse

“In a traumatized child with multiple injuries and an inconsistent history, the presence of RH is pathognomonic of battering.”26 However, RH may also occur in the absence of any evidence of child abuse. 16/26 battered children <3 yrs age had RH on funduscopy, whereas 1/32 non-battered traumatized children with head injury had RH (the single false positive: traumatic parturition, where the incidence of RH is 15–30%).

Differential diagnosis of etiologies of retinal hemorrhage:

1. child abuse (including “shaken baby syndrome”, see above)
2. benign subdural effusion in infants (p.904)
3. acute high altitude sickness (p.848)
4. acute increase in ICP: e.g. with a severe seizure (may be similar to Purtscher’s retinopathy – see below)
5. Purttscher's retinopathy: loss of vision following major trauma (chest crush injuries, airbag deployment...), pancreatitis, childbirth or renal failure, among others. Posterior pole ischemia with cotton-wool exudates and hemorrhages around the optic disc due to microemboli of possibly fat, air, fibrin clots, complement-mediated aggregates or platelet clumps. No known treatment

60.6.4 Skull fractures in child abuse

A series comparing 39 cases of skull fracture from documented child abuse to 95 cases of probable accidental injury showed the following:

1. the parietal bone was the most common site of fracture in both groups (≈ 90%)
2. depression of skull fractures was frequently missed clinically due to overlying hematoma
3. clinical features in patients with skull fractures did not reliably differentiate child abuse from trauma (retinal hemorrhages (RH) were seen in 1 child abuse and 1 accidental trauma patient: note that RH is more common in “shaken child” syndrome which is not commonly associated with skull fractures)
4. 3 characteristics more frequently seen after child abuse than after other trauma:
   a) multiple fractures
   b) bilateral fractures
   c) fractures that cross sutures

References

61.1 Airway management

**Practice guideline: Timing of tracheostomy**

Level II*: early tracheostomy reduces the number of days of mechanical ventilation but does not affect mortality or incidence of pneumonia.

**Practice guideline: Timing of extubation**

Level III*: early extubation for patients meeting extubation criteria does not increase the risk of pneumonia.

61.2 Deep-vein thrombosis (DVT) prophylaxis

Also see further details about thromboembolism (p. 167) in neurosurgical patients. The risk of developing DVT is ≈20% in untreated severe TBI. See also Practice guideline: DVT prophylaxis in severe TBI (p. 918).

**Practice guideline: DVT prophylaxis in severe TBI**

Level III*

- unless contraindicated, graduated compression stockings or intermittent compression boots are recommended until patients are ambulatory
- low molecular weight heparin (LMWH) (p. 164) or low-dose unfractionated heparin in conjunction with mechanical measures lowers the DVT risk, but a trend suggests they increase the risk of expansion of intracranial hemorrhage (note: there is insufficient evidence: to support use of one pharmacologic agent over another, or to define the optimal dose or timing of agents).

61.3 Nutrition in the head-injured patient

61.3.1 Summary of recommendations (see text for details)

**Practice guideline: Nutrition**

Level II*: full caloric replacement should be attained by post-trauma day 7

Σ

1. by post-trauma day 7, replace the following (enterally or parenterally):
   a) non-paralyzed patients: 140% of predicted basal energy expenditure (BEE)
   b) paralyzed patients: 100% of predicted BEE
2. provide ≥15% of calories as protein
3. nutritional replacement should begin within 72 hrs of head injury in order to achieve goal #1 by day 7
4. the enteral route is preferred (IV hyperalimentation is preferred if higher nitrogen intake is desired or if there is decreased gastric emptying)
61.3.2 Caloric requirements

Rested comatose patients with isolated head injury have a metabolic expenditure that is 140% of normal for that patient (range: 120–250%). Paralysis with muscle blocker or barbiturate coma reduced this excess expenditure in most patients to \( \approx 100–120\% \) of normal, but some remained elevated by 20–30%. Energy requirements rise during the first 2 weeks after injury, but it is not known for how long this elevation persists. Mortality is reduced in patients who receive full caloric replacement by day 7 after trauma (a beneficial effect with an earlier goal of replacement by 3 days post-trauma was not found). Since it generally takes 2–3 days to get nutritional replacement up to speed whether the enteral or parenteral route is utilized, it is recommended that nutritional supplementation begin within 72 hrs of head injury.

61.3.3 Enteral vs. IV hyperalimentation

Caloric replacement that can be achieved is similar between enteral or parenteral routes. The enteral route is preferred because of reduced risk of hyperglycemia, infection and cost. IV hyperalimentation may be utilized if higher nitrogen intake is desired or if there is decreased gastric emptying. No significant difference in serum albumin, weight loss, nitrogen balance, or final outcome was found between enteral and parenteral nutrition.

Estimates of basal energy expenditure (BEE) can be obtained from the Harris-Benedict equation, shown in Eq (61.1), (61.2) and (61.3), where \( W \) is weight in kg, \( H \) is height in cm, and \( A \) is age in years.

For Males: \[ \text{BEE} = 66.47 + 13.75 \times \frac{W}{5.0} - 5.0 \times \frac{H}{6.76} + 6.76 \times \frac{A}{6.76} \]

For Females: \[ \text{BEE} = 65.51 + 9.56 \times \frac{W}{1.85} - 1.45 \times \frac{H}{4.68} - 5.0 \times \frac{A}{6.76} \]

For Infants: \[ \text{BEE} = 22.1 + 31.05 \times \frac{W}{1.16} - 1.60 \times \frac{H}{6.76} \]

61.3.4 Enteral nutrition

Isotonic solutions (such as Isocal® or Osmolyte®) should be used at full strength starting at 30 ml/hr. Check gastric residuals q 4 hrs and hold feedings if residuals exceed \( \approx 125 \text{ ml} \) in an adult. Increase the rate by \( \approx 15–25 \text{ ml/hr} \) every 12–24 hrs as tolerated until the desired rate is achieved. Dilution is not recommended (may slow gastric emptying), but if it is desired, dilute with normal saline to reduce free water intake.

Cautions:
- NG tube feeding may interfere with absorption of phenytoin; see phenytoin (PHT, Dilantin®) (p.446). Reduced gastric emptying may be seen following head-injury (NB: some may have temporarily elevated emptying) as well as in pentobarbital coma, patients may need IV hyperalimentation until the enteric route is usable. Others have described better tolerance of enteral feedings using jejunal administration.

61.3.5 Nitrogen balance

A normal subject fed a protein-free diet for 3 days will excrete 85 mg of nitrogen/kg/d. These loses increase with injury. The rise in urinary N is due primarily to an increase in urea (comprises 80–90% of urinary N). This is thought to represent an increase in mobilization and breakdown of amino acids, which are felt to originate mainly from skeletal muscle. Some of this represents a primary reaction to injury in which certain vital organs seem to be maintained at the expense of less active organs, and a significantly higher nitrogen balance cannot be achieved by increasing the amount of calories supplied as protein beyond a certain level. Catabolism of protein yields 4 kcal/g (compared to 1 kcal/g for carbohydrates and 9 kcal/g for fat), and in the non-injured adult normally supplies only \( \approx 10\% \) of energy needs.

As an estimate, for each gram of N excreted (mostly in the urine, however, some is also lost in the feces), 0.25 gm of protein have been catabolized. It is recommended that at least 15% of calories be supplied as protein. The percent of calories consumed (PCC) derived from protein can be calculated...
from Eq (61.4), where $N$ is nitrogen in grams, and BEE is the basal energy expenditure\(^5\) (see Eq (61.1), (61.2) and (61.3)).

\[
PCC_{\text{from protein}} = \frac{N \text{ gm N}}{BEE} \times 6.25 \frac{\text{gm protein}}{\text{gm N}} \times 4.9 \frac{\text{kcal}}{\text{gm protein}} \times \frac{1}{100}
\]

Thus, to supply $PCC$ (protein) = 15\% once the BEE is known, use Eq (61.5). Some enteral formulations include Magnacal\® (PCC=14\%) and Traumacal\® (PCC=22\%).

\[
N \text{ gm N} \times 0.006 \times \frac{1}{BEE}
\]

61.4 Posttraumatic hydrocephalus

61.4.1 General information

Hydrocephalus was found in 40\% of 61 patients with severe head injury ($GCS=3–8$) and in 27\% of 34 patients with moderate head injury ($GCS=9–13$).\(^20\) Hydrocephalus developed by 4 weeks after injury in 58\% and by 2 months in 70\%.\(^20\) There was no statistically significant relationship between posttraumatic hydrocephalus and age, the presence of SAH, or type of lesion (focal or diffuse). Posttraumatic hydrocephalus was associated with worse outcome.\(^20\)

Hydrocephalus after traumatic subarachnoid hemorrhage

Incidence of clinically symptomatic hydrocephalus within 3 months of traumatic subarachnoid hemorrhage (tSAH) is \(\approx 12\%\).\(^21\) In this series of 301 tSAH patients, multivariate analysis showed the risk of developing hydrocephalus increased with age, intraventricular hemorrhage, blood thickness \(\geq 5\) mm, and diffuse distribution of blood (vs. focal distribution). There was no correlation with gender, admission GCS score, basal location of tSAH, or use of decompressive craniectomy.\(^21\) NB: this is potentially confusing, univariate analysis shows the risk of hydrocephalus increases with increasing severity of TBI.

61.4.2 Differentiating true hydrocephalus from hydrocephalus ex vacuo

Delayed ventricular enlargement months to years after TBI may instead be due to atrophy (hydrocephalus ex vacuo) secondary to diffuse axonal injury, and may not represent true hydrocephalus. It may not be possible to accurately differentiate these two conditions, and the decision to shunt may therefore be difficult (similar to the dilemma in patients with NPH vs. atrophy).

61.4.3 Indications for surgical treatment

Factors favoring hydrocephalus, for which shunt should be considered:
1. elevated pressure on 1 or more LPs
2. papilledema on funduscopic exam
3. symptoms of headache/pressure
4. findings of “transependymal absorption” on CT or T2WI MRI (p.406)
5. \(\pm\) patient’s whose neurologic recovery seems worse than expected
6. provocative tests have been recommended (p.255)\(^22\)

Patients with enlarged ventricles who are asymptomatic and are doing well following their head injury should be managed expectantly.

61.5 Outcome from head trauma

61.5.1 Age

In general, the degree of recovery from closed head injury is better in infants and young children than in adults. In adults, decerebrate posturing or flaccidity with loss of pupillary or oculovestibular
reflex is associated with a poor outcome in most cases, these findings are not as ominous in pediatrics.

61.5.2 Outcome prognosticators

General information

The frequency of poor outcome from closed head injury is increased with persistent ICP > 20 mm Hg after hyperventilation, increasing age, impaired or absent pupillary light response or eye movement, hypotension (SBP < 90), hypercarbia, hypoxemia, or anemia. This is probably due at least in part to the fact that some of these are markers for significant injury to other body systems. One of the most important predictors for poor outcome is the presence of a mass lesion requiring surgical removal. High ICP during the first 24 hrs is also a poor prognosticator.

Obliteration of basal cisterns on CT

The status of the basal cisterns (BCs) is evaluated on axial CT scan at the level of the midbrain (Fig. 61.1) where they are divided into 3 limbs (1 posterior limb = quadrigeminal cistern, 2 lateral limbs = posterior portion of the ambient cisterns). Note: “basal cisterns” in the trauma literature are a subset of the perimesencephalic cisterns (p. 1232). Possible findings:

1. open: all 3 limbs open
2. partially closed: 1 or 2 limbs obliterated
3. completely closed: 3 limbs obliterated

Compression or absence of the BCs carries a threefold risk of increased ICP, and the status of the BCs correlates with outcome. In a study of 218 patients with GCS ≤ 8, the BCs were classified on initial CT (within 48 hrs of admission) as: absent, compressed, normal, or not visualized (quality of CT too poor to tell). The relationship of the BCs to outcome is shown in Table 61.1. 18 patients had a shift of brain structures > 15 mm associated with absent BCs, all of them died. The status of the BCs were more important within each GOS score than across scores. Also, see Table 58.3 for further information on CT.

Midline shift (MLS)

The presence of MLS correlates with a worse outcome. For the purpose of standardizing measurements in trauma, MLS is defined at the level of the foramen of Monro as shown in Fig. 61.2, and is calculated using Eq (61.6).
where the midline is found by dividing the biparietal diameter (BPD) (the width of intracranial compartment at this location) by 2, and subtracting SP (the distance from the inner table to the septum pellucidum on the side of the shift). Measurements may be inaccurate if the vertical axis of the patient’s head is not parallel to the long axis of the CT scanner.

Midline shift may be associated with altered levels of consciousness (p. 298).

**Apolipoprotein E (apoE) e4 allele**

The presence of this genotype portends a worse prognosis following traumatic brain injury.²⁷ Furthermore, the incidence of severe brain injury in individuals with the apoE-4 allele greatly exceeds the rate of the allele in the general population.²⁸ This allele is also a risk factor for Alzheimer’s disease (see below) as well as for chronic traumatic encephalopathy (p. 924).

Head Trauma
61.6 Late complications from traumatic brain injury

61.6.1 General information

Long term complications include:
1. posttraumatic seizures (p. 462)
2. communicating hydrocephalus: incidence \( \approx 3.9\% \) of severe head injuries
3. posttraumatic syndrome (or postconcussive syndrome): see below
4. hypogonadotropic hypogonadism (p. 836)
5. chronic traumatic encephalopathy (p. 924)
6. Alzheimer’s disease (AD): head injury (especially if severe) promotes the deposition of amyloid proteins, especially in individuals possessing the apolipoprotein E (apoE) \( \varepsilon 4 \) allele, which may be related to the development of AD\(^{29,30,31,32} \)

61.6.2 Postconcussive syndrome

General information

Variously defined collection of symptoms (see below) that is usually considered as a possible sequelae to minor head trauma (although some of these features can certainly be seen following more serious head trauma). Loss of consciousness is not a prerequisite to the development of the syndrome.

Controversy exists over the relative contribution of actual organic dysfunction vs. psychological factors (including conversion reaction, secondary gain which may be for attention, financial reward, drug seeking…). Furthermore, the presence of some of these symptoms can undoubtedly lead to the development of others (e.g. headache can cause difficulty concentrating and thus poor job performance and thence depression).

Presentation

A paradox has been noted by clinicians that the complaints following minor head injury seem out of proportion when considered in the context of the frequency of complaints after serious head injury. It has also been noted that patients with early post-traumatic complaints generally improve with time, whereas the late development of symptoms is often associated with a more protracted and fulminant course.

Symptoms commonly considered part of this syndrome include the following (with headache, dizziness and memory difficulties being the most frequent):

1. somatic
   a) headache
   b) dizziness or light-headedness
   c) visual disturbances: blurring is a common complaint
   d) anosmia
   e) hearing difficulties: tinnitus, reduced auditory acuity
   f) balance difficulties

2. cognitive
   a) difficulty concentrating
   b) dementia: more common with multiple brain injuries than with a single concussion (p. 924)
      - loss of intellectual ability
      - memory problems: usually impairs short-term memory more than long-term
   c) impaired judgement

3. psychosocial
   a) emotional difficulties: including depression, mood swings (emotional lability), euphoria/giddiness, easy irritability, lack of motivation, abulia
   b) personality changes
   c) loss of libido
   d) disruption of sleep/wake cycles, insomnia
   e) easy fatigability
   f) intolerance to light (photophobia) and/or loud (or even moderate) noise
   g) increased rate of job loss and divorce (may be related to any of above)

Virtually any symptom can be ascribed to the condition. Other symptoms that may be described by patients which are generally not included in the definition:
1. fainting (vaso-vagal episodes): may need to rule out posttraumatic seizures, as well as other causes of syncope
2. altered sense of taste
3. dystonia

Treatment

Treatment for symptoms attributed to this syndrome tends to be more supportive and reassuring than anything else. Often times these patients obtain treatment from primary care physicians, neurologists, physiatrists, and/or psychiatrists/psychologists. Neurosurgical involvement in the continuing care for these patients is usually at the discretion of the individual physician based on his or her practice patterns. Recovery follows a highly variable course.

Early follow-up care (consisting mainly of reassurance, providing information and neuropsychological assessment and counselling) was found to reduce post-concussion symptoms at 6 months in patients with post-traumatic amnesia lasting ≥ 1 hour or those who required hospitalization, but had no benefit in those not requiring hospitalization or having amnesia < 1hr.

Some symptoms may need to be evaluated for possible correctable late complications (seizures, hydrocephalus, CSF leak…). Alves and Jane perform a head CT, MRI, BAER and neuropsychological battery if symptoms after minor head injury persist >3 months. An EEG may be appropriate in cases where there is a question of seizures. The authors tell the patient (and the lawyer) that there is no objective evidence for disease and that psychiatric evaluation is warranted. Non-correctable abnormalities on these studies prompt reassurance that significant symptoms should subside by 1 year, and that no specific treatment, other than psychological counselling, is helpful.

61.6.3 Chronic traumatic encephalopathy

General information

Often described in retired boxers, chronic traumatic encephalopathy (CTE) encompasses a spectrum of symptoms that range from mild to a severe form AKA dementia pugilistica, or punch drunk syndrome (among others). Symptoms involve motor, cognitive and psychiatric systems. CTE is distinct from post-traumatic dementia (which may follow a single closed head injury) or from post-traumatic Alzheimer’s syndrome. Although generally accepted, not all authorities agree that repeated concussions have any long-term sequelae.

There are some similarities with Alzheimer’s disease (AD), including the presence of neurofibrillary tangles having similar microscopic characteristics (the main difference is that they tend to be more superficial in CTE than in AD) and the development of amyloid angiopathy with the attendant risk of intracerebral hemorrhage. EEG changes occur in one-third to one-half of professional boxers (diffuse slowing or low-voltage records).

Neuropathology

Findings include:
1. cerebral and cerebellar atrophy
2. neurofibrillary degeneration of cortical and subcortical areas
3. deposition of β-amyloid protein
   a) forming diffuse amyloid plaques
   b) in a subset of CTE patients this involves the vessel walls giving rise to cerebral amyloid angiopathy

Clinical

Clinical features of CTE are shown in Table 61.2 and include
1. cognitive: mental slowing and memory deficits (dementia)
2. personality changes: explosive behavior, morbid jealousy, pathological intoxication with alcohol, and paranoia
3. motor: cerebellar dysfunction, symptoms of Parkinson’s disease, pyramidal tract dysfunction

Grading scales have been devised to rank patients as having probable, possible, and improbable CTE. The chronic brain injury scale (CBIS) assesses involvement of motor, cognitive, and psychological axes as shown in Table 61.3.
Risk factors for dementia pugilistica in boxing:

See reference.\[36\]

- Risk increases with length of boxing career, especially >10 yrs
- Age at retirement: risk goes up after age 28 yrs
- Number of bouts: especially ≥20 (more important than the number of knock-outs)
- Boxing style: increased risk among poorer performers, those known as sluggers rather than “scientific” boxers, those known to be hard to knock out or known to take a punch and keep going
- Age at examination: long latency causes increased prevalence with age
- And possibly, the number of head blows
- Risk increases in patients with the apolipoprotein E (apo E) ε4 allele (as in Alzheimer’s disease) as shown in Table 61.4
- Professional boxers (more risk than amateurs)
Table 61.4 Odds ratio for developing Alzheimer’s disease

Neuro-imaging

The most common finding is cerebral atrophy. A cavum septum pellucidum (CSP) is observed in 13% of boxers. CSP in this setting probably represents an acquired condition and correlates with cerebral atrophy.

62 General Information, Neurologic Assessment, Whiplash and Sports-Related Injuries, Pediatric Spine Injuries

62.1 Introduction

20% of patients with a major spine injury will have a second spinal injury at another level, which may be noncontiguous. These patients often have simultaneous but unrelated injuries (e.g., chest trauma, TBI...). Injuries directly associated with spinal cord injuries include arterial dissections (carotid and/or vertebral arteries).

62.2 Terminology

62.2.1 Spinal stability

Many definitions have been proposed. A conceptual definition of clinical stability from White and Panjabi: the ability of the spine under physiologic loads to limit displacement so as to prevent injury or irritation of the spinal cord and nerve roots (including cauda equina) and, to prevent incapacitating deformity or pain due to structural changes.

Biomechanical stability refers to the ability of the spine ex vivo to resist forces. Predicting spinal stability is often difficult, and to this end various models have been developed, none of which is perfect. See models of stability for cervical spine injuries (p. 987), and thoracolumbar fractures (p. 1002).

62.2.2 Level of injury

There is disagreement over what should be defined as “the level” of a spinal cord injury. Some define the “level” of a spinal cord injury as the lowest level of completely normal function (thus a patient would be termed a C5 quadriplegic even with minor C6 motor function). However, most sources define the “level” as the most caudal segment with motor function that is at least 3 out of 5 and if pain and temperature sensation is present.

62.2.3 Completeness of lesion

Categorization is important for treatment decisions and prognostication.

Incomplete lesion

Definition: any residual motor or sensory function more than 3 segments below the level of the injury. Look for signs of preserved long-tract function.

Signs of incomplete lesion:
1. sensation (including position sense) or voluntary movement in the LEs in the presence of a cervical or thoracic spinal cord injury
2. “sacral sparing”: preserved sensation around the anus, voluntary rectal sphincter contraction, or voluntary toe flexion
3. an injury does not qualify as incomplete with preserved sacral reflexes alone (e.g., bulbocavernosus)

Types of incomplete lesion:
1. central cord syndrome (p. 944)
2. Brown-Séquard syndrome (cord hemisection) (p. 947)
3. anterior cord syndrome (p. 946)
4. posterior cord syndrome (p. 947): rare

Complete lesion

No preservation of any motor and/or sensory function more than 3 segments below the level of the injury in the absence of spinal shock. About 3% of patients with complete injuries on initial exam will
develop some recovery within 24 hours. Recovery is essentially zero if the spinal cord injury remains complete beyond 72 hours.

**Spinal shock**

This term is often used in two completely different senses:

1. hypotension (shock) that follows spinal cord injury (SBP usually \( \approx 80 \) mm Hg). See Hypotension (p. 950) for treatment. Caused by multiple factors:
   a) interruption of sympathetics: implies spinal cord injury above T1
      - loss of vascular tone (vasoconstrictors) below level of injury
      - leaves parasympathetics relatively unopposed causing bradycardia
   b) loss of muscle tone due to skeletal muscle paralysis below level of injury results in venous pooling and thus a relative hypovolemia
   c) blood loss from associated wounds → true hypovolemia

2. transient loss of all neurologic function (including segmental and polysynaptic reflex activity and autonomic function) below the level of the SCI
   a) Duration: may abate in as little as 72 hours, but typically persists 1–2 weeks, occasionally several months
   b) Accompanied by loss of the bulbocavernosus reflex
   c) Spinal cord reflexes immediately above the injury may also be depressed on the basis of the Schiff-Sherrington phenomenon
   d) When spinal shock resolves, there will be spasticity below the level of the lesion and return of the bulbocavernosus reflex
   e) A poor prognostic sign

### 62.3 Whiplash-associated disorders

#### 62.3.1 General information

“Whiplash” was initially a lay term, which is currently defined as a traumatic injury to the soft tissue structures in the region of the cervical spine (including: cervical muscles, ligaments, intervertebral discs, facet joints…) due to hyperflexion, hyperextension, or rotational injury to the neck in the absence of fractures, dislocations, or intervertebral disc herniation. It is the most common non-fatal automobile injury. Symptoms may start immediately, but more commonly are delayed several hours or days. In addition to symptoms related to the cervical spine, common associated complaints include headaches, cognitive impairment, and low back pain.

#### 62.3.2 Clinical grading

A proposed clinical classification system of WAD is shown in Table 62.1.

#### 62.3.3 Evaluation and treatment

A consensus regarding diagnosis and management of these injuries is shown in Table 62.2 and Table 62.3. Keep in mind that conditions such as occipital neuralgia may occasionally follow whiplash type injuries and should be treated appropriately (Table 62.3).

<table>

</tr>
</tbody>
</table>

*the definition of whiplash excludes these patients*
In a study of 117 patients <56 years of age having WAD due to automobile accidents (excluding those with cervical fractures, dislocations, or injuries elsewhere in the body) conducted in Switzerland (where all medical costs were paid by the state and there was no opportunity for litigation and no compensation for pain and suffering, although there was the possibility of permanent disability), the recovery rate was as shown in Table 62.4. Of the 21 patients with continued symptoms at 2 yrs, only 5 were restricted with respect to work (3 reduced to part-time work, 2 on disability). Patients with persistent symptoms were older, had more varied complaints on initial exam, had a more rotated or inclined head position at the time of impact, had a higher incidence of pretraumatic headaches, and had a higher incidence of certain pre-existing findings (such as radiologic evidence of cervical osteoarthritis). The amount of damage to the automobile and the speed of the cars had little relationship to the degree of injury, and outcome was not influenced by gender, vocation, or psychological factors.
62.4 Pediatric spine injuries

62.4.1 General information
Spinal cord injury is fairly uncommon in children, with the ratio of head injuries to spinal cord injuries being ≈ 30:1 in pediatrics. Only ≈ 5% of spinal cord injuries occur in children. Due to ligamentous laxity together with a high head to body weight ratio, immaturity of paraspinal muscles and the underdeveloped uncinate processes, these tend to involve ligamentous rather than bony injuries, see SCIWORA (p. 999). There is also the potential for physisal (growth plate) separation in young children, which may have good potential to heal. The cervical spine is the most vulnerable segment (with subaxial injuries being fairly uncommon), with 42% of injuries occurring here, 31% thoracic, and 27% lumbar. The fatality rate is higher with pediatric spine injuries than with adults (opposite to the situation with head injury), with the cause of death more often related to other severe injuries than to the spinal injury.\textsuperscript{10}

62.4.2 Evaluation
Practice guidelines for diagnostic workup is shown below (see Practice guideline: Evaluation of pediatric C-spine injuries (p.934)).

62.4.3 Pediatric cervical spine injuries and mimics

General information
See pediatric C-spine anatomy (p.214). In the age group ≤ 9 yrs, 67% of cervical spine injuries occur in the upper 3 segments of the cervical spine (occiput-C2).\textsuperscript{11}

Synchondroses
Normal synchondroses (p.215) may be mistaken for fractures, especially the dentocentral synchondrosis of the atlas (p.214) which may be mistaken for an odontoid fracture. Conversely, actual fractures may occur through synchondroses.\textsuperscript{12,13} Recommended treatment for fractures through synchondroses: the tendency for synchondroses to fuse suggests that emergency reduction followed by external immobilization be attempted. Internal immobilization/fusion should be reserved for persistent instability.\textsuperscript{13}

Pseudospread of the atlas
See reference.\textsuperscript{14}

Pseudospread of the atlas (defined as ≥ 2 mm total overlap of the two C1 lateral masses on C2 on AP open-mouth view) is present in most children 3 mos to 4 yrs age. Prevalence is 91–100% during the second year of life. Youngest example at 3 mos, oldest at 5.75 yrs. Normal total offset is typically 2 mm during the first year, 4 mm during the second, 6 mm during the third, and decreasing thereafter. The maximum is 8 mm. Trauma is not a contributing factor.

Pseudospread is probably a result of disproportionate growth of the atlas on the axis. This could be misdiagnosed as a Jefferson fracture (p.971), which rarely occurs prior to the teen-ages (owing to lower weight of children, more flexible necks, increased plasticity of skull, and shock absorbing synchondroses of C1).

Neck rotation can also sometimes simulate the appearance of a Jefferson fracture.

When suspicion of fracture is high: CT scan through C1 can resolve the issue of whether or not there is a fracture.

Table 62.4 Recovery of patients with WAD
Pseudosubluxation

Either anterior displacement of C2 (axis) on C3 and/or significant angulation at this level. Seen in children (up to age 10 yrs) on lateral C-spine x-ray after trauma. Up to age 10 yrs, flexion and extension are centered at C2–3; this moves down to C4–5 or C5–6 after age 10. C2 normally moves forward on C3 up to 2–3 mm in peds.15 When the head is flexed, displacement is expected; may be exacerbated by spasm.16 Does not represent pathological instability. Fractures and dislocations are unusual in children, and when they do occur, they resemble those in adults.

10 cases reported between ages 4–6 yrs:17 pain was not uncommon. In each case, either the head or neck was flexed (sometimes minimally); the pseudosubluxation corrected when x-ray was repeated with head in true neutral position.

Recommendation: treat patient for soft-tissue injury and not for subluxation.

Practice guideline: Evaluation of pediatric C-spine injuries

Level I18

- Use CT to assess the condyle-C1 interval (CCI) for pediatric patients with potential atlanto-occipital dislocation (AOD)

Level II18:

- Do not perform C-spine imaging in children >3 years age with trauma who are:
  - alert
  - neurologically intact
  - without posterior midline cervical tenderness (with no distracting pain)
  - not hypotensive without explanation
  - not intoxicated

- Do not perform C-spine imaging in children <3 years age with trauma who meet all of the following conditions:
  - have a GCS>13
  - are neurologically intact
  - have no cervical midline tenderness (without distracting injury)
  - are not intoxicated
  - do not have unexplained hypotension
  - were not in a motor vehicle collision, a fall>10 feet, or non-accidental trauma (NAT) as the known or suspected mechanism of injury

- Obtain cervical spine x-rays or high-resolution cervical CT in pediatric trauma victims who do not meet either set of criteria above

- Obtain 3-position CT with C1-C2 motion analysis to confirm and classify the diagnosis for children suspected of having atlantoaxial rotatory fixation (AARF)

Level III18:

- children <8 yrs age: when restrained, immobilize with thoracic elevation or an occipital recess (allows more neutral alignment due to the relatively large head)

- children <7 yrs age with injuries of the C2 synchondrosis (p.215): closed reduction and halo immobilization

- patients with AARF:
  - acute AARF (<4 weeks duration) that does not reduce spontaneously: reduction with manipulation or halter traction
  - chronic AARF (>4 weeks duration): reduction with halter or tong/halo traction
  - recurrent or irreducible AARF: internal fixation and fusion

- for isolated cervical spine ligamentous injuries and unstable or irreducible fractures of dislocations with associated deformity: consider primary operative treatment

- for cervical spine injuries that fail non-operative management: operative treatment

Level III19:

- children <8 yrs age: immobilize with thoracic elevation or an occipital recess (allows more neutral alignment due to the relatively large head)
62.5 Cervical bracing

62.5.1 Soft collars
Soft (sponge rubber) collar: does not immobilize the cervical spine to any significant degree. Its function is primarily to remind the patient to reduce neck movements.

62.5.2 Rigid cervical collars
Inadequate for stabilizing upper and mid-cervical spine and for preventing rotation.

Common rigid collars:
- Miami J collar & Aspen collar: have removable pads
- Philadelphia collar: no removable pads. Feels hotter to wear

62.5.3 Poster braces
Distinguished from cervicothoracic orthoses (see below) by the lack of straps under the axilla. Includes the four poster brace. Generally good for preventing flexion at midcervical levels.

62.5.4 Cervicothoracic orthoses
Cervicothoracic orthoses (CTO) incorporate some form of body vest to immobilize the cervical spine. The following are presented in increasing degree of immobilization.

- Guilford brace: essentially a ring around the occiput and chin connected by two posts to anterior and posterior thoracic pads.
- SOMI brace: acronym for Sternal Occipital Mandibular Immobilizer. Good for bracing against flexion (especially upper cervical spine). Inadequate for hyper-extension type injuries because of weak occipital support. Has special forehead attachment to allow patient to eat comfortably without mandibular support.
- “Yale brace”: a sort of extended Philadelphia collar. The most effective CTO for bracing against flexion-extension and rotation. Major shortcoming is poor prevention of lateral bending (only ≈ 50% reduced).

62.5.5 Halo-vest brace
Can immobilize the upper or lower cervical spine, not very good for mid-cervical spine (due to snaking of the midcervical spine). Unable to provide adequate distraction support following vertebral body resection when patient assumes upright position (i.e. it is not a portable cervical traction device). Overall reduction of flexion/extension as well as lateral bending is ≈ 90–95% rotation is reduced by 98% See placement (p.958).

62.6 Follow-up schedule
After initial management (surgical or nonsurgical) of cervical spine problems (stable or unstable) the follow-up schedule shown in Table 62.5 is suggested to permit recognition of problems in time for treatment1 (start with 3 weeks and keep doubling the interval to 1 year).

62.7 Sports-related cervical spine injuries

62.7.1 General information
Any of the spine injuries described in this book can be sports-related. This section considers some injuries peculiar to sports.
Bailes et al.\(^\text{20}\) classified sports-related spinal cord injuries (SCI) as shown in Table 62.6. Type I injuries may be complete or may have features of any of the incomplete SCI syndromes (often in mixed or partial forms). Type II injuries include spinal concussion, spinal neuropraxia (see below), and the burning hands syndrome (see below), all in the absence of radiographic abnormalities and all with complete resolution of symptoms. Patients should be carefully evaluated, and return to competition should not be allowed in the presence of neurologic deficit, radiographically demonstrated injury, certain congenital C-spine abnormalities, and possibly for “repeat offenders” (p. 937). Type III injuries are the most common. Unstable injuries should be treated appropriately (p. 997).

### 62.7.2 Football-related cervical spine injuries

#### General information

Football players with suspected C-spine injury should not have their helmet removed in the field (p. 949).

#### Terminology

The following terms probably originated as locker-room jargon for various cervical spine-related injuries usually sustained in playing football. Medical definitions have subsequently been retro-fitted to them. As a result, the precise definitions may not be uniformly agreed upon. Although the semantics may differ, it is more important from a diagnostic and therapeutic standpoint to distinguish nerve root injuries, brachial plexus injuries, and spinal cord injuries.

1. **cervical cord neuropraxia**\(^\text{21}\) (CCN): sensory changes which may involve numbness, tingling or burning. May or may not be associated with motor symptoms of weakness or complete paralysis. Typically lasts < 15 mins (although may persist up to 48 hrs), involves all 4 extremities in 80% of cases. Narrowing of the sagittal diameter of the cervical spinal canal is felt to be a contributory factor. With resumption of contact activities, recurrence rate is ≈ 56% with higher risks of recurrence among those with narrower canal diameters. Evaluation should include cervical MRI.

   Torg\(^\text{21}\) feels that uncomplicated cases of CCN (no spinal instability and no MRI evidence of cord defect or edema) have a low risk of permanent injury and does not recommend activity restrictions

2. “**stinger**” or “**burner**”: distinct from the burning hands syndrome. Unilateral, burning dysesthetic pain radiating down one arm from the shoulder, sometimes associated with weakness involving the C5 or C6 nerve roots. Usually follows a tackle. May result from downward traction on the upper trunk of the brachial plexus (when the shoulder is forcefully depressed with the neck

flexed to the contralateral side) or by direct nerve root compression in the neural foramina (not a SCI)
3. burning hands syndrome: similar to a stinger, but bilateral. Probably represents a SCI; possibly a mild variant of a central cord syndrome (p. 944)
4. other neurologic injuries include: vascular injury to carotid or vertebral arteries. Usually related to intimal dissection (p. 1018) following a direct blow to the neck or by extreme movements. Symptoms are those of a TIA or stroke

Spear tackler’s spine

Rule changes in 1976 banned spearing (the practice of using the football helmet as a battering ram to tackle an opponent) and resulted in a reduction of the number of football-related occurrences of cervical spine fractures and quadriplegia.

Four characteristics of spear tackler’s spine:
1. cervical spinal stenosis
2. loss of normal cervical lordosis: as a result, the stress of axial loading is more likely to be imparted to the vertebral bodies, rather than being absorbed by the cervical musculature and ligaments, increasing the risk of burst fractures and quadriplegia
3. evidence of pre-existing traumatic abnormalities
4. documented spear-tackler’s technique

Suggested management:
The athlete is removed from competition until the cervical lordosis returns and the player learns to use other tackling techniques. This tackling technique has been banned since 1976.

62.7.3 Return to play and pre-participation guidelines

Return to play (RTP) and pre-participation evaluation guidelines related to the cervical spine are shown in Table 62.7 (modified24). These are just guidelines, and do not insure safety. Clinical judgement must always be employed.

   b. stable two-level fusion | relative |
   c. fusion >2 levels | absolute |

*organized contact sports includes boxing, football, ice hockey, lacrosse, rugby & wrestling

b see also cranial-related (and craniocervical) conditions (p. 1151) (e.g. Chiari I malformation…)

C.L. = contraindications, classified as absolute, relative (i.e. uncertain) or none

d congenital abnormalities may have particular relevance to Special Olympics

NB: Klippel-Feil may be associated with abnormalities in other organ systems (e.g. cardiac) which may impact on participation in contact sports (p. 271)

Pavlov ratio (p. 1088) has a low positive predictive value for injuries in contact sports and is therefore not a useful screening test (i.e. an asymptomatic Pavlov ratio <0.8 is not a contraindication to participation)
62.8 Neurological assessment

62.8.1 General information

Evaluation of the level of the lesion requires familiarity with the following concepts about the relationship between the bony spinal canal and the spinal cord and nerves (Fig. 62.1).
1. since there are 8 pairs of cervical nerves and only 7 cervical vertebra
   a) cervical nerves 1 through 8 exit above the pedicles of their like-numbered vertebra
   b) thoracic, lumbar and sacral nerves exit below the pedicles of their like-numbered vertebra
2. due to disproportionately greater growth of the spinal column than the spinal cord during development, the following relationships of the spinal cord to the vertebral column exist:
   a) to determine which segment of the cord underlies a given vertebra:
      - from T2 through T10: add 2 to the number of the spinous process
      - for T11, T12 and L1, remember that these overlie the 11 lowest spinal segments (L1 through L5, S1 through S5, and Coxygeal-1)
   b) the conus medullaris in the adult lies at about L1 or L2 of the spine

62.8.2 Motor level assessment

General information

The following tables are for rapid assessment (see Table 29.5 and Table 29.7 for detailed tables of motor innervation).

**ASIA (American Spinal Injury Association) motor scoring system**

A system that may be rapidly applied to grade 10 key motor segments using the MRC Grading Scale (Table 29.2) from 0–5 on the left and the right, for a total score of 100 possible points (see Table 62.8). NB: most muscles receive innervation from two adjacent spinal levels, the levels listed in Table 62.8 are the lower of the two. The standard considers a segment intact if the motor grade is fair (≥ 3). For additional information, see www.asia-spinalinjury.org.

\(^a\)also use sensory level to help evaluate these segments

\(^b\)Beever’s sign: used to assess abdominal musculature for level of lesion. Patient lifts head off of bed by flexing neck; if lower abdominal muscles (below ≈ T9) are weaker than upper abdominal musculature, then umbilicus moves cephalad. Not helpful if both upper and lower abdominals are weak

\(^c\)the abdominal cutaneous reflex: scratching one quadrant of abdomen with sharp object causes contraction of underlying abdominal musculature, causing umbilicus to migrate toward that quadrant. Upper abdominal reflex: T8–9. Lower abdominal reflex: T10–12. This is a cortical reflex (i.e. reflex loop ascends to cortex, and then descends to abdominal muscles). The presence of this response indicates an incomplete lesion for cord injuries above the lower thoracic level

\(^d\)cremasteric reflex: L1–2 superficial reflex

\(^e\)anal-cutaneous reflex: AKA anal wink. Normal reflex: mild noxious stimulus (e.g. pinprick) applied to skin in region of anus results in involuntary anal contraction. bulbocavernosus (BC) reflex: see section 62.8.5

### 62.8.3 Sensory level assessment (dermatomes and sensory nerves)

ASIA standards

28 key points identified in Table 62.11 are scored separately for pinprick and light touch on the left & right side using the grading scale shown in Table 62.12, for a maximum possible total of 112 points for pinprick (left & right) and 112 points for light touch (left & right).
NB: regarding the “C4 cape” AKA “bib” region across the upper chest and back: sensory segments “jump” from C4 to T2 with the intervening levels distributed exclusively on the UEs (Fig. 1.14). The location of this transition is not constant from person to person.

62.8.4 Rectal exam
1. external anal sphincter is tested by insertion of the examiner’s gloved finger
   a) perceived sensation is recorded as present or absent. Any sensation felt by the patient indicates that the injury is sensory incomplete
   b) record resting sphincter tone and any voluntary sphincter contraction
2. bulbocavernous (BC) reflex (p.941); see also below: Absence suggests the presence of spinal shock, and it may not be possible to declare a suprasacral SCI as complete because there might be spinal shock which could transiently suppress spinal cord function

62.8.5 Bulbocavernous (BC) reflex
A polysynaptic spinal cord mediated reflex relayed via S2-S4 nerve roots. Contraction of anal sphincter in response to squeezing the glans penis in males, or to tugging on the Foley catheter in either sex is a normal response (must be differentiated from the movement of the Foley catheter balloon). Loss of reflex can occur with:
1. spinal shock: the BC reflex may be lost with spinal shock as can occur with suprasacral injuries. Reportedly, the return of the BC reflex may be the earliest clinical indicator that spinal shock has subsided.
2. injuries involving the cauda equina or conus medullaris

Presence of BC reflex used to be taken as an indication of an incomplete injury, but its presence alone is no longer considered to have a good prognosis for recovery.

62.8.6 Additional sensory exam
The following elements are considered optional but it is recommended that they be graded as absent, impaired or normal:
1. position sense: test index finger and great toe on both sides
2. awareness of deep pressure/deep pain

62.8.7 ASIA impairment scale
The ASIA impairment scale is shown in Table 62.13 (a modified Frankel Neurological Performance scale).
* NB: this scale indicates the completeness of spinal cord injury and is distinct from the other ASIA grading scales; see also motor and sensory scoring (p.940).

62.9 Spinal cord injuries
62.9.1 Complete spinal cord injuries
See definition of complete vs. incomplete spinal cord injury (p.930).
   In addition to loss of voluntary movement, sphincter control and sensation below the level of the injury, there may be priapism. Hypotension and bradycardia (p.931) (spinal shock) may also present.
62.9.2 Bulbar-cervical dissociation

Occurs as a result of spinal cord injury at or above ≈ C3 (includes SCI from atlanto-occipital and atlantoaxial dislocation). Bulbar-cervical dissociation produces immediate pulmonary and, often, cardiac arrest. Death results if CPR is not instituted within minutes. Patients are usually quadriplegic and ventilator dependent (phrenic nerve stimulation may eventually allow independence from ventilator).

62.9.3 Incomplete spinal cord injuries

Central cord syndrome

General information

<table>
<thead>
<tr>
<th>Key concepts</th>
</tr>
</thead>
<tbody>
<tr>
<td>• disproportionately greater motor deficit in the upper extremities than lower</td>
</tr>
<tr>
<td>• usually results from hyperextension injury in the presence of osteophytic spurs</td>
</tr>
<tr>
<td>• surgery is often employed for ongoing compression, usually on a non-emergency basis except for rare cases of progressive deterioration</td>
</tr>
</tbody>
</table>

Originally described by Schneider et al.29 in 1954. Central cord syndrome (CCS) is the most common type of incomplete spinal cord injury syndrome. Usually seen following acute hyperextension injury in an older patient with pre-existing acquired stenosis as a result of bony hypertrophy (anterior spurs) and infolding of redundant ligamentum flavum (posteriorly), sometimes superimposed on congenital spinal stenosis. Translational movement of one vertebra on another may also contribute. A blow to the upper face or forehead is often disclosed on history, or is suggested on exam (e.g. lacerations or abrasions to face and/or forehead). This often occurs in relation to a motor vehicle accident or to a forward fall, often while intoxicated. Younger patients may also sustain CCS in sporting injuries; see burning hands syndrome (p.1421). CCS may occur with or without cervical fracture or dislocation.30 CCS may be associated with acute traumatic cervical disc herniation. CCS may also occur in rheumatoid arthritis.

Pathomechanics

Theory: the centermost region of the spinal cord is a vascular watershed zone which renders it more susceptible to injury from edema. Long tract fibers passing through the cervical spinal cord are somatotopically organized such that cervical fibers are located more medially than the fibers serving the lower extremities (Fig. 1.13).

Presentation

See reference.29
The clinical syndrome is somewhat similar to that seen in syringomyelia.
1. motor: weakness of upper extremities with lesser effect on lower extremities
2. sensory: varying degrees of disturbance below level of lesion may occur
3. myelopathic findings: sphincter dysfunction (usually urinary retention)

Hyperpathia to noxious and non-noxious stimuli is also common, especially in the proximal portions of the upper extremities, and is often delayed in onset and extremely distressing to the patient.\textsuperscript{31} Lhermitte’s sign occurs in $\approx 7\%$ of cases.

Natural history
There is often an initial phase of improvement (characteristically: LEs recover first, bladder function next, UE strength then returns with finger movements last; sensory recovery has no pattern) followed by a plateau phase and then late deterioration.\textsuperscript{32} 90\% of patients are able to walk with assistance within 5 days.\textsuperscript{33} Recovery is usually incomplete, and the amount of recovery is related to the severity of the injury and patient age.\textsuperscript{34}

If CCS results from hematomyelia with cord destruction (instead of cord contusion), then there may be extension (upward or downward).

Evaluation
Findings: young patients tend to have disc protrusion, subluxation, dislocation or fractures.\textsuperscript{33} Older patients tend to have multi-segmental canal narrowing due to osteophytic bars, discs, and inbuckling of ligamentum flavum.\textsuperscript{33}

C-spine x-rays: may demonstrate congenital narrowing, superimposed osteophytic spurs, traumatic fracture/dislocation. Occasionally, AP narrowing alone without spurs may be seen.\textsuperscript{30} Plain x-rays will fail to demonstrate canal narrowing due to: thickening or inbuckling of ligamentum flavum, hypertrophy of facet joints, and poorly calcified spurs.\textsuperscript{30}

Cervical CT scan: also helpful in diagnosing fractures and osteophytic spurs. Not as good as MRI for assessing status of discs, spinal cord and nerves.

MRI: discloses compromise of anterior spinal canal by discs or osteophytes (when combined with plain C-spine x-rays, it increases the ability to differentiate osteophyte from traumatic disc herniation). Also good for evaluating ligamentum flavum. T2WI may show spinal cord edema acutely,\textsuperscript{35} and can detect hematomyelia. MRI is poor for identifying fractures.

Treatment
The indications, timing and best treatment method for CCS remains controversial.

**Practice guideline: Acute traumatic central cord injuries (ATCCS)**

**Level II\textsuperscript{34,36}**

- ICU management of patients with acute traumatic central cord syndrome, especially for those with severe neurologic deficits (because of possible cardiac, pulmonary & BP disturbances)
- medical management to include the following: cardiac, hemodynamic and respiratory monitoring and maintenance of MAP 85–90 mm Hg (use BP augmentation if necessary) for the 1st week after injury to improve spinal cord perfusion
- early reduction of fracture-dislocation injuries
- surgical decompression of the compressed spinal cord, particularly if the compression is focal and anterior. Unresolved: the role of surgery in ATCCS with long segment cord compression or with spinal stenosis without bony injury\textsuperscript{36} (see text for details)

**Indications for surgery**

1. continued compression of the spinal cord\textsuperscript{37} (p.1010) that correlates with the level of deficit with any of the following:
   a) persistent significant motor deficit following a varying period of recovery (below)
   b) deterioration of function
   c) continued significant dysesthetic pain
2. instability of the spine
Improvement has been shown in short and long-term follow-up with subacute decompression of the offending lesion. Nonsurgical treatment results in a longer period of pain and weakness in many cases.

Timing of surgery: A perennial point of controversy. Classic teaching was that early surgery for this condition is contraindicated because this may worsen the deficit. In the absence of spinal instability, traditional management consisted of bed rest in a soft collar for 3–4 weeks, with consideration for surgery after this time, or else gradual mobilization in the same collar for an additional 6 weeks. However, the basis for this recommendation was at least in part derived from an early report of only 8 patients with CCS, 2 of which underwent surgery, with 1 being worse post-op (the operation consisted of laminectomy, opening the dura, sectioning the dentate ligament, and manipulation of the spinal cord in order to inspect the anterior spinal canal). It is presently felt that there is no solid evidence that early decompressive surgery (without cord manipulation) is actually harmful, but there is also no evidence that it is helpful, either. There may be good justification for early surgery in the rare patient who is improving and then deteriorates, however, great restraint must be used in avoiding what would be an inappropriate operation in many patients. Surgery may improve the rate and degree of recovery in selected patients. Surgery has been recommended for patients with gross spinal instability or for patients with significant persistent cord compression (e.g., by osteophytic spurs) who fail to progress consistently after an initial period of improvement, often within 2–3 weeks following the trauma. Better results occur with decompression within the first few weeks or months rather than very late (e.g., ≥1–2 years).

There is no role for surgery without ongoing compression or instability. The rare patient with ongoing compression undergoing documented progressive deterioration should be decompressed ASAP. Patients that are improving should be followed and decompression can be done electively for ongoing compression. There is controversy regarding timing of surgery for stable CCS and ongoing compression: while Class I or II data are lacking, there seems to be a trend to decompress these patients as soon as they are medically stable without an arbitrary waiting period.

Technical considerations: The most rapid procedure to decompress the cord is often a multi-level laminectomy. This is frequently accompanied by dorsal migration of the spinal cord which may be seen on MRI. With myelopathy, fused patients fare better than those that are just decompressed without fusion. Fusion may be accomplished posteriorly (e.g., with lateral mass screws and rods) at the time of decompression, or anteriorly (e.g., multi-level discectomy, or corpectomy with strut graft and anterior cervical plating) at the same sitting as the laminectomy or staged at a later date.

Prognosis
In patients with cord contusion without hematomyelia, ≈50% will recover enough LE strength and sensation to ambulate independently, although typically with significant spasticity. Recovery of UE function is usually not as good, and fine motor control is usually poor. Bowel and bladder control often recovers, however bladder spasticity is common. Elderly patients with this condition generally do not fare as well as younger patients, with or without surgical treatment (only 41% over age 50 become ambulatory, versus 97% for younger patients).

Anterior cord syndrome

General information
AKA anterior spinal artery syndrome. Cord infarction in the territory supplied by the anterior spinal artery. Some say this is more common than central cord syndrome.

May result from occlusion of the anterior spinal artery, or from anterior cord compression, e.g., by dislocated bone fragment, or by traumatic herniated disc.

Presentation
1. paraplegia, or (if higher than C7) quadriplegia
2. dissociated sensory loss below lesion:
   a) loss of pain and temperature sensation (spinothalamic tract lesion)
   b) preserved two-point discrimination, joint position sense, deep pressure sensation (posterior column function)
Evaluation
It is vital to differentiate a non-surgical condition (e.g. anterior spinal artery occlusion) from a surgical one (e.g. anterior bone fragment). This requires one or more of: myelography, CT, or MRI.

Treatment
Surgical intervention is indicated for patients with evidence of cord compression (e.g. by large central disc herniation) or for spinal instability (ligamentous or bony).

Prognosis
The worst prognosis of the incomplete injuries. Only $\approx 10–20\%$ recover functional motor control. Sensation may return enough to help prevent injuries (burns, decubitus ulcers...).

Brown-Séquard syndrome

General information
Spinal cord hemisection. First described in 1849 by Brown-Séquard.\textsuperscript{43}

Etiologies
Usually a result of penetrating trauma, it is seen in 2–4% of traumatic spinal cord injuries.\textsuperscript{44} Also may occur with radiation myelopathy, cord compression by spinal epidural hematoma, large cervical disc herniation\textsuperscript{45,46,47} (rare), spinal cord tumors, spinal AVMs, cervical spondylosis, and spinal cord herniation (p. 1150).

Presentation
Classical findings (rarely found in this pure form):
1. ipsilateral findings:
   a) motor paralysis (due to corticospinal tract lesion) below lesion
   b) loss of posterior column function (proprioception & vibratory sense)
2. contralateral findings: dissociated sensory loss
   a) loss of pain and temperature sensation inferior to lesion beginning 1–2 segments below (spinothalamic tract lesion)
   b) preserved light (erude) touch due to redundant ipsilateral and contralateral paths (anterior spinothalamic tracts)

Prognosis
This syndrome has the best prognosis of any of the incomplete spinal cord injuries. $\approx 90\%$ of patients with this condition will regain the ability to ambulate independently as well as anal and urinary sphincter control.

Posterior cord syndrome
AKA contusio cervicis posterior. Relatively rare. Produces pain and paresthesias (often with a burning quality) in the neck, upper arms, and torso. There may be mild paresis of the UEAs. Long tract findings are minimal.

References
63 Management of Spinal Cord Injury

63.1 General information

The major causes of death in spinal cord injury (SCI) are aspiration and shock.\(^1\) Initial survey under ATLS protocol: assessment of airway takes precedence, then breathing, then circulation & control of hemorrhage (“ABCs”). This is followed by a brief neurologic exam.

NB: other injuries (e.g. abdominal injuries) may be masked below the level of SCI.

Any of the following patients should be treated as having a SCI until proven otherwise:

1. all victims of significant trauma
2. trauma patients with loss of consciousness
3. minor trauma victims with complaints referable to the spine (neck or back pain or tenderness) or spinal cord (numbness or tingling in an extremity, weakness, paralysis)
4. associated findings suggestive of SCI include
   a) abdominal breathing
   b) priapism (autonomic dysfunction)

Trauma patients are triaged as follows:

1. no history of significant trauma, completely alert, oriented and free of drug or alcohol intoxication with no complaints referable to the spine: most may be cleared clinically without the need for C-spine x-rays; see Radiographic evaluation (p. 952)
2. significant trauma, but no strong evidence of spine or spinal cord injury: the emphasis here is in ruling-out a bony lesion and preventing injury
3. patients with neurologic deficit: the emphasis here is to define the skeletal injury and to take steps to prevent further cord injury and loss of function and minimize or reverse the present deficit. The pros and cons of the high-dose methylprednisolone protocol (p.951) should be weighed if a neurologic deficit is identified

63.2 Management in the field

1. Spine immobilization prior to and during extrication from vehicle and transport to prevent active or passive movements of the spine.
   a) For possible C-spine injuries in football players, see Table 63.1 for the National Athletic Trainers’ Association (NATA) guidelines for helmet removal. When CPR is necessary it takes precedence. Caution with intubation (see below)
   b) place patient on back-board

<table>
<thead>
<tr>
<th>Table 63.1 NATA helmet removal guidelines(^a)</th>
</tr>
</thead>
<tbody>
<tr>
<td>NB: do not remove the helmet in the field.</td>
</tr>
<tr>
<td>• most injuries can be visualized with the helmet in place</td>
</tr>
<tr>
<td>• neurological exam can be done with the helmet in place</td>
</tr>
<tr>
<td>• the patient may be immobilized on a spine board with the helmet in place</td>
</tr>
<tr>
<td>• the facemask can be removed with special tools to access the airway</td>
</tr>
<tr>
<td>• hyperextension must be avoided following removal of the helmet and shoulder pads</td>
</tr>
</tbody>
</table>

In a controlled setting (usually after x-rays) the helmet and shoulder-pads are removed together as a unit to avoid neck flexion or extension

Possible indications for removal of helmet

• face mask cannot be removed in a reasonable amount of time
• airway cannot be established even with face mask removed
• life threatening hemorrhage under the helmet that can be controlled only by removal
• helmet & strap do not hold head securely so that immobilizing the helmet does not adequately immobilize the spine (e.g. poor fitting or damaged helmet)
• helmet prevents immobilization for transportation in an appropriate position
• certain situations where the patient is unstable (M.D. decision)

\(^a\)for more details, see http://www.nata.org
c) sandbags on both sides of the head with a 3 inch strip of adhesive tape from one side of the
back-board to the other across the forehead immobilizes the spine as well as a rigid orthosis but
allows movement of the jaw and access to the airway
d) a rigid cervical collar (e.g. Philadelphia collar) may be used to supplement

2. maintain blood pressure, see below under Hypotension (p.950)
a) pressors treat the underlying problem (SCI is essentially a traumatic sympathectomy). Dop-
amine is the agent of choice, and is preferred over fluids (except as necessary to replace losses); see Cardiovascular agents for shock (p.127) for pressors. Avoid phenylephrine (see below)
b) fluids as necessary to replace losses
c) military anti-shock trousers (MAST): immobilizes lower spine, compensates for lost muscle
tone in cord injuries (prevents venous pooling)

3. maintain oxygenation (adequate FiO₂ and adequate ventilation)
a) if no indication for intubation: use NC or face mask b) intubation: may be required for airway compromise or for hypopnea. In SCI, hypopnea may be due to: paralyzed intercostal muscles, paralysis of diaphragm (phrenic nerve = C3, 4 & 5). Hypopnea may also be due to depressed LOC in TBI
c) caution with intubation with uncleared C-spine
• use chin lift (not jaw thrust) without neck extension
• nasotracheal intubation may avoid movement of C-spine but patient must have spontane-
ous respirations
• avoided tracheostomy or cricothyroidotomy if possible (may compromise later anterior cer-
vical spine surgical approaches)

4. brief motor exam to identify possible deficits (also to document delayed deterioration); ask pa-
tient to:
a) move arms
b) move hands
c) move legs
d) move toes

63.3 Management in the hospital
63.3.1 Stabilization and initial evaluation

1. immobilization: maintain backboard/head-strap (see above) to facilitate transfers to CT table,
etc. Log-roll patient to turn. Once studies are completed, remove patient from backboard ASAP (early removal from board reduces risk of decubitus ulcers)

2. hypotension (spinal shock): maintain SBP ≥ 90 mm Hg. Spinal cord injuries cause hypotension by a combination of factors (p.931) which may further injure spinal cord or other organ systems
a) pressors if necessary: dopamine is agent of choice ( avoid phenylephrine: non-inotropic and possible reflex increase in vagal tone → bradycardia)
b) careful hydration (abnormal hemodynamics → propensity to pulmonary edema)
c) atropine for bradycardia associated with hypotension

3. oxygenation (see above)

4. NG tube to suction: prevents vomiting and aspiration, and decompresses abdomen which can interfere with respirations if distended (paralytic ileus is common, and usually lasts several days)

5. indwelling (Foley) urinary catheter: for I's & O's and to prevent distension from urinary retention

6. DVT prophylaxis: see below

7. temperature regulation: vasomotor paralysis may produce poikilothermy (loss of temperature control), this should be treated as needed with cooling blankets

8. electrolytes: hypovolemia and hypotension cause increased plasma aldosterone which may lead to hypokalemia

9. more detailed neuro evaluation (p.939). Patients may be stratified using the ASIA impairment scale ( Table 62.13)
a) focused history: key questions should center on:
• mechanism of injury (hyperflexion, extension, axial loading...)
• history suggestive of loss of consciousness
• history of weakness in the arms or legs following the trauma
• occurrence of numbness or tingling at any time following the injury
b) palpation of the spine for point tenderness, a “step-off”; or widened interspinous space
c) motor level assessment
- skeletal muscle exam (can localize dermatome)
- rectal exam for voluntary anal sphincter contraction

d) sensory level assessment
- sensation to pinprick (tests spinothalamic tract, can localize dermatome): be sure to test sensation in face also (spinal trigeminal tract can sometimes descend as low as \( \approx C4 \))
- light (crude) touch: tests anterior cord (anterior spinothalamic tract)
- proprioception/joint position sense (tests posterior columns)

e) evaluation of reflexes
- muscle stretch reflexes: usually absent initially in cord injury
- abdominal cutaneous reflexes
- cremasteric reflex
- sacral: bulbocavernosus (p. 941), anal-cutaneous reflex

f) examine for signs of autonomic dysfunction
- altered patterns of perspiration (abdominal skin may have low coefficient of friction above lesion, and may seem rough below due to lack of perspiration)
- bowel or bladder incontinence
- priapism: persistent penile erection

10. radiographic evaluation: see below

11. medical management specific to spinal cord injury:
a) methylprednisolone (see below)
b) experimental/investigational drugs: none of these agents shown to have unequivocal benefit in man: naloxone, DMSO, Lazaroid®. Tirilazad mesylate (Freedox®) was less beneficial than methylprednisolone

63.3.2 General information

Practice guideline: Assessment of SCI in the hospital

Clinical Assessment
Level III: the ASIA international standards for neurological and functional assessment of spinal cord injury (SCI) is recommended (p. 940)

Functional outcome assessment
Level II: the Functional Impairment Measure™ (FIM™) is recommended (see Table 88.7)
Level III: the modified Barthel index is recommended (Table 88.6)

Practice guideline: In-hospital critical care management of SCI

Level III: monitor patients with acute SCI (especially those with severe cervical level injuries) in an ICU or similar monitored setting

Level III: cardiac, hemodynamic & respiratory monitoring after acute SCI is recommended

Level III: hypotension (SBP < 90 mm Hg) should be avoided or corrected ASAP

Level III: maintain MAP at 85–90 mm Hg for the first 7 days after SCI to improve spinal cord perfusion

63.3.3 Methylprednisolone

Practice guideline: Methylprednisolone in SCI

Level I
- Methylprednisolone (MP) for the treatment of acute SCI is not recommended.
- GM-1 ganglioside (Sygen) for the treatment of acute SCI is not recommended.
MP is not FDA approved for use in treating acute SCI. There is no Class I or II evidence of benefit supporting this use of MP. Class III data that had been used to advocate its use, but the benefits were likely due to random chance and/or selection bias.8 Conversely, there is Class I, II and III level evidence that high dose steroids are associated with harmful side effects and even death.5 Use of high-dose MP among spine surgeons has shown a steady decline,9 however, it was still used by as many as 56% of respondents to one survey.9

63.3.4 Hypothermia for spinal cord injury

The position statement of the joint sections of the AANS and the CNS is that there is not enough evidence to recommend for or against local or systemic hypothermia for acute SCI, and that it should be noted that systemic hypothermia is associated with medical complications in TBI.10

63.3.5 Deep-vein thrombosis in spinal cord injuries

General information

Also see Thromboembolism in neurosurgery (p.167). Incidence of DVT may be as high as 100% when 125I-fibrinogen is used.11 Overall mortality from DVT is 9% in SCI patients.

Practice guideline: DVT in patients with cervical SCI

Prophylaxis

Level I12:
- prophylactic treatment of venous thromboembolism (VTE) in patients with severe motor deficits due to SCI. Choices include:
  - LMW heparin, rotating beds, adjusted dose heparin, or some combination of these measures
  - or, low-dose heparin + pneumatic compression stockings or electrical stimulation

Level II12:
- early administration of VTE prophylaxis (within 72 hours)
- treat for 3 months
  - low-dose heparin should not be used alone
  - oral anticoagulation should not be used alone

Level III12:
- vena cava interruption filters should not be used for routine prophylaxis; they may be used for select patients who fail anticoagulation or are not candidates for anticoagulation

Diagnosis

Level III12:
- duplex doppler ultrasound, impedance plethysmography, venography, and the clinical examination are recommended as diagnostic tests for DVT in patients with SCI

Prophylaxis

A study of 75 patients found titrating dose of SQ heparin q 12 hrs to a PTT of 1.5 times control resulted in lower incidence of thromboembolic events (DVT, PE) than “mini-dose” heparin (5000 U SQ q 12 hrs) (7% vs. 31%).13 Heparin can cause thrombosis, thrombocytopenia and chronic therapy may produce osteoporosis; see heparin (p.164).

63.4 Radiographic evaluation and initial C-spine immobilization

63.4.1 Clinical criteria to rule-out cervical spine instability

There is almost no chance of a significant occult cervical spine injury14,15 in a trauma patient who met all of the criteria in the Practice Guideline below. (Note: Although reports of bony or
ligamentous abnormalities have been described as possibly occurring in these patients, there has been no report of a patient who had neurologic injury as a result of these abnormalities.)

**Practice guideline: Radiographic evaluation in awake, asymptomatic trauma patients**

**Level I**

- Radiographic studies are not indicated in patients who meet all of the following criteria:
  - No mental status changes (and no evidence of alcohol or drugs). Note: altered mental status can include GCS ≤ 14; disorientation to person, place, time or events; inability to remember 3 objects at 5 minutes; delayed response to external stimuli. Evidence of alcohol or drugs includes information from the history, physical findings (slurred speech, ataxia, odor of alcohol on the breath) or positive blood or urine tests.
  - No neck pain or posterior midline tenderness (and no distracting pain).
  - No focal neurologic deficit (on motor or sensory exam).
  - Do not have significant associated injuries that detract/distract from their evaluation.

Cervical immobilization may be discontinued without cervical spine imaging in these patients.

The Canadian C-Spine Rule (CCR) was found to be more sensitive & specific, but the EAST has not embraced it as of this writing.

**63.4.2 Cervical immobilization**

**General information**

Cervical collars should be removed as soon as it can be determined that it is safe to do so. The benefits from early collar removal include: reduction of skin breakdown, fewer days of mechanical ventilation, shorter ICU stays, reduction of ICP.

**Guidelines**

Guidelines for “clearing” the cervical spine and removing the cervical collar are shown in Practice guideline: Cervical immobilization in trauma patients (p. 953).

**Practice guideline: Cervical immobilization in trauma patients**

A cervical collar is not needed in trauma patients who meet these criteria:

- Asymptomatic patients as in Practice guideline: Radiographic evaluation in asymptomatic trauma patients (p. 953): patients who are alert, without neurologic deficit or distracting injury who have no neck pain or tenderness and full ROM of the cervical spine (Level II)
- Penetrating brain trauma: unless the trajectory suggests direct cervical spine injury (Level III)
- Level III & Level III: Patients who are awake with neck pain or tenderness and normal cervical CT scan after either (these tests are performed in the absence of an identifiable fracture or obviously unstable dislocation to rule-out ligamentous or other soft-tissue injury that might be occult and unstable):
  - Normal & adequate dynamic flexion-extension C-spine x-rays
  - Or a normal cervical MRI is obtained. Note: AANS/CNS guidelines from 2002 recommended getting the MRI within 48 hours. MRI is usually employed in this setting when the patient is unable to co-operate for flex-ext x-rays; see MRI findings and issues related to timing (p. 957), etc.

In obtunded patients with normal cervical CT scan and gross movement of all 4 extremities:

- Flexion-extension C-spine x-rays should not be performed (Level II)
- Options:
  - Maintain cervical collar until a clinical exam can be performed.
- remove the collar on the basis of the normal CT scan alone\(^\text{17}\) (the incidence of ligamentous injury with negative CT is <5\%, and the incidence of clinically significant injury is unknown but is much <1\%\(^\text{17}\))
- obtain cervical MRI (AANS/CNS guidelines from 2002 recommended getting the MRI within 48 hours\(^\text{25}\)):
  - Level III\(^\text{17}\): the risk and benefit of cervical MRI in addition to CT is unclear, and must be individualized
  - Level II\(^\text{17}\): If the MRI is normal, the collar may be safely removed

63.4.3 Minimum radiographic evaluation

General information

There is controversy regarding what constitutes a minimum radiographic evaluation of the cervical spine in multiple trauma patient. No imaging modality is 100\% accurate.

Asymptomatic patients – meeting criteria outlined in Practice guideline: Radiographic evaluation in awake, asymptomatic trauma patients (p.953) – may be considered to have a stable cervical spine and no radiographic studies of the cervical spine are indicated.\(^\text{25}\) Factors associated with increased risk of failing to recognize spinal injuries include: decreased level of consciousness (due to injury or drugs/alcohol), multiple injuries, technically inadequate x-rays (p.1019).\(^\text{26}\)

Primary imaging recommendations

Practice guideline: Radiographic imaging in trauma patients who are obtunded or unevaluable

Includes unresponsive patients or unreliable exam (altered mental status, distracting pain or injuries)

- Level I\(^\text{18}\)
  - high-quality computed tomography (CT) imaging is the modality of choice
    - if high-quality CT imaging is available, routine 3-view cervical spine x-rays are not recommended
    - if high-quality CT imaging is not available, 3-view cervical spine x-rays (AP, lateral and open-mouth odontoid view) are recommended. Supplement with CT when available if needed to further define areas that are suspicious or poorly visualized on plain x-rays
- Level II\(^\text{18}\)
  - if high-quality CT imaging is normal but the index of suspicion is high, further management should fall to physicians trained in the diagnosis and treatment of spine injuries
- Level III\(^\text{18}\)
  - if high-quality CT imaging is normal, options include:
    - continue cervical immobilization until asymptomatic
    - obtain cervical MRI within 48 hours of injury and, if normal, D/C cervical immobilization*
    - D/C cervical immobilization at the discretion of the treating physician
    - the routine use of dynamic imaging (flexion-extension) is of marginal benefit and is not recommended in this situation

* limited and conflicting Class II & III medical evidence

CT scan, while extremely sensitive for bony injuries, is not adequate for assessing soft tissues (e.g. traumatic disc herniation, spinal cord contusion...) or ligamentous injuries (may require flexion-extension x-rays (see below) and/or MRI).
When CT scan is not appropriate/available as the initial radiographic exam

When CT cannot be done, the following guidelines are offered:

See X-rays, C-Spine (p. 212) for normal vs. abnormal findings. Table 63.2 lists some indicators that should alert the reviewer that there may be significant C-spine trauma (they do not indicate definite instability by themselves).

1. cervical spine: must be cleared radiographically from the cranio-cervical junction down through and including the C7-T1 junction (incidence of pathology at C7-T1 junction may be as high as 9%27):
   a) lateral portable C-spine x-ray while in rigid collar: this study by itself will miss ≈ 15% of injuries28
   b) if all 7 cervical vertebra AND the C7-T1 junction are adequately visualized and are normal, and if the patient has no neck pain or tenderness and is neurologically intact (neurologically intact implies patient is alert, not drugged/intoxicated, & able to report pain reliably), then remove the cervical collar and complete the remainder of the cervical spine series (AP and open-mouth odontoid (OMO) view). Lateral, AP, and OMO views together detect essentially all unstable fractures in neurologically intact patients29 (although the AP view rarely provides unique information30). In a severely injured patient, limitation to an AP and lateral view usually suffices for the acute (but not complete) evaluation31
   c) if the above studies are normal, but there is neck pain, tenderness or neurologic findings (there may be a spinal cord injury even with normal plain films), or if the patient is unable to reliably verbalize neck pain or cannot be examined for neurologic deficit, then further studies are indicated, which may include any of the following:
   • oblique views (some authors include oblique views in a “minimal” evaluation31; others do not29): demonstrates the neural foramina – may be blocked with a unilateral locked facet (p. 992) - , shows a different projection of the uncinate processes than the AP view, and helps assess the integrity of the articular masses and lamina (the lamina should align like shingles on a roof)31
   • flexion-extension views: see below
   • CT scan: helpful in identifying bony injuries, especially in areas difficult to visualize on plain radiographs. However, CT cannot exclude significant soft-tissue or ligamentous injury32
   • MRI: utility is limited to specific situation (p. 957) and the accuracy has not been determined
   • polytomograms: becoming less available
   • pillar view: devised to demonstrate the cervical articular masses en face (reserved for cases of suspected of having articular mass fracture)33; the head is rotated to one side (requires that the upper cervical spine injury has been excluded by previous radiographs), the x-ray tube is centered 2 cm from midline in the opposite direction and the beam is angled 25° caudad, centered at the superior margin of the thyroid cartilage

</tbody>
</table>
d) if subluxation is present at any level and is $\leq 3.5$ mm and the patient is neurologically intact (neurologically intact implies patient is alert, not drugged/intoxicated, and able to report pain reliably), then obtain flexion-extension films (see below)
  - if no pathologic movement, may discontinue cervical collar
  - even if no instability is demonstrated, may need delayed films once pain and muscle spasms have resolved to reveal instability

e) if lower C-spine (and/or cervical-thoracic junction) are not well visualized
  - repeat lateral C-spine x-ray with caudal traction on the arms (if not contraindicated based on other injuries, e.g. to shoulders)
  - if still not visualized, then obtain a “swimmer’s” (Twining) view: the x-ray tube is positioned above the shoulder furthest from the film, and aimed towards the axilla closest to the film with the tube angled 10–15° toward the head while the arm is elevated above the head
  - if still not visualized: CT scan through non-visualized levels (CT is poor for evaluating alignment and for fractures in the horizontal plane, thin cuts with reconstructions ameliorates this shortcoming)

f) see questions regarding stability of the subaxial spine (p.987)

g) patients with C-spine fractures or dislocations should have daily C-spine x-rays during initial traction or immobilization

2. thoracic and lumbosacral LS-spine: AP and lateral x-rays for all trauma patients who:
   a) were thrown from a vehicle, or fell $\geq 6$ feet to the ground
   b) complain of back pain
   c) are unconscious
   d) are unable to reliably describe back pain or have altered mental status preventing adequate exam (including inability to verbalize regarding back pain/tenderness)
   e) have an unknown mechanism of injury, or other injuries that cast suspicion of spine injury

3. reminder: when abnormalities of questionable vintage are identified, a bone scan may be helpful to distinguish an old injury from an acute one (less useful in the elderly; in an adult, a bone scan will become “hot” within 24–48 hrs of injury, and will remain hot for up to a year; in the elderly, the scan may not become hot for 2–3 weeks and can remain so for over a year)

4. if a bony abnormality is identified or if there is a level of neurologic deficit ascribable to a specific spinal level, either a CT or MRI scan through that area should be done if possible

**Flexion-extension cervical spine x-rays**

**Purpose:** to disclose occult ligamentous instability.

**Rationale:** It is possible to have a purely ligamentous injury involving the posterior ligamentous complex without any bony fracture (p.991). Lateral flexion-extension views help detect these injuries, and also evaluate other injuries (e.g. compression fracture) for stability. For patients with limited flexion due to paraspinal muscle spasm (sometimes resulting from pain), a rigid collar should be prescribed, and if the pain persists 2–3 weeks later the flexion-extension films should be repeated.

**Options:** a cervical MRI done within 48–72 hours of the trauma (may be more sensitive with STIR sequences or equivalent) may identify ligamentous or other soft-tissue injury, especially in patients who cannot cooperate for flexion-extension x-rays.

**Contraindications**
- the patient must be cooperative and free of mental impairment (i.e. no head injury, street or prescription drugs, alcohol...)
- there should not be any subluxation $>3.5$ mm at any level on cross-table C-spine x-rays, which is a marker for possible instability (p.991)
- patient must be neurologically intact (if there is any degree of spinal cord injury, proceed instead first with imaging studies, e.g. MRI)
- F/E x-rays are no longer recommended in obtunded patients due to a low yield, poor cost-effectiveness, and they may be dangerous

**Technique**
The patient should be sitting, and is instructed to flex the head slowly, and to stop if it becomes painful. Serial x-rays are taken at 5–10° increments (or followed under fluoro with spot films at the end of movement), and if normal, the patient may be encouraged to flex further. This is repeated until evidence of instability is seen, or the patient cannot flex further because of pain or limitation of motion. The process is then repeated for extension.
Findings
Normal flexion-extension views demonstrate slight anterior subluxation distributed over all cervical levels with preservation of the normal contour lines (Fig. 12.1). Abnormal findings include: “flaring” of the spinous processes, see exaggerated widening (p.214).

Emergent MRI (or myelogram)

General information
Indications for emergent MRI in spinal cord injury (SCI) are listed below.

When an MRI cannot be performed, a myelogram is required (employing intrathecal contrast with CT to follow) Caution: cervical myelogram in patients with cervical spine injuries usually requires C1–2 puncture to achieve adequate dye concentration in the cervical region without dangerous extension of the neck or tilting of the patient as required when dye is injected via LP. Furthermore, pressure shifts from LP exacerbates deficit in 14% of cases with complete block.

36

Indications
1. incomplete SCI (to check for R/O soft tissue compressing cord) with normal alignment: to check for soft tissue compressing cord
2. neurologic deterioration (worsening deficit or rising level) including after closed reduction
3. neurologic deficit not explained by radiographic findings, including:
   a) fracture level different from level of deficit
   b) no bony injury identified: further imaging is done to R/O soft tissue compression (disc herniation, hematoma…) that would require surgery
   c) always keep in mind the possibility of arterial dissection in this setting (p.1322)

MRI (non-emergent)

General information
MRI may be used to identify potentially unstable occult ligamentous or soft tissue injury. Note: abnormal signal on MRI is not always associated with instability on flexion-extension x-rays. It has been recommended that this MRI should be done within 48 hours or 72 hrs of injury. MRI is not reliable for identifying osseous injury.

Indications for non-emergent MRI (modified): See reference
1. inconclusive cervical spine radiography, including questionable fractures
2. significant midline paraspinal tenderness and patient unable to have flexion-extension x-rays
3. obtunded or comatose patients

T2WI and STIR are the most helpful sequences. Significant abnormal findings:
1. ventral signal abnormalities with prevertebral swelling
2. dorsal signal abnormalities. Abnormal signal limited to the interspinous is probably not as unstable as when it extends into the ligamentum flavum. These patients were treated with rigid collars or Minerva jackets for 1–3 months, and one that was felt to be very unstable underwent fusion
3. disc disruption indicated by abnormal signal intensity within the disc, increased disc height, or frank disc protrusions

63.5 Traction/reduction of cervical spine injuries

63.5.1 General information
Purpose
To reduce fracture-dislocations, maintain normal alignment and/or immobilize the cervical spine to prevent further spinal cord injury. Reduction decompresses the spinal cord and roots, and may facilitate bone healing.
Practice guidelines

Practice guideline: Initial closed reduction in fracture/dislocation cervical SCI

Level III
- early closed reduction of C-spine fracture/dislocation injuries with craniocervical traction to restore anatomic alignment in awake patients
- not recommended: closed reduction in patients with an additional rostral injury
- patients with C-spine fracture-dislocation who cannot be examined during attempted closed reduction, or before open posterior reduction, should undergo cervical MRI before attempted reduction (see note below). The presence of a significant herniated disc in this setting is a relative indication for anterior decompression (e.g. by an anterior cervical discectomy and fusion – ACDF) before reduction
- cervical MRI is also recommended for patients who fail attempts at closed reduction (see note below).

Controversies
1. the rapidity with which reduction should be done
2. whether MRI should be done prior to attempted closed reduction (prereduction MRI (p.958), will show disrupted or herniated discs in 33–50%of patients with facet subluxation. These findings do not seem to significantly influence outcome after closed-reduction in awake patients; the usefulness of prereduction MRI in this setting is uncertain)
   a) in intact patients, to R/O a condition that might cause worsening of neurologic condition with reduction (e.g. traumatic disc herniation) – must be balanced against risks of transferring patients to MRI
   b) in patients with neurologic deficit (complete or partial SCI)

Contraindications
1. atlantooccipital dislocation (p.963): traction may worsen deficit. If immobilization with tongs/halo is desired, use no more than ≈ 4 lbs
2. types IIA or III hangman’s fracture (p.973)
3. skull defect/fracture at anticipated pin site: may necessitate alternate pin site
4. use with caution in pediatric age group (do not use if age ≤ 3 yrs)
5. very elderly patients
6. demineralized skull: some elderly patients, osteogenesis imperfecta...
7. patients with an additional rostral injury
8. patients with movement disorders: constant motion may cause pin erosion through the skull

63.5.2 Application of tongs or halo ring

General information
Supplies: gloves, local anesthetic (typically 1% lidocaine with epinephrine), betadine ointment. Optional equipment: razor or hair clipper, scalpel.
Choice of device: a number of cranial "tongs" are available. Crutchfield tongs require predrilling holes in the skull. Gardner-Wells tongs are the most common tongs in use. If, after the acute stabilization, the later use of halo-vest immobilization is anticipated, a halo ring may be used for the initial cervical traction, and then converted to vest traction at the appropriate time (e.g. post-fusion).
Preparation: placed with patient supine on a gurney or bed. Option: shave hair around proposed pin sites (see below). Betadine skin prep, then infiltrate local anesthetic. Option: incise skin with scalpel (prevents pins from driving in surface contaminants).

Gardner-Wells tongs
Pin sites: the pins are placed in the temporal ridge (above the temporalis muscle), 2–3 finger-breadths (3–4 cm) above pinna. Place directly above external acoustic meatus for neutral position traction; 2–3 cm posterior for flexion (e.g. for locked facets); 2–3 cm anterior for extension.
One pin has a central spring-loaded force-indicator. Tighten pins until the indicator protrudes 1 mm beyond the flat surface. Retighten the pins daily until indicator protrudes 1 mm for 1 or 2 days only, then stop.

Halo ring

Supplies (in addition to above): optional paddle AKA “spoon” to support the head beyond the edge of the bed, traction adapter (called a “traction bail” from the circular handle on a baille, the old French word for bucket). Read all of this (including pointers) before starting

1. ring size: choose an appropriately sized ring that leaves a ≈ 1–2 cm gap between the scalp and the ring all the way around

2. ring position: generally placed at or just below the widest portion of the skull (the “equator”)

3. pin sites: choose the threaded holes in the ring that place the pins as perpendicular to the skull as possible as follows
   a) anterior pins: above the lateral two-thirds of the orbit
   b) posterior pins: just behind the ears
   c) in pediatrics, additional pins may be placed to further distribute the load on the thinner skull

4. pin insertion: the pins are gradually brought close to the scalp which is then anesthetized with local anesthetic. Pins are then sequentially tightened, starting with any pin then going to the kitty-corner pin, then a third pin and finally its opposite. Most halos provide some type of torque wrench to permit approximately 8 in-lb of torque for most adults; 2–5 in-lb for peds

5. placement pointers
   a) the cervical collar is left in place until traction/immobilization is established
   b) try to place the halo as level from left to right as possible. While a skewed placement can be compensated for when attaching the vest, it looks bad
   c) prior to penetrating the forehead skin for anterior pins, have the patient close their eyes and hold them closed as the pins are advanced (this avoids “pinning the eyes open”)
   d) avoid placing pins in the temporalis muscle or the temporal squamosa
   e) do not place pins above the medial third of the orbit to avoid the supraorbital and supratrochlear nerves, and to reduce theorist of penetrating the relatively thin anterior wall of the frontal sinus

Application of traction

For traction, transfer to a bed with ortho headboard with the tongs or halo ring in place. Tie a rope to tongs/halo and feed through a pulley at the head of bed. Slight flexion or extension is achieved by changing the height of the pulley relative to the patient’s long axis.

X-rays: lateral C-spine x-rays immediately after application of traction and at regular intervals and after every change in weights and every move from bed. Check alignment and rule-out overdis- traction at any level and atlanto-occipital dislocation; BDI should be ≤ 12 mm (p.963).

Weight: if there is no malalignment and traction is being used just to stabilize the injury and to compensate for ligamentous instability, use 5 lbs for the upper C-spine or 10 lbs for lower levels. See information on reducing locked facets (p.992). May remove cervical collar once patient is in traction with adequate reduction or stabilization.

Post-placement care

Pin tightening: pins are re-torqued in 24 hours. Some authors do one additional tightening the day after that. Avoid further tightenings which can penetrate the skull

Pin care: clean (e.g. half strength hydrogen peroxide), then apply povidone-iodine ointment. Frequency: in hospital: q shift. At home following discharge: twice daily.

Alternatively, simple cleaning with soap and water twice daily is acceptable.

Application of halo vest

For vest placement (i.e. patients not remaining in traction) once the halo ring is placed (see above) it needs to be attached to the vest by posts. The mechanism varies between manufacturers. If possible, have the patient in a cotton T-shirt prior to placing the vest (this may require cutting the neck opening to accommodate the ring).
The vest should be snug, but too tight so as to restrict respirations. Shoulder straps should be contacting the shoulders (the vest will tend to ride up when the patient is sitting). Most vests come with a wrench that is taped to the vest for emergency removal e.g. for cardiopulmonary resuscitation.

Reduction of locked facets

See Practice guideline: Initial closed reduction in fracture/dislocation cervical SCI (p.958) for background information and Reduction of locked facets (p.992) for technique.

Complications

1. skull penetration by pins. May be due to:
   a) pins torqued too tightly
   b) pins placed over thin bone: temporal squamosa or over frontal sinus
   c) elderly patients, pediatric patients, or those with an osteoporotic skull
   d) invasion of bone with tumor: e.g. multiple myeloma
   e) fracture at pin site
2. reduction of cervical dislocations may be associated with neurologic deterioration which is usually due to retropulsed disc and requires immediate investigation with MRI or myelogram/CT
3. overdistraction from excessive weight (especially with upper cervical spine injuries), may also endanger supporting tissues
4. caution with C1-C3 injury, especially with posterior element fracture (traction may pull fragments in towards canal)
5. infection:
   a) osteomyelitis in pin sites: risk is reduced with good pin care
   b) subdural empyema (p.327): rare

63.6 Indications for emergency decompressive surgery

63.6.1 Cautions and contraindications

Caution: laminectomy in the face of acute spinal cord injury has been associated with neurologic deterioration in some cases. When emergency decompression is indicated, it is usually combined with a stabilization procedure.

Contraindications to emergent operation
- complete spinal cord injury ≥24 hrs (no motor or sensory function below level of lesion) in the absence of spinal shock (i.e. the deficit is attributable to a complete spinal cord injury and not a temporary condition due to spinal shock). Bulbocavernous reflex is generally used as a guide to the presence of spinal shock (see Bulbocavernous reflex)
- medically unstable patient
- central cord syndrome (p.944): controversial

63.6.2 Modified recommendations of Schneider

See reference. In patients with complete spinal cord lesions, no study has demonstrated improvement in neurologic outcome with either open decompression or closed reduction. In general, surgery is reserved for incomplete lesions – possibly excluding central cord syndrome (p.944) – with extrinsic compression, who, following maximal possible reduction of subluxation show:

1. progression of neurologic signs
2. complete subarachnoid block by Queckenstedt test or radiographically (on myelography or MRI)
3. compression of spinal cord (on CT/myelogram, CT, or MRI) e.g. by bone fragments or soft tissue elements (e.g. traumatic disc herniation)
4. necessity for decompression of a vital cervical root
5. compound fracture or penetrating trauma of the spine
6. acute anterior spinal cord syndrome (p.946)
7. non-reducible fracture-dislocations from locked facets causing spinal cord compression
References

64 Occiptoatlantoaxial Injuries (Occiput to C2)

64.1 Atlanto-occipital dislocation

64.1.1 General information

See Occiptoatlantoaxial-complex anatomy (p. 68) for relevant anatomy. Atlanto-occipital dislocation (AOD) AKA cranio cervical junction dislocation. Disruption of the stability of the cranio cervical junction (which results from ligamentous injuries). Probably under-diagnosed, may be present in ≈ 1% of patients with “cervical spine injuries”1 (definition of cervical spine injuries not specified), found in 8–19% of fatal cervical spine injury autopsies.2,3 More than twice as common in pediatrics as adults, possibly owing to the flatter (i.e. less cupped) condyles in peds, the higher ratio of cranium to body weight, and increased ligamentous laxity. Patients usually either have minimal neurological deficit or exhibit bulbar-cervical dissociation (BCD) (p.944). Some may exhibit cruciate paralysis (p.1419). Most mortality results from anoxia due to respiratory arrest as a result of BCD.

Classification

See reference.4

For illustration, see Fig. 64.1.

Type I. Anterior dislocation of occiput relative to the atlas

Type II. Longitudinal dislocation (distraction)

Type III. Posterior dislocation of occiput

Combinations (e.g. anterior-distracted AOD5) may also occur.

Practice guideline: Diagnosis of atlanto-occipital dislocation

Level I

- In pediatric patients, CT to assess the condyle-C1 interval (CCI) is recommended to diagnose AOD

Level II

- In pediatric patients, CCI measured on CT has the highest sensitivity and specificity for AOD. The utility in adults has not been reported

- A lateral cervical spine x-ray is recommended to diagnose AOD. If it is desired to employ a radiologic method of measurement, the BAI-BDI method is recommended (see Table 64.1). Prevertebral soft tissue swelling in the upper cervical spine on an otherwise nondiagnostic x-ray should be followed with a cervical CT to rule out AOD

**Comments**

- **BAI** (basion-axial interval): distance from basion (inferior tip of the clivus) to rostral extension of posterior axial line (PAL) (the posterior cortical margin of the body of C2). AKA Harris line. Better for anterior or posterior AOD.
- **BDI** (basio-dental interval): distance from basion to the closest point on the tip of the dens. Better for distracted AOD.
- **PAL** (posterior axial line): the posterior cortical margin of the body of C2. AKA Harris line. Better for anterior or posterior AOD.
- **AOI** (atlanto-occipital interval): AKA condylar gap. Distance between occipital condyle and superior articular surface of C1 measured on lateral x-ray or sagittal CT reconstructions thru O-C1 junction. Pang averaged the interval between the condyle and C1 at 4 equidistant points on sagittal and 4 on coronal images (8 points total).
- **Powers’ ratio** = \( \frac{BC}{AO} \) for AOD, \( A \) = anterior arch of C1, \( C \) = posterior arch of C1, \( B \) = basion, \( O \) = opisthion.
- **Dublin measure** = \( \frac{C2}{Cl} \) ≤ 13 mm.
- **X-Line method** requires identification of 6 reference points and 2 lines (sensitivity 75%). Uses a 6 ft target-film distance in a sitting patient which is not always practical in the E/R system.
64.1.2 Clinical presentation
1. may be neurologically intact, therefore must be ruled-out in any major trauma
2. bulbar-cervical dissociation (p.944)
3. may have lower cranial nerve deficits (as well as VI palsies) ± cervical cord injury
4. worsening neurologic deficit with the application of cervical traction: check lateral C-spine films immediately after applying traction (p.959)

64.1.3 Radiographic evaluation
Numerous methodologies have been devised to radiographically diagnose AOD. Most utilize surrogate markers for the end-point of interest: viz. instability of the occipital-cervical junction. None are completely reliable. Measurements on CT scans are more accurate than plain radiographs (landmarks are easier to identify, no magnification or rotation error) – however, normal values differ from plain radiographs. Some methods are shown in Table 64.1. The BAI-BDI method and the AOI method are recommended.

A helpful rule-of-thumb: the inferior tip of the clivus should point directly to tip of dens (this may be obscured on x-ray).

Additional CT clues: there may be blood in the basal cisterns (an indirect sign). On thin-cut axial CT, there may be one or more slices showing no bone at all due to the gap between the occiput and C1.

64.1.4 Technical suggestions for radiographic evaluation
1. X-rays: verify that the film is a true lateral (e.g. check alignment of the two mandibular rami as well as of the posterior clinoids)
2. CT: sensitivity, specificity, and positive/negative predictive values of most of these measures improves when sagittal CT reconstructions are used instead of plain radiographs (relevant landmarks could be identified in >99%of CTs, vs. 39–84%on x-ray)

Powers’ ratio: distance BC (basion to posterior arch of atlas) is divided by distance AO (opisthion to anterior arch of atlas), see Table 64.1. Interpretation is shown in Table 64.2.

64.1.5 Management
Initial management
If AOD is suspected, immediately immobilize the neck with halo orthosis or with sandbags. Do not apply cervical traction in an attempt to reduce AOD because there is a 10% risk of neurologic deterioration with the use of traction in AOD.
**Subsequent management**

Controversial whether operative fusion vs. prolonged immobilization (4–12 months) with halo brace is required. However, posterior occipitocervical fusion is usually recommended (p. 1138).

**Practice guideline: Treatment of atlanto-occipital dislocation**

**Level III**
- internal fixation & arthrodesis (fusion) using one of a variety of methods
- CAUTION: traction is not recommended in the management of AOD

Horn et al.\(^\text{10}\) suggest that patients be grouped and then managed as shown in Table 64.3.

In infants: reduce in the OR and fuse (usually with transarticular screws).

**64.1.6 Prognosis**

The most important predictor of outcome is the severity of neurologic injuries at the time of presentation.\(^\text{10}\) Among AOD patients who survived the initial injury, those with severe TBI and brainstem dysfunction or complete bulbar-cervical dissociation all had poor outcome.\(^\text{10}\) Those with incomplete SCI or nonsevere TBI may improve.

**64.2 Occipital condyle fractures**

**64.2.1 General information**

**Key concepts**
- uncommon (0.4% of trauma patients)
- may present with lower cranial nerve deficits which may be delayed in onset (e.g. hypoglossal nerve palsy), mono-, para-, or quadriparesis or plegia
- W/U: CT scan with reconstructions (rarely detected on plain x-rays)
Occipital condyle fractures (OCF) were first described in 1817 by Bell. Rare. Incidence: 0.4% (in a series of 24,745 consecutive trauma patients surviving to the E/R).

### 64.2.2 Diagnosis

Clinical suspicion of occipital condyle fracture (OCF) should be raised by the presence of ≥1 of the following:

- blunt trauma with high energy
- craniocervical injuries
- altered consciousness
- occipital pain or tenderness
- impaired cervical movement
- lower cranial nerve palsies
- retropharyngeal soft-tissue swelling

**Practice guideline: Diagnosis of occipital condyle fractures**

*Level II*^4^  
- CT to establish the diagnosis of occipital condyle fracture (OCF)

*Level III* ^4^  
- MRI to assess the integrity of the ligaments of the cranioce rvical complex

### 64.2.3 Classification

A widely used classification system is that of Anderson & Montesano as shown in Table 64.4. Maserati et al. classified patients simply on the basis of whether craniocervical misalignment was present or absent on CT with reconstructions (they defined craniocervical misalignment as an occipital condyle-C1 interval > 2.0 mm). They felt other classification systems were superfluous as they did not affect outcome in their retrospective review (see Treatment below).

### 64.2.4 Treatment

Controversial. Lower cranial nerve deficits often develop in untreated cases of OCF, and may resolve or improve with external immobilization. Anderson & Montesano Types I & II have been treated with or without external immobilization (cervical collar or, occasionally, halo) without obvious difference. External immobilization × 6–8 weeks is suggested for Type III fractures because of the higher risk of delayed deficits.

<table>

<td>extension of linear basilar skull fracture</td>
</tr>
<tr>
<td>III</td>
<td>avulsion of condyle fragment (traction injury): may occur during rotation, lateral bending, or a combination of mechanisms. Considered unstable by many</td>
</tr>
</tbody>
</table>
Practice guideline: Treatment of occipital condyle fractures

Level III:
- For OCF with associated atlanto-occipital ligamentous injury or evidence of instability: halo vest immobilization or occipitocervical stabilization (fusion).
- For bilateral OCFs, consider halo vest instead of a collar to provide increased immobilization.
- External cervical immobilization for all other OCFs.

64.2.5 Outcome

In a retrospective review of 100 patients with OCF, 3 patients underwent occipitocervical fusion for craniocervical misalignment (2) or unrelated Cl–2 fracture (1). The remainder (without craniocervical misalignment) were treated with a rigid collar and delayed clinical & radiographic follow-up. None of their unoperated patients had neurologic deficit, and none developed delayed instability, malalignment, or neurologic deficit (regardless of their classification on the other systems in use).

64.3 Atlantoaxial subluxation/dislocation

64.3.1 General information

Lower morbidity and mortality than atlantooccipital dislocation. See Occiptoatlantoaxial-complex anatomy (p.68) for relevant anatomy.

Types of atlantoaxial subluxation:
1. rotatory: (see below) usually seen in children after a fall or minor trauma
2. anterior: more ominous (see below)
3. posterior: rare. Usually from erosion of odontoid. Unstable. Requires fusion

64.3.2 Atlantoaxial rotatory subluxation

General information

Key concepts

- typically seen in children
- associations: trauma, RA, respiratory tract infections in peds (Grisel syndrome)
- often present with cock-robin head position (tilt, rotation, sl. flexion)
- classification: Fielding & Hawkins (Table 64.5)
- Tx: early traction often successful. Treat infection in Grisel syndrome. Subluxation unreducible in traction may need transoral release then posterior fusion

Table 64.5 Fielding & Hawkins classification of rotatory atlantoaxial subluxation

</tbody>
</table>

*TAL = transverse atlantal ligament, AD = anterior displacement of Cl on C2
Rotational deformity at the atlanto-axial junction is usually of short duration and easily corrected. Rarely, the atlantoaxial joint locks in rotation (aka atlantoaxial rotatory fixation\(^{28}\)). Usually seen in children. May occur spontaneously (with rheumatoid arthritis\(^{29}\) or with congenital dens anomalies), following major or minor trauma (including neck manipulation or even with neck rotation while yawning\(^{28}\)), or with an infection of the head or neck including upper respiratory tract (known as Grisel syndrome\(^{30}\): inflammation may cause mechanical and chemical injury to the facet capsules and/or transverse atlantal ligament (TAL)).

The vertebral arteries (VA) may be compromised in excessive rotation, especially if it is combine with anterior displacement.

**Mechanism of subluxation**

The dislocation may be at the occipito-atlantal and/or the atlanto-axial articulations.\(^{31}\) The mechanism of the irreducibility is poorly understood. With an intact TAL, rotation occurs without anterior displacement. If the TAL is incompetent as a result of trauma or infection, there may also be anterior displacement with more potential for neurologic injury. Posterior displacement occurs only rarely.\(^{28}\)

**Classification**

The Fielding and Hawkins classification\(^{28}\) is shown in Table 64.5.

**Clinical findings**

Patients are usually young. Neurologic deficit is rare. Findings may include: neck pain, headache, torticollis – characteristic "cock robin" head position with \(\approx 20^\circ\) lateral tilt to one side, \(20^\circ\) rotation to the other, and slight \(\approx 10^\circ\) flexion, see DDx (p.1390) -, reduced range of motion, and facial flattening.\(^{28}\) Although the patient cannot reduce the dislocation, they can increase it with head rotation towards the subluxed joint with potential injury to the high cervical cord.

Brainstem and cerebellar infarction and even death may occur with compromise of circulation through the VAs.\(^{32}\)

**Radiographic evaluation**

X-rays: Findings (may be confusing) include:
- Pathognomonic finding on AP C-spine x-ray in severe cases: frontal projection of C2 with simultaneous oblique projection of C1.\(^{33}\) In less severe cases, the C1 lateral mass that is forward appears larger and closer to the midline than the other
- Asymmetry of the atlantoaxial joint that is not correctable with head rotation, which may be demonstrated by persistence of asymmetry on open mouth odontoid views with the head in neutral position and then rotated 10–15\(^\circ\) to each side
- The spinous process of the axis is tilted in one direction and rotated to the other (may occur in torticollis of any etiology)

CT scan: Demonstrates rotation of the atlas.\(^{31}\)

MRI: May assess the competence of the transverse ligament.

**Treatment**

Grisel’s syndrome

Appropriate antibiotics for causative pathogen with traction (see below) and then immobilization for the subluxation as follows:\(^{30}\): Fielding ( Table 64.5) Type I: soft collar, Type II: Philadelphia collar or SOMI, Type III or IV: halo. After 6–8 weeks of immobilization, check stability with flexion-extension x-rays. Surgical fusion for residual instability.

**Traction**

If treated within the first few months\(^{34}\) the subluxation can usually be reduced with gentle traction (in children start with 7–8 lbs and gradually increase up to 15 lbs over several days, in adults start with 15 lbs and gradually increase up to 20). If the subluxation is present >1 month, traction is less successful. Active left-right neck rotation is encouraged in traction.

If reducible, immobilization in traction or halo is maintained \(\times 3\) months\(^{28}\) (range: 6–12 weeks).
Surgical fusion
Subluxation that cannot be reduced or that recurs following immobilization should be treated by surgical arthrodesis after 2–3 weeks of traction to obtain maximal reduction. The usual fusion is C1 to C2 (p.1479) unless other fractures or conditions are present.28 Fusion may be performed even if the rotation between C1 & C2 is not completely reduced. For irreducible fixation, a staged procedure can be done with anterior transoral release of the atlantoaxial complex (the exposure is taken laterally to expose the atlantoaxial joints which must be done carefully to avoid injury to the VAs, soft tissue is carefully removed from the joints and the atlantodental interval, no attempt at reduction was made at the time of this 1st stage) followed by gradual skull traction and then a second stage posterior C1–2 fusion.

64.3.3 Anterior atlantoaxial subluxation (AAS)
See reference.27

General information
One third of patients with AAS have neurologic deficit or die. For relevant anatomy, see Occipitoatlantoaxial-complex anatomy (p.68).
Subluxation may be due to:
1. disruption (rupture) of the transverse (atlantal) ligament (TAL): the atlantodental interval (ADI) (see below) will be increased
   a) attachment points of the TAL may be weakened in rheumatoid arthritis (p.1479)
   b) trauma: may cause anatomic or functional ligament disruption (see below)
2. incompetence of the odontoid process: ADI will be normal
   a) odontoid fracture
   b) congenital hypoplasia, e.g. Morquio syndrome (p.1151)

Presentation
Neck pain is common. There are no specific patterns to the pain that is characteristic.

“V” shaped pre-dens space
See reference.35
Widening of the upper space between the anterior arch of C1 and the odontoid seen on lateral C-spine flexion x-ray. It is not known if this increased mobility represents elongation or laxity of the transverse ligament and/or the posterior ligamentous complex. This may also be a normal finding in flexion in peds.
True subluxation will result in malalignment between C1 and C2. The key differentiating feature is whether the ADI is increased or normal, as indicated above.

Evaluation and classification
Both CT & MRI are recommended to evaluate fractures, TAL & its bony attachments.

Assessing the integrity of the transverse ligament
1. disruption of the TAL may be inferred indirectly from
   a) Rule of Spence: on open-mouth odontoid x-ray, if the total overhang of both C1 lateral masses on C2 is ≥7 mm
   b) atlantodental interval (ADI) (p.213): >3 mm in adults, >4 mm in peds
2. MRI may be able to image the TAL directly. Findings of disruption (axial MRI): high signal within TAL on gradient-echo MRI, loss of continuity of TAL, blood at insertion site
3. CT demonstrates bony injuries in regions of TAL insertion on C1 tubercles

Classification of TAL disruption
See reference.37
Type I. Anatomic disruption. Tear of TAL itself. Rare (the odontoid usually fractures before the TAL tears). Unlikely to heal. Requires surgical stabilization
Type II. Physiologic disruption. Detachment of the tubercle of C1 to which TAL is attached (Fig. 1.12) as may occur in comminuted C1 lateral mass fractures. 74% chance of healing with immobilization (halo recommended\textsuperscript{37})

**Treatment**

- For TAL disruption: One approach is to fuse all Type I TAL injuries, and those Type II TAL injuries that are still unstable after 3–4 months of immobilization.\textsuperscript{37} Fusion is also recommended with irreducible subluxations. If C1 is intact, a C1–2 fusion is usually adequate. For situations involving C1 fractures, see below.
- For odontoid fractures with intact TAL managed as outlined (p. 979)

### 64.4 Atlas (C1) fractures

#### 64.4.1 General information

Acute C1 fractures account for 3–13% of cervical spine fractures.\textsuperscript{38} 56% of 57 patients had isolated C1 fractures; 44% had combination C1–2 fractures; 9% had additional non-contiguous C-spine fractures. 21% had associated head injuries.\textsuperscript{38}

#### 64.4.2 Classification of C1 fractures

See reference.\textsuperscript{39}
- Type I: fractures involving a single arch (31–45% of C1 fractures)
- Type II: burst fracture (37–51%): the classic Jefferson fracture (see below)
- Type III: lateral mass fractures of the atlas (13–37%)

#### 64.4.3 Jefferson fracture

Described by Sir Geoffrey Jefferson.\textsuperscript{40} Classically a four-point (burst) fracture of the C1 ring,\textsuperscript{41} but the term is now often used to include the more common three or two-point fractures,\textsuperscript{42} the latter through the C1 arches (thinnest portion). Usually from axial load (a “blow-out” fracture). 41% chance of an associated C2 fracture.

In pediatrics, it is critical to differentiate a C1 fracture from the normal synchondroses (p. 214) and from pseudospread of the atlas (p. 933). A fracture may also occur through the unfused synchondroses.

#### 64.4.4 Stability

To reiterate: stability of the occipitoatlantoaxial complex is primarily due to ligaments, with little contribution from bony articulations; see Occipitoatlantoaxial-complex anatomy (p. 68). Integrity of transverse ligament (TAL) is the most important determinant of stability (see Assessing the integrity of the transverse ligament above).

Jefferson fractures are unstable, however, there is usually no neurologic deficit for isolated Jefferson fractures (due to the large canal diameter at this level, plus the tendency for fragments to be forced outwards away from spinal cord).

#### 64.4.5 Clinical

Neurologic deficit is rare. 3 of 25 patients with Jefferson fractures sustained neurologic injuries (1 complete injury, 2 central cord syndromes) in one series.

#### 64.4.6 Evaluation

Thin cut high-resolution CT is the diagnostic test of choice. It is critical to evaluate from C1 through C3 to delineate details of the C1 fracture and to assess for associated C2 injury.

MRI may be able to assess the integrity of the TAL, but images are often difficult to interpret for this.
64.4.7 Treatment

Treatment options depend heavily on the status of the TAL. Practice guidelines are shown here. Specifics are delineated in Table 64.6. When external immobilization is employed, it is used for 8–16 weeks (mean =12).

Practice guideline: Treatment of isolated atlas fractures

Level III\textsuperscript{44}: for isolated atlas fractures:
- treatment is based on the fracture type and integrity of transverse atlantal ligament
- if the transverse ligament is intact: cervical immobilization alone
- if the transverse ligament is disrupted: either (note: disruption of the TAL may be anatomic or physiologic; see text for details)
  a) cervical immobilization alone
  b) or, surgical fixation and fusion

Fusion options when surgery is indicated\textsuperscript{37}:
1. unilateral ring or anterior C1 arch fractures: C1–2 fusion
2. multiple ring fractures or posterior C1 arch fractures: occipital-cervical fusion

Surgical options: 1. fusion A. unilateral ring..., B. multiple ring... 2. Surgical options that do not involve arthrodesis include: posterior C1 screw placement, anterior transoral screw/plate placement.

64.4.8 Outcome

In many series\textsuperscript{38,45} treatment without surgery results in satisfactory outcome when the TAL is not disrupted.

64.5 Axis (C2) fractures

64.5.1 General information

Acute fractures of the axis represent \( \approx 20\% \) of cervical spine fractures. Neurological injury is uncommon, and occurs in <10% of cases. Most injuries may be treated by rigid immobilization.

Steele’s rule of thirds: each of the following occupies one–third of the area of the canal at the level of the atlas: dens, space, spinal cord.\textsuperscript{36}

64.5.2 Types of C2 fractures

1. odontoid fractures (p.978): type II odontoid fracture is the most common injury of the axis
2. hangman’s fracture: see below
3. miscellaneous C2 fractures (p.982)

64.5.3 Hangman’s fracture

General information

Key concepts

- bilateral fracture through the pars interarticularis of C2 with traumatic subluxation of C2 on C3, most often due to hyperextension + axial loading
- most are stable with no neurologic deficit
- classification: Levine system (Table 64.7). Critical dividing line: disruption of C2–3 disc (Types II and higher) which may render the fracture unstable
- W/U: cervical CT with sagittal & coronal recons for all. Cervical MRI to assess C2–3 disc disruption (Levine II). CTA for dissection if fx passes thru foramen transversarium (consider for all C2 fractures – see Table 55.7)
- most do well with non-halo immobilization x 8–14 weeks. Exceptions: severe/unstable fractures (p.975) or those that do not remain aligned in brace

AKA traumatic spondylolisthesis of the axis (a term first used in 196447).

Description: bilateral fracture through the pars interarticularis (isthmus) of the pedicle of C2 (Fig. 64.2; the configuration of C2 is unique, and the distinction between the pars and the pedicle is ambiguous). There is often anterior subluxation of C2 on C3.

The term “hangman’s fracture” (HF) was coined by Schneider et al.48 although the mechanism of most modern HFs (hyperextension and axial loading, from MVAs or diving accidents) differs from that sustained in judicial hangings (where submental placement of the knot results in hyperextension and distraction49). Some cases may be due to forced flexion or compression of the neck while in extension.

Pediatrics: rare in children < 8 years old where the forces tend to fracture the incompletely fused odontoid, see epiphyseal fracture (p.214). In pediatrics, consider pseudosubluxation in the differential diagnosis (p.934).

Usually stable. Deficit is rare. Nonunion is rare. 90% heal with immobilization only. Operative fusion is rarely needed. Fractures of C2 that do not go through the isthmus are not true hangman’s fractures and may require different management (p.982).

Fig. 64.2 Anatomy of axis (C2). The pars interarticularis is shown in dark blue
Classification

Levine/Effendi classification

The system of Effendi et al.\textsuperscript{50} as modified by Levine\textsuperscript{51} and others (Table 64.7) is widely used in grading adult HF (not applicable to peds). Angulation is measured as the angle between the inferior endplates of C2 and C3. Anterior subluxation of C2 on C3 > 3 mm (Type II) is a surrogate marker for C2–3 disc disruption which can be evaluated more directly with cervical MRI.

Grading system of Frances et al.

The grading system\textsuperscript{54} is shown in Table 64.8. The methodology of measurements is depicted in Fig. 64.3.

Levine/Francis correlation

In a series of 340 axis fractures,\textsuperscript{55} the most common fracture type was Type I in the Levine system (72%) and Grade I in the Francis system (65%); and there was a close correlation as follows:

- Levine Type I $\approx$ Francis Grade I
- Levine Type III $\approx$ Francis Grade IV

Table 64.7 Levine classification of hangman’s fractures (modified Effendi system)\textsuperscript{a}

\textsuperscript{b}amount of angulation was not specified in original article, but $>10^\circ$ has been suggested by some
Other fracture types
Not all fractures fit into one or both of these classification systems. Example: coronally oriented fracture extending through the posterior C2 vertebral body.

**Presentation**
Most (≈ 95%) are neurologically intact, those few with deficits are usually minor (paresthesias, monoparesis…) and many recover within one month. Almost all conscious patients will have cervical pain usually in the upper posterior cervical region, and occipital neuralgia is not uncommon. There is a high incidence of associated head injury and there will be other associated C-spine injuries – e.g. C1 fracture (see above) or clay shoveler’s fracture (p.988) – in ≈ one third, with most occurring in the upper 3 cervical levels. There are usually external signs of injury to the face and head associated with the hyperextending and axial force.

**Evaluation**
Cervical CT: with sagittal & coronal reconstructions should be done to fully assess the fracture.
CTA: should be done to evaluate the vertebral arteries if fracture extends through foramen transversarium (especially Levine Type IA) and in patients with symptoms suggestive of stroke. Some

recommend CTA for all C2 fractures — Table 55.7). Angiography or MRA may be done as an alternative to CTA.

MRI: cervical MRI should be done to look for C2–3 disc disruption (a marker for instability (Levine grade II) which usually requires surgical stabilization). Findings may include abnormal increased signal intensity on MRI (best seen on sagittal FLAIR images or T2WI).

X-Rays: lateral C-spine x-rays show the fracture in 95% of cases. Also demonstrates C2 angulation and/or subluxation. Most fractures pass through the pars or the transverse foramen, 74 7% go through the body of C2 (p. 982). Instability can usually be identified as marked anterior displacement of C2 on C3 (guideline 74; unstable if displacement exceeds 50% of the AP diameter of C3 vertebral body), excessive angulation of C2 on C3, or by excessive motion on flexion-extension films.

Patients suspected of having Levine Type I fractures and are neurologically intact should have physician-supervised flexion-extension x-rays to rule out a reduced type II fracture.

**Treatment**

**General information**

Nonsurgical management produces adequate reduction in 97–100% and results in a fusion rate of 93–100% 73,75,59 if the external immobilization is adequately maintained for 8–14 weeks 60 (average time for healing is ≈ 11.5 weeks 54). Specific treatment depends on the reliability of the patient and the degree of stability as described below. Most cases do well with non-halo immobilization. 59 Practice guidelines are shown here, and details follow.

**Practice guideline: Management of isolated hangman’s fracture**

**Level III** 61,62

- hangman’s fractures may initially be managed with external immobilization in most cases (halo or collar)
- surgical stabilization should be considered in cases of:
  a) severe angulation of C2 on C3 (Levine II, Francis II & IV)
  b) disruption of the C2–3 disc space (Levine II, Francis V)
  c) or inability to establish or maintain alignment with external immobilization

**Stable fractures (Levine Types I or IA, or Francis Grades I or II)**

Treat with immobilization (Aspen or Philadelphia collar 63 (p. 2326) or cervicothoracic orthosis (CTO) (e. g. SOMI) is usually adequate) × 3 months. 53 Halo-vest may be needed in unreliable patients or for combination C1–C2 fractures. Schneider reported 50 cases of Type I fracture treated with non-halo fixation, only 1 was taken to surgery and was found to already be fused.

**Unstable fractures**

**Levine Type II**

Reduce with gentle cervical traction (most reduce with ≤ 30 lbs 53) with the head in slight extension (preferably in halo ring) under close x-ray monitoring to prevent “iatrogenic hanging” in cases with ligamentous instability. 54 Place in halo-vest × 3 months. Follow patients with serial x-rays. Stabilize surgically if fracture moves.

Type II fractures with ≤ 5 mm of subluxation and angulation < 10°

Once reduced, apply halo-vest and begin to mobilize (usually within 24 hrs of injury). Verify that immobilization is adequate in the halo with upright lateral C-spine x-ray, operate if inadequate. After 8–12 weeks, change to Philadelphia collar or CTO until fusion is definitely complete (usually 3–4 months).

Type II fractures with > 5 mm subluxation or ≥ 10° of angulation

Surgical fusion in these patients is recommended because of the following concerns:

1. risk of settling if immediately mobilized in halo-vest
2. healing with significant angulation may result in chronic pain
3. if not reduced, the gap may be too large for bony bridging using traction alone
Alternatively, cervical traction can be maintained for \( \approx 4 \) weeks and then reduction should be re-assessed 1 hour after removing weight from traction, and if stable, again 24 hours after mobilizing in a halo vest. If unstable, return to traction and repeat trial at 5 & 6 weeks. If still unstable at 6 weeks, surgical fusion is recommended.\(^{33}\)

Levine Type II A

Traction will accentuate the deformity.\(^{33}\) Fractures should be reduced by immediate placement in halo vest (bypassing traction) with extension and compression applied. Halo-vest immobilization \( \times 3 \) months produces \( \approx 95\% \) union rate.

Levine Type III

Reduction with traction may be dangerous with locked facets. ORIF is recommended.\(^{27}\) MRI prior to surgery is recommended to assess the C2–3 disc. Can follow ORIF with halo-vest for the fracture, or can fuse at the same time as ORIF.

Surgical treatment

Indications

Few patients have indications for surgical treatment of HF, and include those with:

1. inability to reduce the fracture (includes most Levine Type III & some Type II)
2. failure of external immobilization to prevent movement at fracture site
3. traumatic C2–3 disc herniation with compromise of the spinal cord\(^{64}\)
4. established non-union: evidenced by movement on flexion-extension film (p.956)\(^{34}\); all failures of nonoperative treatment had displacement >4 mm\(^{27}\)

Hangman’s fractures likely to need surgery\(^{55}\):

1. Levine Type II or III
2. or Francis grade II, IV or V
3. or if either:
   a) anterior displacement of C2 VB >50% of the AP diameter of the C3 VB
   b) or if angulation produces widening of either the anterior or posterior borders of the C2–3 disc space >the height of the normal C3–4 disc below

Surgical options

1. fusion techniques:
   a) posterior approach: if the fracture is not transfixed (osteosynthesis – see below) then a C1–2 fusion is required. This depends on the integrity of the C2–3 disc and facet joint capsules, otherwise a C1–3 fusion is required. Occasionally the occiput is incorporated as well. Options for C1–2 fusion:
      • C1–2 wiring and fusion
      • C1–2 lateral mass screws/rods (p.1481)
   b) anterior C2–3 discectomy\(^{54}\) with fusion. Optional anterior plating or zero-profile graft/plate. Performed via a transverse anterior cervical incision midway between the angle of the jaw and the thyroid cartilage\(^{55,64}\)
      • preserves more motion by excluding C1
      • this approach is also recommended for established non-union\(^{54}\)
      • not optimal for Levine Type III requiring ORIF for locked facets
      • also used when at least a partial reduction cannot be achieved
      • technique: for special considerations for approach to the C2–3 junction, see the section on operative techniques

2. osteosynthesis: screw placement from posterior approach through the C2 pedicle across the fracture fragment.\(^{53}(p\,443)\) Reduction must be achieved before the screw holes are drilled.\(^{65}\) The technique for C2 pedicle screws (p.1481) is used. The posterior fracture fragment may be overdrilled with a 3.5 mm drill. A “top hat” is placed in the hole and a 2.7 mm drill is used to drill the VB. Screw length: 30–35 mm for average adults. Alternatively, a lag screw may be used (with 20 mm unthreaded)

Treatment endpoint

Plain x-rays should show trabeculation across the fracture site or interbody fusion of C2 to C3. Flexion-extension lateral radiographs should show no movement at the fracture site.
64.5.4 Odontoid fractures

General information

Key concepts

- 10–15% of C-spine fx. Can occur in older patients with minor trauma (GL F), or in younger patients typically following MVA, falls from a height, skiing...
- may be fatal at time of injury, most survivors are intact. Neck pain is common
- classification: Anderson & D’Alonzo (Table 64.9). Type II (at base) is the most common
- Tx: surgery is considered for: Type II if age > 50 yrs, Type IIA, or Type II & III if displacement ≥ 5 mm or if alignment cannot be maintained with halo

Significant force is required to produce an odontoid fracture in a young individual, and is usually sustained in a motor vehicle accident (MVA), a fall from a height, a skiing accident, etc. In patients > 70 years age, simple ground level falls (GL F) with head trauma may produce the fracture. Odontoid fractures comprise ≈ 10–15% of all cervical spine fractures. They are easily missed on initial evaluation, especially since significant associated injuries are frequent and may mask symptoms. Pathologic fractures can also occur, e.g. with metastatic involvement (p.1391).

Flexion is the most common mechanism of injury, with resultant anterior displacement of C1 on C2 (atlantoaxial subluxation). Extension only occasionally produces odontoid fractures, usually associated with posterior displacement.

Signs and symptoms

The frequency of fatalities at the time of the accident resulting directly from odontoid fractures is unknown, it has been estimated as being between 25–40% of patients with Type II fractures in a review of 7 reports in the literature were neurologically intact, 8% had minor deficits of scalp or limb sensation, and 10% had significant deficit (ranging from monoparesis to quadriplegia). Type III fractures are rarely associated with neurologic injury.

Common symptoms are high posterior cervical pain, sometimes radiating in the distribution of the greater occipital nerve (occipital neuralgia). Almost all patients with high posterior cervical pain will also have paraspinal muscle spasm, reduced range of motion of the neck, and tenderness to palpation over the upper cervical spine. A very suggestive finding is the tendency to support the head with the hands when going between the upright and supine position. Paresthesias in the upper extremities and slight exaggeration of muscle stretch reflexes may also occur. Myelopathy may develop in patients with non-union (p.980).

Classification

The most widely used classification system of Anderson and D’Alonzo is shown in Fig. 64.4 and Table 64.9.

Type I fractures are due to avulsion of the attachment of the alar ligament. They are very rare. Although long considered to be a stable injury, they may not occur as an isolated fracture and may

<table>

be a manifestation of atlanto-occipital dislocation. Also, it may be a marker for possible disruption of the transverse ligament which may result in atlanto-axial instability.

Imaging pearl. A type III odontoid fracture may be misinterpreted as type II on sagittal CT reconstructions because the fracture appears to lie above the VB. Always check the coronal reconstruction which more readily demonstrates the relationship of the fracture to the VB.

Treatment

Practice guidelines
Practice guidelines are shown below. Details appear in the following sections.

**Practice guideline: Management of isolated odontoid fractures**

- **Level II**: isolated Type II odontoid fractures in adults ≥ 50 years age should be considered for surgical stabilization & fusion
- **Level III**
  - Nondisplaced type I, II & III fractures may be managed initially with external cervical immobilization, recognizing that type II odontoid fractures have a higher rate of nonunion
  - Type II & III: consider surgical fixation for:
    - dens displacement ≥ 5 mm
    - or Type IIA fracture (comminution of fracture)
    - or inability to maintain or achieve alignment with external immobilization
  - For surgical intervention, either an anterior or posterior approach may be used

**Immobilization**

For those not meeting surgical indications, 10–12 weeks of immobilization as suggested in Table 64.10 is recommended. There is no Class I medical evidence comparing immobilization options.

Halo vest: fusion rate = 72% appears superior to a SOMI. If a halo is used, obtain supine and upright lateral C-spine x-rays in the halo. If there is movement at the fracture site, then surgical stabilization is recommended.

Rigid collar, fusion rate = 53%.

In patients who are poor surgical candidates, there is theoretical and anecdotal rationale to consider calcitonin therapy (p. 1010) in conjunction with a rigid cervical orthosis.

**Type I**

So rare that meaningful analysis is difficult. If there is associated atlanto-axial instability, surgical fusion may at times be necessary.

**Type II**

General information

Treatment remains controversial. No agreement has been reached after many attempts to identify factors that will predict which type II fractures are most likely to heal with immobilization and
which will require operative fusion. Critical review of the literature reveals a paucity of well designed studies. A wide range of nonunion rates with immobilization alone (5–76%) is quoted: 30% is probably a reasonable estimate for overall nonunion rate, with 10% nonunion rate for those with displacement <6 mm. Possible key factors in predicting nonunion include:

1. degree of displacement: probably the most important factor
   a) some authors feel that displacement >4 mm increases nonunion
   b) some authors use ≥6 mm as the critical value, citing a 70% nonunion rate in these regardless of age or direction of displacement

2. age:
   a) children <7 yrs old almost always heal with immobilization alone
   b) some feel that there is a critical age above which the nonunion rate increases, and the following ages have been cited: age > 40 yrs (possibly doubling the nonunion rate), age > 55 yrs, age > 65 yrs, yet others do not support increasing age as a factor

Indications for surgery for odontoid Type II fractures
Given the above, there can be no hard and fast rules. The following is offered as a guideline (also, above).

Surgical treatment (instead of external immobilization) is recommended for odontoid Type II fractures in patients ≥7 years age with any of the following:

1. displacement ≥5 mm
2. instability at the fracture site in the halo vest (see below)
3. age ≥50 years: increases nonunion rate (with halo) 21-fold
4. nonunion (see Table 64.11 for radiographic criteria) including firm fibrous union, especially if accompanied by myelopathy
5. disruption of the transverse ligament: associated with delayed instability

Surgical options

1. odontoid compression screw (p.1480): appropriate for acute type II fractures with transverse ligament intact and attached
2. C1–2 arthrodesis (p.1479): for options including wiring/fusion, transarticular screws, halifax clamps...

Type IIA
Early surgery is recommended for all type IIA fractures

Type III
<90% heal with external immobilization (and analgesics) if adequately maintained for 8–14 weeks. Halo-vest brace is probably best, fusion rate ∼100% in 1 series. Rigid collar: fusion rate = 50–70% if used, monitor the patient with frequent C-spine x-rays to rule-out nonunion.

Surgical treatment options
See Atlantoaxial fusion (C1–2 arthrodesis) (p.1479) and Anterior odontoid screw fixation (p.1476) for surgical options and operative details.

Nonunion
The radiographic criteria for nonunion are shown in Table 64.11.
The most common symptom of nonunion is continued high posterior cervical pain beyond the time that the brace is removed. Late myelopathy can develop in as many as 77% of mobile nonunions as a result of motion and soft tissue proliferation around the unstable fracture site.

Os odontoideum

General information
A separate bone ossicle of variable size with smooth cortical borders separated from a foreshortened odontoid peg, occasionally may fuse with the clivus. May mimic Type 1 or 2 odontoid fracture. Etiology is debated with evidence to support both of the following (diagnosis & treatment do not depend on which etiologic theory is correct):
1. congenital: developmental anomaly (nonunion of dens to body of axis). However, does not follow known ossification centers and has been demonstrated in 9 patients with previously normal odontoid processes.
2. acquired: postulated to represent an old nonunion fracture or injury to vascular supply of developing odontoid.

True os odontoideum is rare. Ossiculum terminale: nonunion of the apex at the secondary ossification center, is more common.

Two anatomic types:
1. orthotopic: ossicle moves with the anterior arch of C1
2. dystopic: ossicle is functionally fused to the basion. May sublux anterior to the C1 arch

Presentation
Main groups identified in the literature:
1. occipitocervical/neck pain
2. myelopathy: further subdivided
   a) transient myelopathy: common following trauma
   b) static myelopathy
   c) progressive myelopathy
3. intracranial signs or symptoms: from vertebrobasilar ischemia
4. incidental finding

Most patients are neurologically intact and present with atlantoaxial instability which may be discovered incidentally. Many symptomatic and asymptomatic patients have been reported with no new problems over many years of follow-up. Conversely, cases of precipitous spinal cord injury after seemingly minor trauma have been reported.

Evaluation

Practice guideline: Diagnosis of os odontoideum

Level III
- recommended: the following plain C-spine x-rays: AP, open-mouth odontoid, lateral (static & flexion-extension) with or without tomography (CT or plain) and/or MRI of cranio cervical junction

The natural history is variable, and predictive factors for deterioration, especially in asymptomatic patients, have not been identified.
It is critical to R/O C1–2 instability. However, myelopathy does not correlate with the degree of C1–2 instability. An AP canal diameter < 13 mm does correlate with the presence of myelopathy.

Treatment
Regardless of whether os odontoideum is congenital or an old non-union fracture, immobilization is unlikely to result in fusion. Therefore, when treatment is elected, surgery – usually atlantoaxial arthrodesis (p. 1479) – is required.

Practice guideline: Management of os odontoideum

Level III
- patients without neurologic signs or symptoms:
  - may be followed with clinical & radiographic surveillance
  - or posterior C1–2 fusion may be done
- patients with neurologic signs or symptoms or C1–2 instability: posterior C1–2 internal fixation and fusion
- if surgery is done: post-op halo immobilization is recommended (e.g. following posterior wiring & fusion) unless rigid internal instrumentation is used
- for patients with irreducible cervicomедullary compression and/or evidence of associated occipitoatlantal instability: occipital-cervical fusion ± C1 laminectomy
- for patients with irreducible cervicomедullary compression, consider ventral decompression

64.5.5 Miscellaneous C2 fractures
Comprise ≈ 20% of C2 fractures. Includes fractures of spinous process, lamina, facets, lateral mass or C2 vertebral body. Fractures of spinous process or lamina may be treated with Philadelphia collar or cervicothoracic orthosis (CTO). Fractures which compromise the anterior or middle columns (i.e. fractures of facets, C2 body, or lateral mass) requires CTO or halo-vest if nondisplaced, or halo if displaced.

Practice guideline: Management of fractures of the axis (C2) body

Level III:
- fractures may initially be managed with external immobilization in most cases (halo or collar)
- surgical stabilization should be considered in cases of:
  a) severe ligamentous instability
  b) or inability to establish or maintain alignment with external immobilization
- evaluate for vertebral artery injury in cases of comminuted fracture of the axis body

64.6 Combination C1–2 injuries
64.6.1 General information
Combination C1–2 injuries are relatively common and may imply more significant structural and mechanical injury than isolated C1 or C2 fractures. The frequency of C2 fractures in C1–2 combination injuries is shown in Table 64.12. 5–53% of patients with Type II or III odontoid fractures and 6–26% of hangman’s fractures have an associated C1 fracture.

64.6.2 Treatment

**Practice guideline: Treatment of combination atlas and axis fractures**

**Level III**

1. **recommended:** base treatment primarily on the type of C2 injury
2. **recommended:** external immobilization of most C1–C2 fractures
3. **consider surgical stabilization** for these situations. Note: loss of integrity of the C1 ring may necessitate modification of the surgical technique; these injuries are potentially unstable: see Axis (C2) fractures (p. 972):
   a) C1-Type II odontoid combination fractures with an ADI ≥ 5 mm
   b) C1-hangman’s combination fractures with C2–3 angulation ≥ 11°

**Treatment options are summarized in Table 64.13.**

65.1 Classification systems

65.1.1 General information

Various systems have been proposed to help assess stability and/or guide management. The Allen-Ferguson system (p.987) is based on the mechanism of injury. Attempts at quantifying biomechanical stability include the White and Panjabi system (p.987) and the more recent subaxial injury classification (SLIC) (see below). Measurements for spine injuries are based on methods outlined by Bono et al.1

Practice guideline: Subaxial cervical spine injury classification

Level II
- Use the Subaxial Injury Classification (SLIC) and severity scale for SCI (see section 65.1.2)
- Classify the stability and fracture pattern using the Cervical Spine Injury Severity Score (CSISS): the CSISS is somewhat complicated and may be better suited to clinical trials than daily practice (see reference2)

65.1.2 Spine Trauma Study Group subaxial cervical spine injury classification (SLIC)

General information. The subaxial injury classification (SLIC)3 is shown in Table 65.1 and assesses injuries to the disco-ligamentous complex (DLC) in addition to neurologic and bony injuries. Inter-rater reliability intraclass correlation coefficient is 0.71.

DLC integrity. The DLC includes: anterior longitudinal ligament (the strongest component of the anterior DLC), posterior longitudinal ligament, ligamentum flavum, facet capsule (the strongest component of the posterior DLC), interspinous and supraspinous ligaments. The DLC is the hardest SLIC parameter to evaluate. Largely inferred indirectly from MRI findings. Healing is less predictable than bone healing in the adult. More data needs to be accrued before this parameter can be reliably quantified.

Management based on the total SLIC score is shown in Table 65.2.

A given injury can be described using the SLIC as follows:
1. spinal level
2. SLIC morphology (from Table 65.1): use the most severe injury type at this level
3. description of bony injury: e.g. fracture or dislocation of transverse process, pedicle, endplate, superior or inferior articular process, lateral mass...
4. SLIC DLC status (from Table 65.1) with descriptors: e.g. herniated disc...
5. SLIC neurologic status (from Table 65.1)
6. confounders: e.g. presence of ankylosing spondylitis, DISH, osteoporosis, previous surgery, degenerative disease...

### 65.1.3 Cervical spine injury classification on the basis of mechanism of trauma

A modification of the Allen-Ferguson system divides cervical spine fracture/dislocations into 8 major groups based on the dominant loading force and neck position at the time of injury as shown in Table 65.3. Grades of severity within each group are described, and any of these fractures may also be associated with damage from rotatory loads.

Details on some of these fracture types are provided in following sections.

### 65.1.4 Stability model of White and Panjabi

Guidelines for determination of clinical instability (p. 930) of the subaxial cervical spine published by White and Panjabi (p. 314) are shown in Table 65.4. In general, all else being equal, compromise of

a abbreviations: ALL = anterior longitudinal ligament; VB = vertebral body; fx = fracture; numbers in parentheses are page numbers for that topic
b any of the extension injuries may produce SCIWORA in young patients, or central cord syndrome in the presence of stenosis
anterior elements produces more instability in extension, whereas compromise of the posterior elements produces more instability in flexion (important in patient transfers and immobilization). NB: certain conditions such as ankylosing spondylitis (p.1123) may cause an otherwise stable injury to be unstable.

**Stretch test:** The cervical stretch test may be helpful in cases where stability is difficult to determine based on other factors. It may also be useful in detecting instability in cases such as an athlete with no obvious bony or ligamentous disruption. It is performed by applying graduated cervical traction with the patient lying supine on an x-ray table. Serial neurologic exams and lateral radiographs are performed as outlined in the footnote of Table 65.4.

<sup>a</sup>if there is inadequate information for any item, add half of the value for that item to the total

<sup>b</sup>in the C-spine, posterior elements = anatomic components posterior to the posterior longitudinal ligament

<sup>c</sup>stretch test: apply incremental cervical traction loads of 10 lbs q 5 mins up to 33% body wt. (65 lbs max). Check x-ray and neuro exam after each q. Positive if separation > 1.7 mm or angle > 7.5° on x-ray or change in neuro exam. This test is contraindicated if obvious instability

<sup>d</sup>Pavlov ratio = the ratio of (distance from the midlevel of the posterior VB to the closest point on the spinolaminar line): (the AP diameter of the middle of the VB)

<sup>e</sup>e.g. heavy laborers, contact sports athletes, motorcyclists

### 65.2 Clay shoveler’s fracture

Avulsion of spinous processes (usually C7) first described in Perth, Australia (pathomechanics: during the throwing phase of shoveling, clay may stick to the shovel jerking the trapezius and other muscles which are attached to cervical spinous processes).<sup>7</sup> Can also occur with: whiplash injury,<sup>8</sup> injuries that jerk the arms upwards (e.g. catching oneself in falling), neck hyperflexion, or a direct blow to the spinous process.
65.3 Vertical compression injuries

In order to apply a purely compressive force to the cervical spine without flexion or extension, reversal of the normal cervical lordosis is required, as may occur in a slightly flexed posture. Burst fractures are the most common result, with the possibility of retropulsion of bone into the spinal canal with neurologic deficit.

65.4 Flexion injuries of the subaxial cervical spine

65.4.1 General information

Constitute up to 15% of cervical spine trauma. Common causes include: MVAs, falls from a height, and diving into shallow water.

65.4.2 Compression flexion injuries

The classic diving injury is the prototypical example. Posterior element fractures occur in up to 50% of compression flexion injuries. Although flexion-compression injuries do distract the posterior elements to some degree, most do not produce posterior ligamentous injuries. Subtypes of compression-flexion fractures include: teardrop fractures (see below), quadrangular fractures (p.991).

Treatment: mild cervical compression fractures without neurologic deficit or retropulsion of bone into the spinal canal are usually treated with a rigid orthosis until x-rays show healing has occurred (usually 6–12 wks). Stability is assessed with flexion-extension views (p.956) before completely discontinuing the brace. More severe compression fractures heal in a halo brace with ≥ 90% rate of ankylosing fusion.

65.4.3 Teardrop fractures

General information

Originally described by Schneider & Kahn. Results from hyperflexion or axial loading at the vertex of the skull with the neck flexed (eliminating the normal cervical lordosis) (often mistakenly attributed to hyperextension because of the retrolisthesis). Two forces are involved: 1) compression of the anterior column, and 2) tension on DLC. There are varying degrees of severity. In its most severe form, the injury consists of complete disruption of all of the ligaments, the facet joints and the intervertebral disk and ≥ 3 mm of posterior displacement of the body into the canal. As originally described, an important feature is displacement of the inferior margin of the fractured vertebral body posteriorly into the spinal canal. Usually unstable.

Seen in ≈ 5% of patients in a large series of patients with x-ray evidence of cervical spine trauma. Patients are often quadriplegic, although some may be intact and some may have anterior cervical cord syndrome (p.947).

Findings

Possible associated injuries and radiographic findings include:

1. a small chip of bone (the “teardrop”) just beyond the anterior inferior edge of the involved vertebral body (VB) on lateral cervical spine film
2. often associated with a fracture through the sagittal plane of the VB (sagittal split) which can almost always be seen on AP view (may be midline or off-center). Thin cut CT scan is more sensitive
3. a large triangular fragment of the anterior inferior VB
4. other fractures through the vertebral body may also occur
5. the fractured vertebrae is usually displaced posteriorly on the vertebra below (easily appreciated on oblique x-rays, Fig. 65.1). However, cases without retrolisthesis are also described
6. the fractured body is often wedged anteriorly (kyphosis), and may also be wedged possibly laterally
7. disruption of the facet joints which may be appreciated as separation of the joints on lateral x-ray, often unmasked by cervical traction
Distinguishing between teardrop fracture and avulsion fracture

Rationale: Teardrop fractures must be distinguished from a simple avulsion fracture which may also result in a small chip of bone off the anterior inferior VB, usually pulled off by traction of the anterior longitudinal ligament (ALL) in hyperextension. Although there may be disruption of the ALL in these cases, it does not usually cause instability.

Methodology: In a patient with a small bone chip off of the inferior anterior VB, a “teardrop” fracture needs to be ruled-out. Determine if the following criteria are met:

- neurologically intact (because of the need for cooperation, this includes mental status, and excludes the inebriated or concussed patient)
- size of bone fragment is small
- no malalignment of vertebral bodies
- no evidence of VB fracture in sagittal plane on AP C-spine x-rays or on CT
- no posterior element fracture on x-ray or CT
- no prevertebral soft tissue swelling (p.214) at level of fragment
- and no loss of vertebral body height or disc space height

If the above criteria are met, obtain flexion-extension C-spine x-rays (p.956). If no abnormal movement, discharge patient in rigid collar (e.g. Philadelphia collar), and repeat the films in 4–7 days (i.e. after the pain has subsided to be certain that alignment is not being maintained by cervical muscle spasm from pain), D/C collar if 2nd set of films is normal.
If the patient does not meet the above criteria, treat them as an unstable fracture and obtain a CT scan through the fractured vertebra to evaluate for associated fractures (e.g. sagittal plane fracture that may not be apparent on plain x-ray).

MRI assesses the integrity of the disc and gives some information about the posterior ligaments.

65.4.4 Treatment of teardrop fracture
If the disc and ligaments are intact (determined by MRI) then an option is to employ a halo brace until the fragment is healed (perform flexion-extension x-rays after removing the halo to rule-out persistent instability). Alternatively, surgical stabilization may be performed, especially if ligamentous or disc injury is seen on MRI. When the injury is primarily posterior due to disruption of the posterior ligaments and facet joints, and if there is no anterior compromise of the spinal canal, then posterior fusion suffices (p.998). Severe injuries with canal compromise often require a combined anterior decompression and fusion (performed first) followed by posterior fusion using either a modified Böhmman triple-wire technique or lateral mass screws and rods.

65.4.5 Quadrangular fractures
See reference.16

Four features:
1. oblique vertebral body (VB) fracture passing from anterior-superior cortical margin to inferior end plate
2. posterior subluxation of superior VB on the inferior VB
3. angular kyphosis
4. disruption of disc and anterior and posterior ligaments

Treatment:
May require combined anterior and posterior fusion.

65.5 Distraction flexion injuries

65.5.1 General information
Ranges from hyperflexion sprain (mild, see below) to minor subluxation (moderate) to bilateral locked facets (severe, see below). Posterior ligaments are injured early and are usually evidenced by widening of the interspinous distance (p.214).

65.5.2 Hyperflexion sprain
A purely ligamentous injury that involves disruption of the posterior ligamentous complex without bony fracture. May be missed on plain lateral C-spine x-rays if they are obtained in normal alignment; requires flexion-extension views (p.956). Instability may be concealed when films are obtained shortly after the injury if spasm of the cervical paraspinal muscles splints the neck and prevents true flexion.17 For patients with limited flexion, a rigid collar should be prescribed, and if the pain persists 1–2 weeks later the films should be repeated (including flexion-extension).

Radiographic signs of hyperflexion sprain18 (x-rays may also be normal):
1. kyphotic angulation
2. anterior rotation and/or slight (1–3 mm) subluxation
3. anterior narrowing and posterior widening of the disc space
4. increased distance between the posterior cortex of the subluxed vertebral body and the anterior cortex of the articular masses of the subjacent vertebra
5. anterior and superior displacement of the superior facets (causing widening of the facet joint)
6. fanning (abnormal widening) of the interspinous space on lateral C-spine x-ray, or increased interspinous distance on AP; see Interspinous distances (p.214)

65.5.3 Subluxation
Cadaver studies have shown that horizontal subluxation >3.5 mm of one vertebral body on another, or >11° of angulation of one vertebral body relative to the next indicates ligamentous instability19,20 (Table 65.4). Thus, if subluxation of ≥3.5 mm on plain films is seen, and there is no neuro deficit,
obtain flexion-extension films; see Flexion-extension cervical spine x-rays (p. 956). If no abnormal movement, remove cervical collar.

### 65.5.4 Locked facets

#### General information

Severe flexion injuries can result in locked facets (AKA “sprung” facets AKA “jumped” facets) with reversal of the normal “shingled” relationship between facets (normally the inferior facet of the level above is posterior to the superior facet of the level below). Involves disruption of facet capsule. Facets that have not completely locked but have had significant ligamentous disruption allowing distraction just short of the point of locking are known as “perched facets.”

**Flexion + rotation → unilateral locked facets. Hyperflexion → bilateral locked facets.**

#### Unilateral locked facets

25% of patients are neurologically intact, 37% have root deficit, 22% have incomplete cord injuries, and 15% are complete quadriplegics.²¹

#### Bilateral locked facets

Occurs with disruption of ligaments of apophyseal joints, ligamentum flavum, longitudinal and interspinous ligaments, and the annulus. Rare. Most common at C5–6 or C6–7. 65–87% have complete quadriplegia, 13–25% incomplete, ≤10% are intact. Adjacent fractures (VB, facet, lamina, pedicle...) occur in 40–60%.²² Nerve root deficits may also occur.

#### Diagnosis

**Sagittal CT:** usually the optimal manner to identify locked facets.

- C-spine x-rays: both unilateral (ULF) and bilateral locked facets (BLF) will produce subluxation (ULF → rotatory subluxation).
- BLF: usually produces >50% subluxation on lateral C-spine x-ray.
- ULF:
  1. AP: spinous processes above the subluxation rotate to the same side as the locked facet (with respect to those below)
  2. lateral: “bow-tie sign” (visualization of left & right facets at the level of the injury instead of the normal superimposed position²¹). Subluxation may be seen. Disruption of the posterior ligamentous complex may produce widening of the interspace between spinous processes
  3. oblique (Fig. 65.1): may demonstrate the locked facet which will be seen blocking the neural foramen (use ≈ 60° LAO for left locked facet, 60° RAO for right; LAO = left anterior oblique, RAO = right anterior oblique: e.g. with RAO the patient is angled with the right shoulder closer to the film)

**Axial CT:** “naked facet sign”: the articular surface of the facet will be seen with the appropriate articulating mate either absent or on the wrong side of the facet (Fig. 65.2). With ULF, CT also demonstrates the rotation of the level above anteriorly on the level below on the side of the locked facet.

**MRI:** the best test to rule-out traumatic disc herniation (found in 80% of BLF).²³

#### Treatment

**Practice guidelines**

See Practice guideline: Initial closed reduction in fracture/dislocation cervical SCI (p. 958).

**Closed reduction of locked facets**

Contraindicated if traumatic disc herniation is demonstrated on MRI. Patients who cannot be assessed neurologically may be done using SSEP/MEP monitoring. Two methods of closed reduction:

1. traction: more commonly employed in the U.S.
   a) initial weight (in lbs) = 3 × cervical vertebral level, increase in 5–10 lb increments usually at 10–15 minute intervals until desired alignment is attained (assess neurologic exam (or SSEP/MEP) and lateral C-spine x-ray or fluoroscopy after each to avoid overdistraction)
   b) end points (i.e. stop the procedure):
do not exceed 10 lbs per vertebral level (some say 5 lbs/level) under most circumstances. This is a guideline – you are trying to avoid overdistraction at the index level and at normal levels.

- distraction of perched/locked facet or desired reduction is achieved
- if occipitocervical instability develops
- if any disc space height exceeds 10 mm (overdistraction)
- if any neurologic deterioration or deterioration of SSEP/MEP

c) with unilateral locked facets, one may add gentle manual torsion towards the side of the locked facets. With bilateral locked facets, one may add gentle manual posterior tension (e.g. with a rolled towel under the occiput)

d) once the facets are perched or distracted, gradual reduction of the weights will usually result in reduction – verify with x-ray (placing the neck in slight extension, e.g. with small shoulder roll, may help maintain the reduction)

2. manipulation (usually under anesthesia): less commonly employed, more frequently used in Europe. Involves manually applying axial traction and sagittal angulation sometimes with rotation and direct pressure at the fracture level under fluoroscopy

Paraspinal muscle relaxation (but not enough to cause obtundation) may assist in reduction. Use IV diazepam (Valium®) and/or narcotic. General anesthesia may be used in difficult cases (with SSEP/MEP monitoring).

Once reduction is achieved, the patient is left in 5–10 lbs of traction for stabilization.

Disadvantage of closed reduction
1. fails to reduce ≈ 25% of cases of BLF
2. risks overdistraction at higher levels or worsening of other fractures
3. neurologic worsening following closed reduction may occur with traumatic disc herniation and should be evaluated immediately with MRI and if confirmed treated with prompt discectomy
4. adds time and potentially pain to the patient’s care, especially since many will go on to have surgical fusion anyway

Following closed reduction, the need for internal (operative) stabilization vs. external stabilization (i.e. bracing) may be addressed (below).

Open reduction and fixation is usually required if reduction is not achieved. Closed reduction is often more difficult with bilateral locked facets than with unilateral.

Open reduction of locked facets
1. posterior approach: the most common approach. Although rare, still subjects the patient to risk of deterioration from traumatically herniated disc. Therefore a pre-op MRI should be done if
possible. Often requires drilling of the superior aspect of the articular facet of the level below. A foraminotomy is recommended when there are root symptoms to visualize and decompress the root.

2. anterior approach: by removing the disc at the subluxed level and exploring the anterior epidural space, the risk of worsening deficit due to a traumatic herniated disc is theoretically reduced. Reduction may be achieved by adding simultaneous manual traction.

3. combined anterior/posterior (360°) approach: using anterior plate and posterior lateral mass screws/rods eliminates need for post-op external immobilization.

**Stabilization**

Surgical fusion is commonly performed after successful closed reduction, failed closed reduction, or following open reduction.

If there are fracture fragments about the articular surfaces, there may be satisfactory healing with halo vest immobilization (for 3 months) once closed reduction is achieved. Frequent x-rays are needed to rule-out redislocation. Frequent flexion-extension x-rays are obtained upon halo removal and surgery is required for continued instability. Up to 77% of patients with unilateral or bilateral facet dislocation (with or without facet fracture fragments) will have a poor anatomic result with halo vest alone (although late instability was uncommon), suggesting that surgery should be considered for all of these patients. Surgical fusion is more clearly indicated in cases without facet fracture fragments (ligamentous instability alone may not heal) or if open reduction is required.

If surgery is indicated, an MRI should be done beforehand if possible. A posterior approach is preferred if there are no anterior masses (such as traumatic disc herniation or large osteophytic spurs), if subluxation of the bodies is > one-third the VB width (suggesting severe posterior ligamentous injury), or for fractures of the posterior elements. A posterior approach is mandatory if there is an unreducible dislocation. See also Options for posterior approach (p. 998).

**65.6 Extension injuries of the subaxial cervical spine**

**65.6.1 Extension injury without bony injury**

Extension injuries can produce spinal cord injury (SCI) without evidence of bony injury. Injury patterns include central cord syndrome usually in an older adult with cervical spondylosis, and SCIWORA (see below) usually in young children. Middle aged adults with hyperextension dislocations that reduce spontaneously immediately may present with SCI and no bony abnormality on x-ray, but there may be rupture of the anterior longitudinal ligament ALL and/or intervertebral disc on MRI or autopsy. Extension forces may also be associated with carotid artery dissections (p. 1324).

**65.6.2 Minor extension injuries**

Results from extension acting alone. Includes spinous process and lamina fractures. By themselves, are stable.

**65.6.3 Extension compression injury**

This is the most common mechanism of lateral mass/facet fractures (see below).

**65.6.4 Lateral mass and facet fractures of the cervical spine**

**General information**

Often results from extension combined with compression.

**Classification of cervical lateral mass and facet fractures**

4 patterns identified in lateral mass and facet fractures are shown in Table 65.5.

Anterior subluxation of the fractured vertebra was observed in 77% of whole lateral-mass fractures.

**Horizontal facet or separation fracture of the articular mass**

Extension combined with compression and rotation may produce fracture of one pedicle and ipsilateral lamina which permits the detached articular mass (“floating” lateral mass) to rotate forward to
a more horizontal orientation\textsuperscript{29} (horizontalization of the facet) (Table 65.5). May be associated with rupture of the anterior longitudinal ligament (ALL) and fissure of the disc at one or two levels. Neuro deficit is common. Unstable.

**Failure of nonoperative treatment**

A study of CT scans of 26 unilateral cervical facet fractures\textsuperscript{30} identified the risk factors shown below for failure of nonoperative treatment (Fig. 65.3 for illustration of the measurement definitions): where the fracture fragment (FF) height was defined as the maximum tip-to-tip cephalocaudal height on sequential sagittal reconstructions.

Nonoperative management is likely to fail if FF is:

1. $>1$ cm, or
2. $>40\%$ of LM (the height of the intact contralateral lateral mass at the same level, defined as the maximum tip-to-tip cephalocaudal height on sequential sagittal reconstructions)
Surgical treatment of cervical lateral mass and facet fractures

Most cases can be treated with a posterior approach using fixation screws (lateral mass screws or pedicle screws) and rods extending at least 1 level above and below the level of fracture (usually omitting a screw on the side of the fracture at the index level). Simultaneous neural decompression is performed when needed. Additional treatment with an anterior approach may be required for release of rigid deformity or for additional anterior column support. Some separation fractures may be candidates for osteosynthesis (to preserve motion) using a cervical pedicle screw that traverses the fracture.

An anterior approach is an alternative. Advantage: usually only 1 level needs to be fused. Disadvantages: decompression of compressing fragments cannot always be accomplished and requires disrupting an area that may not be compromised (if there is subluxation, the anterior column is probably compromised).

65.7 Treatment of subaxial cervical spine fractures

65.7.1 General information

Practice guideline: Treatment of subaxial cervical spine fractures or dislocations

Level II \(^1\)
- closed or open reduction of subaxial fractures or dislocations with the goal of decompression of the spinal cord and restoration of the spinal canal
- stable immobilization either by internal fixation or by external immobilization to facilitate early patient mobilization and rehabilitation. If surgical treatment is employed, either anterior or posterior fixation is acceptable when a particular approach for decompression of the spinal cord is not required
- treatment with prolonged bed rest in traction if more contemporary treatment options are not available
- for patients with ankylosing spondylitis
65.7.2 Management overview

Management of some specific types of C-spine fractures is covered in the corresponding preceding sections. For injuries not specifically addressed, general management principles are as follows:

1. immobilize and reduce externally (if possible); may use traction × 0–7 days
2. determine if there is an indication for decompression as soon as practical (clinical conditions permitting), and decompress if needed. Although controversial, the following are generally accepted indications for acute decompression in patients without complete spinal cord injury:
   a) radiographic evidence of bone or foreign material in the spinal canal with associated spinal cord symptoms
   b) complete block on CT, myelogram or MRI
   c) clinical judgement: e.g. a progressive incomplete spinal cord injury where the surgeon believes that decompression would be beneficial
3. ascertain stability of the injury (see Table 65.4)
   a) stable fractures: treat in non-halo orthosis for 1–6 weeks (p.935)
   b) unstable fractures: all of the following choices are appropriate, with little evidence (based on long-term spinal stability) to recommend one scheme over another in most cases
   - traction × 7 weeks, followed by orthosis × 8 weeks
   - halo × 11 weeks, followed by orthosis × 4 weeks
   - surgical fusion, followed by orthosis × 15 weeks
   - surgical fusion with internal immobilization (lateral mass screws & rods…) ± orthosis for short period of time (~ several weeks)

65.7.3 Surgical treatment

In patients with complete spinal cord lesions

Operating on a patient with a complete cord injury (ASIA A and not in spinal shock) does not result in significant recovery of neurologic function. If there is ongoing spinal cord compression and the bulbocavernous reflex is absent, the patient may be in spinal shock–operate at the earliest time that is safe to do so at your institution. However, aggressive non-surgical reduction of traumatic subluxation should be pursued.

The primary goal of surgery in this setting is spinal stabilization, allowing the patient to be placed in a sitting position for improved pulmonary function, for psychological benefit, and to allow initiation of rehabilitation. Although the spine will fuse spontaneously in many cases (taking ≈ 8–12 weeks), surgical stabilization expedites the mobilization process and reduces the risk of delayed kyphotic angulation deformity. Early surgery may lead to further neurological injury, and should be delayed until the patient has stabilized medically and neurologically. In most cases, performing surgery within 4–5 days (if the patient is otherwise stable) is probably early enough to help reduce pulmonary complications.

In patients with incomplete lesions

Patients with incomplete cord injuries who have compromise of the spinal canal (by bone, disc, unreducible subluxation or hematoma) and either do not improve with nonoperative therapy or deteriorate neurologically should undergo surgical decompression and stabilization. This may facilitate some further return of spinal cord function. An exception may be the central cord syndrome (p.944).

Anterior or posterior?

The choice of technique depends to a large degree on the mechanism of injury, as the treatment should tend to counteract the instability, and ideally should not compromise structures that are still functioning. Instrumentation (wires/cables, lateral mass screws & rods, clamps…) immobilize the area of instability while bony fusion is occurring. In the absence of bony fusion, all mechanical
devices will eventually fail, and so it becomes a “race” between fusion and instrument failure. Extensive injuries (including teardrop fractures (p.989) and compression burst fractures) may require a combined anterior and posterior approach (staged, or in a single sitting; anterior decompression precedes posterior fusion).

**Posterior immobilization and fusion**

**Indications:** The procedure of choice for most flexion injuries. Useful when there is minimal injury to the vertebral bodies and in the absence of anterior compression of the spinal cord and nerves. Including: posterior ligamentous instability, traumatic subluxation, unilateral or bilateral locked facets, simple wedge compression fractures.

The most common technique consists of open or closed reduction, followed by lateral mass screws & rods (p.972). Interlaminar Halifax clamps are an alternative. Although successes have been reported using methylmethacrylate, it does not bond to bone and weakens with age, and thus its use in the setting of traumatic injury is discouraged.

Choice of posterior technique: If the anterior weight-bearing column is significantly damaged, or if there is absence or compromise of the lamina or spinous processes, then either a combined anterior-posterior approach is needed or posterior rigid instrumentation (e.g. lateral mass screw-plate or rod fixation) with fusion is recommended.

**Anterior approach**

Does not depend on integrity of posterior elements to achieve stability.

**Indications:**
1. fractured vertebral body with bone retropulsed into spinal canal (burst fracture)
2. most extension injuries
3. severe fractures of posterior elements that preclude posterior stabilization and fusion
4. may be used for traumatic subluxation of the cervical spine

Usually consists of:
1. corpectomy: decompresses the neural elements (if necessary) and removes fractured and structurally compromised bone
   a) decompression usually requires wide corpectomy, at least $\approx 16$ mm (palpate anterior surface of vertebral body to determine width; note position of vertebral arteries on pre-op CT). NB: it is suggested to take the corpectomy no wider than $3$ mm lateral to the medial edge of the longus colli muscle, this leaves $\approx 5$ mm margin of safety to the foramen transversarium
   b) if decompression is not needed, $\approx 12$ mm corpectomy suffices (i.e. about the width of a half-inch cottonoid)
2. AND
   a) strut graft fusion: replaces the involved body or bodies with either:
      ● bone (usually iliac crest, rib or fibula, either homologous or cadaveric)
      ● or synthetic cage (e.g. titanium or PEEK)
   b) usually accompanied with compression plates
   c) usually followed with external immobilization
   d) corpectomy of $>1$ level, or presence of injury to posterior elements is usually an indication for augmentation with posterior instrumentation

**Complications of surgical treatment**

1. hardware problems
   a) anterior cage problems
      ● cage displacement/extrusion
      ● cage subsidence/telescoping into endplate
      ● vertebral body fracture
   b) problems with plating
      ● screw pull-out, loosening or breakage
      ● fatigue fracture of plate
      ● screw injury: nerve root, spinal cord or vertebral artery
2. inadequate post-operative immobilization
   a) improper brace selected
   b) poor patient compliance with immobilization device
3. failure of graft to take (nonunion)
4. judgmental error
   a) failure to incorporate all unstable levels
   b) improper surgical approach

65.8 Spinal cord injury without radiographic abnormality (SCIWORA)

65.8.1 General information

Although spinal cord injuries are uncommon in children, there is a subgroup of these in which no radiographic evidence of bony or ligamentous disruption can be demonstrated (including on dynamic flexion-extension x-rays). This is attributed to the normally increased elasticity of the spinous ligaments and paravertebral soft-tissue in the young population and has been dubbed SCIWORA (an acronym for “Spinal Cord Injury Without Radiographic Abnormality”). The age range of children with SCIWORA is 1.5–16 years, it has a much higher incidence in age ≤9 yrs. The spinal cord may undergo contusion, transection, infarction, stretch injuries, or meningeal rupture. Additional etiologies include: blunt abdominal trauma with disruption of blood flow from the aorta or segmental branches, traumatic disc herniation. There may be an increased risk of SCIWORA among young children with asymptomatic Chiari I malformation.

54% of children with SCIWORA had a delay between injury (at which time some children experience transient numbness, paresthesias, Hermitte’s sign, or a feeling of total body weakness) and the onset of objective sensorimotor dysfunction (“latent period”) ranging from 30 minutes to 4 days.

Practice guideline: Diagnosis of SCIWORA

Level III
- MRI of the region of suspected injury
- radiographic screening of entire spine
- assess spinal stability with flexion-extension x-rays in the acute setting and at a late follow-up, even if MRI is negative for extraneural injury

not recommended: spinal angiography or myelography

65.8.2 Radiographic evaluation

In addition to plain films and flexion-extension films (to identify overt instability which would require surgical fusion), should include MRI which may show increased signal within the spinal cord parenchyma on T2WI. There were no intraspinal space occupying lesions in 13 patients studied with myelography/CT.

65.8.3 Management

Practice guideline: Management of SCIWORA

Level III
- external immobilization of the injured spinal segment for up to 12 weeks
- early discontinuation of external immobilization for patients who become asymptomatic and are confirmed to have no instability on flexion-extension x-rays
- avoidance of “high-risk” activities for up to 6 months after SCIWORA

Surgical intervention, including laminectomy, has shown no benefit in the few cases where it has been tried.

Due to a 20% rate of repeat injury (some due to trivial trauma, and some without identifiable trauma) within 10 weeks of the original trauma when treated with only a rigid collar and restriction
of contacts sports (both for 2 months), more aggressive measures were initially recommended (Table 65.6).

66 Thoracic, Lumbar and Sacral Spine Fractures

66.1 Assessment and management of thoracolumbar fractures

66.1.1 General information

A widely used model for thoracolumbar spine stability is the 3-column model of Denis (see below). See also the more recently proposed TLICS system (p. 1006).

66.1.2 Three column model

General information

Denis’ 3 column model of the spine (Fig. 66.1) attempts to identify CT criteria of instability of thoracolumbar spine fractures. This model has generally good predictive value, however, any attempt to create “rules” of instability will have some inherent inaccuracy.

Fig. 66.1 Three column model of the spine (TP = transverse process, see text for other abbreviations) (Adapted from Spine, Denis F, Vol. 8, pp. 317–31, 1983, with permission)
Definitions

- anterior column: anterior half of disc and vertebral body (VB) (includes anterior anulus fibrosus (AF)) plus the anterior longitudinal ligament (ALL)
- middle column: posterior half of disc and vertebral body (includes posterior wall of vertebral body and posterior AF), posterior longitudinal ligament (PLL), & the pedicles
- posterior column: posterior bony complex (posterior arch) with interposed posterior ligamentous complex (supraspinous and interspinous ligament, facet joints and capsule, and ligamentum flavum (LF)). Injury to this column alone does not cause instability

Classification into major and minor injuries

Minor injuries

Involve only a part of a column and do not lead to acute instability (when not accompanied by major injuries). Includes:

1. fracture of transverse process: usually neurologically intact except in two areas:
   a) L4–5 → lumbosacral plexus injuries (there may be associated renal injuries, check U/A for blood)
   b) T1–2 → brachial plexus injuries
2. fracture of articular process or pars interarticularis
3. isolated fractures of the spinous process: in the TL spine: these are usually due to direct trauma. Often difficult to detect on plain x-ray
4. isolated laminar fracture: rare. Should be stable

Major injuries

The McAfee classification describes 6 main types of fractures. A simplified system with four categories follows (also see Table 6.1):

Type 1: Compression fracture: compression failure of anterior column. Middle column intact (unlike the 3 other major injuries below) acting as a fulcrum,
  1. 2 subtypes:
     a) anterior: most common between T6-T8 and T12-L3
        • lateral x-ray: wedging of the VB anteriorly, no loss of height of posterior VB, no subluxation
        • CT: spinal canal intact. Disruption of anterior end-plate
     b) lateral (rare)
  2. clinical: no neurologic deficit

Type 2: Burst fracture: pure axial load → compression of vertebral body → compression failure of anterior and middle columns. Occur mainly at TL junction, usually between T10 and L2
  1. 5 subtypes; L5 burst fractures may constitute a rare subtype (p.1006)
     a) fracture of both end-plates: seen in lower lumbar region (where axial load → increased extension, unlike T-spine where axial load → flexion)
     b) fracture of superior end-plate: the most common burst fracture. Seen at TL junction. Mechanism =axial load + flexion
     c) fracture of inferior end-plate: rare

</table>

adapted1 with permission
d) burst rotation: usually midlumbar. Mechanism = axial load + rotation
e) burst lateral flexion: mechanism = axial load + lateral flexion

2. radiographic evaluation
a) lateral x-ray: cortical fracture of posterior VB wall, loss of posterior VB height, retropulsion of bone fragment from end plate(s) into canal
b) AP x-ray: increase of interpediculate distance (IPD), vertical fracture of lamina, splaying of facet joints: ↑ IPD indicates failure of middle column
c) CT: demonstrates break in posterior wall of VB with retropulsed bone in spinal canal (average: 50% obstruction of canal area), increase in IPD with splaying of posterior arch (including facets)
d) MRI: compromise of anterior canal by bone fragment; possible cord compression usually with fragments occupying >50% of the canal diameter
e) MRI or myelogram: compression in spinal canal

3. clinical: depends on level (thoracic cord more sensitive and less room in canal than conus region), the impact at the time of disruption, and the extent of canal obstruction
a) ≈ 50% intact at initial examination (half of these recalled leg numbness, tingling, and/or weakness initially after trauma that subsided)
b) of patients with deficits, only 5% had complete paraplegia

Type 3: Seat-belt fracture (some call this a flexion-distraction fracture, but that term is also used for a subtype of fracture-dislocation): flexion across a fulcrum anterior to the anterior column (e.g. seat belt) → compression of anterior column & distraction failure of both middle and posterior columns. May be bony or ligamentous
1. 4 subtypes
a) Chance fracture (named for G. Q. Chance, 1948): one level, totally through bone
b) one level, through ligaments
c) two level, through bone in middle column, through ligament in anterior and posterior columns
d) two level, through ligament in all 3 columns
2. radiographic evaluation
a) plain x-ray: ↑ interspinous distance, pars interarticularis fractures, and horizontal split of pedicles and transverse process. No subluxation
b) CT: axial cuts are poor for this type (most of fracture is in plane of axial CT cuts). Sagittal and coronal reconstructions demonstrate well. May demonstrate pars fracture
3. clinical: no neurologic deficit

Type 4: Fracture-dislocation: failure of all 3 columns due to compression, tension, rotation or shear → subluxation or dislocation
1. x-ray: occasionally, may be reduced when imaged. Look for other markers of significant trauma (multiple rib fractures, unilateral articular process fractures, spinous process fractures, horizontal laminar fractures)
2. 3 subtypes
a) flexion rotation: posterior and middle columns totally ruptured, anteriorly compressed → anterior wedging
   • lateral x-ray: subluxation or dislocation. Preserved posterior VB wall. Increased interspinous distance
   • CT: rotation and offset of VBs with → canal diameter. Jumped facets
   • clinical: 25% neurologically intact. 50% of those with deficits were complete paraplegics
b) shear: all 3 columns disrupted (including ALL)
   • when trauma force directed posteriorly to anteriorly (more common) VB above shears forward fracturing the posterior arch (→ free floating lamina) and the superior facet of the inferior vertebra
   • clinical: all 7 cases were complete paraplegics
c) flexion distraction
   • radiographically resemble seat-belt type with addition of subluxation, or with compression of anterior column >10–20%
   • clinical: neurologic deficit (incomplete in 3 cases, complete in 1)

Associated injuries
In addition to the above, associated injuries include: vertebral end-plate avulsion, ligamentous injuries, and hip and pelvic fractures. Thoracolumbar fractures may be associated with hemodynamic
instability as a result of hemothorax or aortic injury. Fractures of the transverse processes may be associated with abdominal trauma (e.g. renal injuries at L4–5).

**Stability and treatment of thoracolumbar spine fractures**

**Minor injuries**

Isolated thoracolumbar transverse process fractures (as demonstrated on spinal CT) do not require intervention or consultation of a spine service.3,4

**Major spine injuries**

Denis categorized the instability as:
- 1st degree: mechanical instability
- 2nd degree: neurological instability
- 3rd degree: both mechanical & neurological instability

**Anterior column injury**

Isolated anterior column injuries are usually stable and are treated as outlined in Table 66.2. The following exceptions may be unstable (1st degree) and often require surgery:

**Unstable compression fractures**

1. a single compression fracture with:
   - a) loss of >50% of height with angulation (particularly if the anterior part of the wedge comes to a point)
   - b) excessive kyphotic angulation at one segment (various criteria are used, none are absolute. Values quoted: >30°, >40°)
2. 3 or more contiguous compression fractures
3. neurologic deficit (generally does not occur with pure compression fracture)
4. disrupted posterior column or more than minimal middle column failure
5. progressive kyphosis: risk of progressive kyphosis is increased when loss of height of anterior vertebral body is >75%. Risk is higher for lumbar compression fractures than thoracic

**Middle column failure**

These are unstable (often requiring surgery) with the following exceptions which should be stable (stable injuries may be treated as outlined in Table 66.2).

**Stable middle column fractures**

- above T8 if the ribs and sternum are intact (provides anterior stabilization)
- below L4 if the posterior elements are intact
- Chance fracture (anterior column compression, middle column distraction)
- anterior column disruption with minimal middle column failure

**Posterior column disruption**

Not acutely unstable unless accompanied by failure of the middle column (posterior longitudinal ligament and posterior anulus fibrosus). However, chronic instability with kyphotic deformity may develop (especially in children).

**Seat-belt type injuries without neurologic deficit**

No immediate danger of neurologic injury. Treat most with external immobilization in extension (e.g. Jewett hyperextension brace or molded TLSO).

---

**Table 66.2 Treatment of stable anterior or middle column thoracolumbar spine injuries**

- treat initially with analgesics and recumbency (bed-rest) for comfort × 1–3 weeks
- diminution of pain is a good indication to commence mobilization with or without external immobilization (corset or Boston brace or extension TLSO × 12 weeks) depending on the degree of kyphosis
- vertebroplasty (± kyphoplasty) may be an option (p. 1011)
- serial x-rays to rule-out progressive deformity
Fracture-dislocation

Unstable. Treatment options:
1. surgical decompression and stabilization: usually needed in cases with
   a) compression with >50% loss of height with angulation
   b) or, kyphotic angulation >40° (or >25%)
   c) or, neurologic deficit
   d) or, desire to shorten length of time of bedrest
2. prolonged bedrest: an option if none of the above are present

When vertebral body resection (vertebral corpectomy) is performed, options to access: transthoracic or transabdominal approach (or combined), transpedicular (for thoracic spine), lateral (retroperitoneal/retropleural) approach. Fracture and compression usually occurs at the superior margin of vertebral body, thus start resection at the inferior disc interspace. Followed by strut graft (cage or bone: iliac crest or fibula or tibia). Posterior instrumentation is usually required; see Spinal instrumentation (p.1007).

Burst fractures

Not all burst fractures are alike. Some burst fractures may eventually cause neurologic deficit (even if no deficit initially). Middle column fragments in canal endanger the neuro elements. Criteria have been proposed to differentiate mild burst fractures from severe ones. No system is uniformly accepted. Recommendations:1,6

Surgical indications for burst fractures: burst fracture with any of the following:
• anterior vertebral body height \(\leq 50\%\) of the posterior height
• residual canal diameter \(\leq 50\%\) of normal (note: retropulsed bone in the canal is often resorbed with either bracing or surgery and is therefore controversial as an isolated indication for surgery7, 8)
• kyphotic angulation \(\geq 20°\)
• when the increased interpediculate distance usually present on the initial film widens further on AP x-ray when standing in brace/cast
• neurologic deficit (incomplete)
• progressive kyphosis

Common surgical options for burst or severe compression fractures:
1. If instrumentation alone is needed
   a) can place pedicle screws in 2 levels above and 2 levels below the fracture
   b) if the index level can be included (i.e. if the pedicles are intact enough to accept shorter screws), similar biomechanical stability can be achieved by placing screws at the index level (the fractured level) and then just 1 above and 1 below9
2. If decompression of the spinal canal and/or anterior support is needed, corpectomy and strut graft (e.g. with expandable cage) with percutaneous pedicle screws may be used. Approaches:
   a) from posterior approach e.g. laminectomy with transpedicular approach and impacting bone anteriorly out of canal with a mallet and reverse angled Scoville curette, or
   b) lateral corpectomy and removal of bone from canal

For those not undergoing surgery (i.e. when surgery is not required or is contraindicated), an option is to treat with recumbency from 1–6 weeks (the duration depending on pain and degree of deformity).6 Avoid early ambulation → further axial loading (even in cast). When appropriate, begin ambulation in an orthosis (e.g. molded thoracolumbar sacral orthosis (TLSO) or a Jewett brace) and follow patient for 3–5 months with serial x-rays to detect progressive collapse or angulation which may need further intervention. L5 burst fractures may be an exception to the usual management (see below).

66.1.3 Thoracolumbar injury classification and severity score (TLICS)

The TLICS system has been proposed to simplify classification and discussion of thoracolumbar fractures.10,11 Points are assigned as shown in Table 66.3. The scores are summed, and management guidelines are given in Table 66.4.

Neurologic deficit, especially when partial, favors surgery.
66.2 Surgical treatment

66.2.1 Ligamentotaxis

May work with fragments retropulsed into the anterior canal if the PLL is intact (may not be the case with middle column failure), distraction may be able to “pull” the fragments back into their normal position (ligamentotaxis) although this is not assured. Ligamentotaxis has a better chance of succeeding if performed within 48 hours of injury. From a posterior approach with laminectomy: intra-operative ultrasound may demonstrate residual canal fragments, and if needed the fragments may be impacted anteriorly out of the canal, e.g. using tamps such as Sypert spinal impactors. It is important not to overdistract to avoid neural injury.

66.2.2 Choice of surgical approach

The posterior approach is preferred when there is not a specific need to go from the front.

66.2.3 Spinal instrumentation

Anterior instrumentation of the lower lumbar spine is difficult, and is usually not recommended below ≈ L4.

66.2.4 Burst fractures

Choice of approach

Surgical considerations: a posterior approach is preferred if there is a dural tear, whereas a burst fracture with partial deficit and canal compromise may be treated more effectively from an anterior approach. A small progression in angular deformity may occur when posterior stabilization is performed alone (since the injury to the anterior column is not corrected), but by itself usually does not require intervention.

For a posterior approach

In ideal situation (good bone quality, pedicle screw placement goes well (i.e. no fracture, no breach), and non-smoking patient) then one can fuse/rod one above and one below the fracture (using pedicle screws; longer constructs are needed with laminar hooks). With a short segment fusion like this, approximately 10° of lordosis be lost with time, therefore, one should try to overcorrect a little to accommodate the anticipated settling. If the patient does not meet the above criteria (e.g. poor bone quality), an option is to “rod long, fuse short” (e.g. rod 2 levels above and below the fracture but fuse only 1 level above and below) and then to remove the hardware when the fusion is solid (e.g. at 8–12 months) – this avoids fusing a nonpathologic segment just to get a better anchor. Junctional deterioration to the point that further surgery is needed often occurs at 3 years when 4 segments are fused, whereas it occurs at 8–9 years when only 3 levels are fused. Fusing across critical levels (i.e. thoracolumbar junction with T11 or L1 compression fractures) requires that the fusion incorporate 2–3 levels on each side of the junction (the forces of the long segment of the relatively immobile thoracic spine with the lumbar spine at the T-L junction increase the risk of nonunion).

For thoracic fractures that are not severe and do not require decompression, an option is to place pedicle screws and rods (which can be done percutaneously) without placing any graft. The concept is that the ribs anteriorly and the screws/rods posteriorly provide adequate stabilization while the fractured VB heals. The hardware can be removed electively once the fusion is solid (usually at 8–12 months). This is more commonly practiced in Europe than the U.S.

66.2.5 Wound infections

Postoperative wound infections with spinal instrumentation are usually due to Staph. aureus. With titanium hardware it may respond to debridement of devitalized tissue (e.g. onlay bone graft) and thorough washout (typically with 3 L of antibiotic irrigation flushed into the wound using a pulse lavage device – avoiding direct irrigation of any exposed dura) without removal of instrumentation, followed by antibiotics. Persistent infection may respond to. If this inadequate, removal of instrumentation may occasionally be required.

66.3 Osteoporotic spine fractures

66.3.1 General information

Osteoporosis is defined as a condition of skeletal fragility as a result of low bone mass, microarchitectural deterioration of bone, or both. It is found most commonly in post-menopausal white females, and is rare prior to menopause. Lifetime risk of symptomatic vertebral body (VB) osteoporotic compression fractures is 16% for women, and 5% for men. There are ≈ 700,000 VB compression fractures per year in the U.S.

These patients are often found to have significant VB compression fractures on plain films after presenting with back pain following a seemingly minor fall. CT often shows an impressive appearing amount of bone retropulsed into the canal.

66.3.2 Risk factors

Factors that increase the risk of osteoporosis include:

1. weight < 58 kg
2. cigarette smoking
3. low-trauma VB fracture in the patient or a first degree relative
4. drugs
   a) heavy alcohol consumption
   b) AEDs (especially phenytoin)
Factors that protect against osteoporosis include impact exercise and excess body fat.

### 66.3.3 Diagnostic considerations

To differentiate osteoporotic compression fractures from other pathologic fractures, see Pathologic fractures of the spine (p.1391).

#### Pre-fracture diagnosis

1. measuring bone fragility is not possible
2. the best correlate with bone fragility is radiographic measurement of bone mineral density (BMD) using DEXA scan (see below)
3. patients with low-trauma fractures or fragility fractures are considered osteoporotic even if their BMD are greater than these cutoffs

**DEXA scan (dual energy x-ray absorptiometry): the preferred way to measure BMD**

1. proximal femur: BMD measurement in this location is the best predictor for future fractures
2. L1 spine: best location to assess response to treatment (need AP and lateral views, since AP often overestimates BMD because of superimposition of overlying posterior elements and aortic calcifications)
3. forearm BMD may be used if hip or spine are unsuitable

**Interpretation of DEXA scan results:**

1. findings are reported as
   a) T-score: norms for healthy young adults
   b) Z-score: norms of subjects of same age and sex as the patient
2. diagnostic criteria: WHO definitions (with a normal distribution 1 SD below the mean is the lowest 25th percentile, 2 SD below is 2.5th percentile)
   a) normal: > –1 standard deviations (SD)
   b) osteopenia: from –1 to –2.5 SD
   c) osteoporosis: < than –2.5 SD

**Post-fracture considerations**

1. other causes of pathologic fracture, especially neoplastic (e.g. multiple myeloma, metastatic breast cancer) should be ruled out

2. Younger patients with osteoporosis require evaluation for a remediable cause of the osteoporosis (hyperthyroidism, steroid abuse, hyperparathyroidism, osteomalacia, Cushing’s syndrome).

### 66.3.4 Treatment

See references 18, 19, 20, 21

#### Prevention of osteoporosis

High calcium intake during childhood may increase peak bone mass. Weight-bearing exercise in adulthood helps slow calcium loss from bones. Also effective: estrogen (see below), bisphosphonates (alendronate and risedronate), and raloxifene.

#### Treating established osteoporosis

Drugs that increase bone formation include:

1. Intermittent low-dose parathyroid hormone: still experimental
2. Sodium fluoride: 75 mg/d increases bone mass but did not significantly reduce the fracture rate. 25 mg PO BID of a delayed-release formulation (Slow Fluoride®) reduced fracture rate but may make bone more fragile and could increase risk of hip fractures. Fluoride increases demand for Ca++, therefore supplement with 800 mg/d Ca++ and 400 IU/d vitamin D. Not recommended for use >2 yrs

Drugs that reduce bone resorption are less effective on cancellous bone (found mainly in the spine and at the end of long bones). Improvement in spine bone mineral density accounts for only a small part of the observed reduction in the risk of vertebral fracture. Medications include:

1. Estrogen: cannot be used in men. Studies of estrogen hormone replacement therapy (HRT) have shown increased vertebral bone mass by >5% and decreased rate of vertebral fractures by 50%. Also relieves post-menopausal symptoms and reduces risk of CAD. However, because HRT increases the risk of breast cancer and of breast cancer recurrence as well as DVT, its use has diminished substantially.
2. Calcium: current recommendation for postmenopausal women: 1,000-1,500 mg/d taken with meals. 3. Vitamin D or analogues: promote calcium absorption from the GI tract. Typically administered with calcium therapy (either calcium or vitamin D alone are less effective). Vitamin D 400–800 IU/d is usually sufficient. If urinary Ca++ remains low, high dose vitamin D (50,000 IU q 7-10 d) may be tried. Since high-dose formulations have been discontinued in the U.S., analogues such as calcifediol (Calderol®) 50 mcg/d or calcitriol (Rocaltril®) up to 0.25 mcg/d may be tried with Ca++ supplement. Serum levels of 25-hydroxyvitamin D [25(OH)D], AKA calcidiol is the best indicator of vitamin D status. The significance of vitamin D levels are shown in Table 66.5. With high dose vitamin D or analogues, monitor serum and urinary Ca++
4. Calcitonin: a hormone synthesized by the thyroid gland which decreases bone resorption by osteoclasts. May be derived from a number of sources, salmon is one of the more common ones. The skeletal response is maximal during the first 18–24 months of therapy. Benefit in preventing fractures is less well established.
   a) Parenteral salmon calcitonin (Calcimar®, Miacalcin®): indicated for patients for whom estrogen is contraindicated. Expensive ($1,500–3,000/yr) and must be given IM or sub-Q. 30–60% of patients develop antibodies to the drug which negates its effect. 0.5 ml (100 U) of calcitonin (given with calcium supplements to prevent hyperparathyroidism) SQ q d
   b) Intranasal forms (Miacalcin nasal spray): less potent (works better in older women >5 yrs post menopause). 200–400 IU/d given in one nostril (alternate nostrils daily) plus Ca++ 500 mg/d and vitamin D
5. Bisphosphonates: carbon-substituted analogues of pyrophosphate have a high affinity for bone and inhibit bone resorption by destroying osteoclasts. Not metabolized. Remain bound to bone for several weeks
   a) Etidronate (Didrolce®), a 1st generation drug. Not FDA approved for osteoporosis. May reduce rate of VB fractures, not confirmed on F/U. Possible increased risk of hip fractures due to inhibition of bone mineralization may not occur with 2nd & 3rd generation drugs listed below. 400 mg PO daily × 2 wks followed by 11–13 weeks of Ca++ supplementation
   b) Alendronate (Fosamax®): can cause esophageal ulcers. Prevention: 5 mg PO daily; treatment 10 mg PO daily; taken upright with water on an empty stomach at least 30 minutes before eating or drinking anything else. Once weekly dosing of 35 mg for prevention and 70 mg for treatment. Taken concurrently with 1000–1500 mg/d Ca++ and 400/d IU of vitamin D.
c) risedronate (Actonel®): Prevention or treatment: 5 mg PO daily, or 35 mg once/week on an empty stomach (as for alendronate, see above)

6. estrogen analogues:
   a) tamoxifen (Nolvadex®), an estrogen antagonist for breast tissue but an estrogen agonist for bone, has a partial agonist effect on uterus associated with an increased incidence of endometrial cancer
   b) raloxifène (Evista®): similar to tamoxifen but is an estrogen antagonist for uterus. Decreases the effect of warfarin (Coumadin®).
      : 60 mg PO q d. Supplied: 60 mg tablets

7. RANK ligand (RANKL) inhibitors: RANKL binds to RANK receptors and stimulates precursor cells to mature into osteoclasts and inhibits their apoptosis. Agents undergoing investigation include denosumab (Prolia®) 60 mg SQ q 6 months appears more effective than alendronate.

Treatment of osteoporotic vertebral compression fractures

Patients rarely have neurologic deficit. They are also usually fragile elderly women who usually do not tolerate large surgical procedures well, and the rest of their bones are also osteoporotic which are poor for internal fixation.

Management consists primarily of analgesics and bed rest followed by progressive mobilization, often in an external brace (often not tolerated well). Surgery is rarely employed. In cases where pain control is difficult to obtain or where neural compression causes deficit, limited bony decompression may be considered. Percutaneous vertebroplasty (see below) is a newer option.

Typical time course of conservative treatment:
1. initially, severe pain may require hospital or subacute care facility admission for adequate pain control utilizing
   a) sufficient pain medication
   b) bed rest for about 7–10 days (DVT prophylaxis recommended)
2. begin physical therapy (PT) after ≈7–10 days as patient tolerates (prolonged bed rest can promote “disuse osteoporosis”)
   a) pain control as patient is mobilized may be enhanced by a lumbar brace which may work by reducing movement which causes repetitive “microfractures”
   b) discharge from the hospital with lumbar brace for outpatient PT
3. pain subsides on the average after 4–6 weeks (range 2–12 weeks)

Vertebral body augmentation

Percutaneous vertebroplasty (PVP)

Transpedicular injection of polymethylmethacrylate (PMMA) AKA “methylmethacrylate cement” into the compressed bone with the following goals (note: PMMA injection is FDA approved for treatment of compression fractures due to osteoporosis or tumor, but not for trauma as PMMA would prevent healing of the fracture):
1. to shorten the duration of pain (sometimes providing pain relief within minutes to hours).
   Remember: the natural history is that pain will eventually diminish in essentially all of these patients. Mechanism of pain relief may be due to stabilization of bone and/or due to disruption of nerve pain transmission by heat released during the exothermic curing of the cement
2. to try and stabilize the bone: may prevent progression of kyphosis

Randomized studies published in 2009 found no benefit in vertebroplasty over a sham procedure at 1 month or at any time up to 6 months post-procedure. NB: kyphoplasty (see below) was not studied; use with metastatic spine tumors was also not evaluated. Patient selection issues may make these results more or less applicable to a specific patient.

Kyphoplasty

Similar to PVP, except first, a balloon is inserted into the compressed VB through the pedicle. The balloon is inflated and then deflated and removed. PMMA is injected into the thusly created defect. Potential benefits of this over vertebroplasty: there may be some restoration of height, and there may be less tendency for PMMA extravasation/embolization (due to the cavity creation and the thicker PMMA used). In the (industry sponsored) randomized non-blinded FREE study there was a significant positive difference in pain reduction and quality of life improvement in the kyphoplasty group compared to the nonoperated group at 1 month that diminished by 1-year post-op.
Indications
1. painful osteoporotic compression fractures:
   a) usually do not treat fractures producing <5–10% loss of height
   b) severe pain that interferes with patient activity
   c) failure to adequately control pain with oral pain medication
   d) pain localized to fracture level
   e) acute fractures: procedure is not effective for healed fractures. In questionable cases, look for changes on STIR MRI (see below)
2. levels: FDA approved for use from T5 through L5, however has been used off-label (primarily for tumor, e.g. multiple myeloma) from T1 through sacrum, and has been described (for tumor) in the cervical spine from an anterior approach
3. vertebral hemangiomas that cause vertebral collapse or neurologic deficit as a result of extension into the spinal canal (not for incidental hemangiomas) (p.795): the first indication for PVP
4. osteolytic metastases and multiple myeloma: pain relief and stabilization
5. pathologic compression fractures from metastases: PVP does not give as rapid pain relief as with osteoporotic compression fractures (it may actually be necessary to increase pain meds for 7–10 days post PVP)
6. pedicle screw salvage when pedicle fractures or screws strip during pedicle screw placement

Contraindications
1. coagulopathy
2. completely healed fractures (no edema on MRI or cold on bone scan)
3. active infections: sepsis, osteomyelitis, discitis and epidural abscess
4. spinal instability
5. focal neurologic exam: may indicate herniated disc, retropulsed fragment in canal. Get CT or MRI to rule these out
6. relative contraindications:
   a) fractures >80% loss of VB height (technically challenging)
   b) acute burst fractures
   c) significant canal compromise from tumor or retropulsed bone
   d) partial or total destruction of the posterior VB wall: not an absolute contraindication
7. iodine allergy: there is a small risk of a balloon rupturing with spill of the iodinated contrast used to fill the balloons prior to injecting the PMMA. Options include: iodine allergy prep (p.221), use of gadolinium instead of iodinated contrast

Complications
Complication rate: 1–9%. Lowest when used to treat osteoporotic compression fractures, higher with vertebral hemangiomas, highest with pathological fractures
1. methacrylate leakage:
   a) into soft tissues: usually of little consequence
   b) into spinal canal: symptomatic spinal cord compression is very rare
   c) into neural foramen: may cause radiculopathy
   d) into disc space
   e) venous: can get into spinal venous plexus or vena cava with risk of clinically significant methacrylate pulmonary embolism (PE)
2. radiculopathy: 5–7% incidence. Some cases may be due to heat released during cement curing. Often treated conservatively: steroids, pain meds, nerve block...
3. pedicle fracture
4. rib fracture
5. transverse process fracture
6. anterior penetration with needle: puncture of great vessels, pneumothorax...
7. increased incidence of future VB compression fractures at adjacent levels

Management of some associated developments
1. chest pain
   a) get rib x-rays
   b) VQ scan if indicated
2. patient starts coughing during injection: fairly common. May be reaction to rib pain or to odor of PMMA, may also indicate solvent in lungs. Stop injecting
3. back pain: take x-ray to rule-out new fracture or PMMA in veins
4. neurologic symptoms: get CT scan
Pre-procedure evaluation
1. plain x-rays: minimum requirement, most practitioners get MRI or bone scan
2. CT: helps rule-out bony compromise of spinal canal which may indicate increased risk of leakage for PMMA into canal during procedure
3. MRI: not mandatory, may be helpful in some cases
   a) short tau inversion recovery (STIR) images demonstrate bone edema indicative of acute fractures (not as good for differentiating pathology)\textsuperscript{37}
   b) MRI can also disclose neurologic compression by soft tissue (e.g. tumor)
4. patients with multiple compression fractures: consider getting bone scan and perform PVP in the VB near the level of pain that lights up the most (↑ activity on bone scan correlates strongly with good outcome from PVP)

Booking the case: Kyphoplasty

Also see default values (p. 27).
1. position: prone
2. anesthesia: may be done under general, or under MAC
3. equipment: 2 C-arms for bi-plane fluoro
4. implants:
   a) kyphoplasty set
   b) iodinated contrast from radiology to fill balloons
5. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: insertion of a needle into the fractured/abnormal bone, sometimes getting a biopsy as well, and then inflating a balloon in the bone to try and bring it back to a more normal size and then to inject a liquid cement which will then harden inside the bone to strengthen it
   b) alternatives: nonsurgical management, open surgery, in cases of tumor sometimes radiation therapy can be done
   c) complications: leakage of cement which can compress nerves and may need to be removed surgically if possible, rib fracture (from positioning), injury to large blood vessel or lung by the needle, failure to achieve the desired pain relief

Procedure
1. pain medication
   a) remember, this procedure is done with the patient lying on their stomach and is usually performed on frail, elderly females who smoke. Therefore use caution to avoid oversedation and respiratory compromise
   b) sedation and pain medication
   c) use of local anesthetic during needle placement
   d) additional pain medication just prior to injection
2. use bi-plane fluoro to pass needle through the pedicle to enter VB – see Percutaneous pedicle screws (p. 1495) – and place tip ≈ 1/2 to 2/3 of the way through the VB
3. test inject with contrast, e.g. iohexol (Omnipaque 300) (p. 219); do digital subtraction study if equipment is available. For kyphoplasty, the balloon is inflated at this time
   a) a little venous enhancement is acceptable
   b) if you visualize vena cava
      • do not pull needle back (the fistula has already been created)
      • push needle in a little further, or
      • push some gelfoam (soaked in contrast) through the needle, or
      • inject a very small amount of PMMA under visualization and allow it to set to block the fistula
4. inject PMMA (that has been opacified with tantalum or barium-sulfate) under fluoroscopic visualization until:
   a) 3–5 cc injected (minimal compression fractures accept more cement, sometimes up to ≈ 8 cc). No correlation between amount of PMMA injected and pain relief\textsuperscript{84}
   b) PMMA approaches posterior VB wall. Stop if cement ever: enters disc space, vena cava, pedicle, or spinal canal
Post-procedure
1. PVP is often an outpatient procedure, but sometimes overnight admission is used
2. watch for
   a) chest or back pain (may indicate rib fracture)
   b) fever: may be reaction to cement
   c) neurologic symptoms
3. activity
   a) gradual mobilization after ≈ 2 hours
   b) ± physical therapy
   c) ± short term use of external brace (most centers do not use)
4. institute medical treatment for osteoporosis: remember the patient with fragility fractures by
   definition has osteoporosis with risk of future fractures

66.4 Sacral fractures

66.4.1 General information
Uncommon. Usually caused by shear forces. Identified in 17% of patients with pelvic fractures (keep in mind that neurologic deficits in patients with pelvic fractures may be due to associated sacral fractures). Neurologic injuries occur in 22–60%.

The sacrum below S2 is not essential to ambulation or support of the spinal column, but may still be unstable since pressure to the area may occur when supine or sitting.

66.4.2 Classification
Three characteristic clinical presentations based on zone of involvement as shown in Table 66.6.

Table 66.6 Classification of sacral fractures

<table>
<thead>
<tr>
<th>Zone I</th>
<th>Zone II</th>
<th>Zone III Vertical</th>
<th>Zone III Transverse</th>
</tr>
</thead>
</table>
| Zone I: Region of ala sparing the central canal and neural foramina. Occasionally associated with partial L5 root injury possibly as a result of entrapment of the L5 root between the upwardly migrated fracture fragment and the transverse process of the L5 vertebra. | Zone II: Region of sacral foramina (sparing the central canal). A vertical fracture which may be associated with unilateral L5, S1 and/or S2 nerve root involvement (producing sciatica). Bladder dysfunction is rare. | Zone III: Region of sacral canal. Frequently associated with sphincter dysfunction (occurs only with bilateral root injuries) and saddle anesthesia. Subdivided:
Vertical: almost always associated with pelvic ring fracture
Transverse (horizontal): rare. Often due to a direct blow to the sacrum as in a fall from a great height. Marked displacement of fracture fragment can produce severe deficit (bowel & bladder incontinence). |

*significant deficit is rare in fractures at or below S4
66.4.3 Treatment

In one series, all 35 fractures were treated without surgery, and only 1 patient with a complete cauda equina syndrome did not improve. Others feel that surgery may have a useful role:

1. operative reduction and internal fixation of unstable fractures may aid in pain control and promote early ambulation
2. decompression and/or surgical reduction/fxation may possibly improve radicular or sphincter deficits

Some observations:

1. reduction of the ala may promote L5 recovery with Zone I fractures
2. Zone II fractures with neurologic involvement may recover with or without surgical reduction and fixation
3. horizontal Zone III with severe deficit: controversial. Reduction & decompression does not ensure recovery, which may occur with nonoperative management

References

67 Penetrating Spine Injuries and Long Term Management / Complications

67.1 Gunshot wounds to the spine

67.1.1 General information
Most are due to assaults with handguns. Distribution: cervical 19–37%, thoracic 48–64%, and lumbo-sacral 10–29% (roughly proportional to lengths of each segment). Spinal cord injury due to civilian GSWs are primarily due to direct injury from the bullet (unlike military weapons which may create injury from shock waves and cavitation). Steroids are not indicated (p.951).

67.1.2 Indications for surgery
1. injury to the cauda equina (whether complete or incomplete) if nerve root compression is demonstrated
2. neurologic deterioration: suggesting possibility of spinal epidural hematoma
3. compression of a nerve root
4. CSF leak
5. spinal instability: very rare with isolated GSW to the spine
6. to remove a copper jacketed bullet: copper can cause intense local reaction
7. incomplete lesions: very controversial. Some series show improvement with surgery, others show no difference from unoperated patients
8. debridement to reduce the risk of infection: more important for military GSW where there is massive tissue injury, not an issue for most civilian GSW except in cases where the bullet has traversed GI or respiratory tract
9. vascular injuries
10. surgery for late complications:
   a) migrating bullet
   b) lead toxicity (plumbism): absorption of lead from a bullet occurs only when it lodges in joints, bursae, or disc space. Findings include: anemia, encephalopathy, motor neuropathy, nephropathy, abdominal colic
   c) late spinal instability: especially after surgery

67.2 Penetrating trauma to the neck

67.2.1 General information
Most often, injuries to the soft-tissues of the neck fall into the purview of general/trauma surgeons and/or vascular surgeons. However, depending on local practice patterns, neurosurgeons may participate in care of these injuries, or they may get involved by virtue of associated spinal injuries (p.1017). The mortality rate for penetrating injury to the neck is ≈ 15% with most early deaths due either to asphyxiation from airway compromise, or exsanguination externally or into the chest or upper airways. Late death is usually due to cerebral ischemia or complications from spinal cord injury.

67.2.2 Vascular injuries
Venous injuries occur in ≈ 18% of penetrating neck wounds, and arterial injuries in ≈ 12%. Of the cervical arteries, the common carotid is most usually involved, followed by the ICA, the ECA, and then the vertebral artery. Outcome probably correlates most closely with neurologic condition on admission, regardless of treatment.

Vertebral artery (VA): the majority of injuries are penetrating. Due to the proximity of other vessels, the spinal cord and nerve roots, injuries are rarely isolated to the VA. 72% of documented VA injuries had no related physical findings on exam.
67.2.3 Classification
Trauma surgeons have traditionally divided penetrating injuries of the neck into 3 zones, and although definitions vary, the following is a general scheme:
- Zone I: inferiorly from the head of the clavicle to include the thoracic outlet
- Zone II: from the clavicle to the angle of the mandible
- Zone III: from the angle of the mandible to the base of the skull

67.2.4 Evaluation
Neurologic examination: global deficits may be due to shock or hypoxemia due to asphyxiation. Cerebral neurologic deficits are usually due to vascular injury with cerebral ischemia. Local findings may be related to cranial nerve injury. Unilateral UE deficits may be due to nerve root or brachial plexus involvement. Median or ulnar nerve dysfunction can occur from compression by a pseudoaneurysm of the proximal axillary artery. Spinal cord involvement may present with complete injury, or with an incomplete spinal cord injury syndrome (p.944). Shock due to spinal cord injury is usually accompanied by bradycardia (p.931), as opposed to the tachycardia seen with hypovolemic shock.
- Cervical spine x-rays: assesses trajectory of injury and integrity C-spine.
- Angiography: indicated in most cases if the patient is stable (especially for zone I or III injuries, and for zone II patients with no other indication for exploration, or for patients with penetration of the posterior triangle or wounds near the transverse processes where the VA may be injured). Patients actively hemorrhaging need to be taken to the OR without pre-op angiography. Angiographic abnormalities include:
  1. extravasation of blood
     a) expanding hematoma into soft tissues: may compromise airway
     b) pseudoaneurysm
     c) AV fistula
     d) bleeding into airways
     e) external bleeding
  2. intimal dissection, with
     a) occlusion, or
     b) luminal narrowing (including possible “string sign”)
  3. occlusion by soft tissue or bone

67.2.5 Treatment
Airway
Stable patients without airway compromise should not have “prophylactic” intubation to protect the airway. Immediate intubation is indicated for hemodynamically unstable patients or for airway compromise. Options:
- endotracheal: preferred
- cricothyroidotomy: if endotracheal intubation cannot be performed (e.g. due to tracheal deviation or patient agitation) or if there is evidence of cervical spine injury and manipulation of the neck is contraindicated, then cricothyroidotomy is performed with placement of a #6 or 7 cuffed endotracheal tube (followed by a standard tracheostomy in the OR once the patient is stabilized)
- awake nasotracheal: may be considered in the setting of possible spinal injury

Indications for surgical exploration
Surgical exploration has been advocated for all wounds that pierce the platysma and enter the anterior triangles of the neck, however, 40–60% of these explorations will be negative. Although a selective approach may be based on angiography, false negatives have resulted in some authors recommending exploration of all zone II injuries.

Surgical treatment for vascular injuries
Endovascular techniques may be suitable for select cases, especially for patients who are already in the endovascular suite for angiography. However, patients who are actively bleeding usually end up in the O.R. with an open procedure.
- Carotid artery: choices are primary repair, interposition grafting, or ligation. Patients in coma or those with severe strokes caused by vascular occlusion of the carotid artery are poor surgical candidates for vascular reconstruction due to a high mortality rate ≥40% however the outcome with
ligation is worse. Repair of injuries is recommended in patients with no or only minor neurologic deficit. ICA ligation is recommended for bleeding that cannot be controlled and was used for extravasation of dye at the base of the skull in 1 patient.10

Vertebral artery: injuries are more often managed by ligation than by direct repair,11 especially when bleeding occurs during exploration. Less urgent conditions (e.g. AV fistula) requires knowledge of the patency of the contralateral VA and the ability to fill the ipsilateral PICA from retrograde flow through the BA before ligation can be considered (arteriographic anomalies contraindicate ligation in 15% of cases). Proximal occlusion may be accomplished with an anterior approach after the sternocleidomastoid is detached from the sternum. The VA is the normally the first branch of the subclavian artery. Alternatively, endovascular techniques may be used, e.g. detachable balloons for proximal occlusion, or thrombogenic coils for pseudoaneurysms. Distal interruption may also be required, and this necessitates surgical exposure and ligation. Optimal management of a thrombosed injured VA in a foramen transversarium is unknown, and may require arterial bypass if ligation is not a viable option.

67.3 Delayed cervical instability

67.3.1 General information

Definition (adapted12): cervical instability that is not recognized until beyond 20 days after the injury (p.930). The instability itself may be delayed, or the recognition may be delayed.

67.3.2 Etiologies

Reasons for delayed cervical instability:
1. inadequate radiologic evaluation13
   a) incomplete studies (e.g. must see all the way down to C7-T1 junction)
   b) suboptimal studies: motion artifact, incorrect positioning... Etiologies include: poor patient cooperation as a result of agitation/intoxication, portable films, poor technique...
2. abnormality missed on x-ray
   a) overlooked fracture, subluxation
   b) injury failed to be demonstrated despite sufficiently adequate x-rays12; see recommendations of extent of radiologic workup (p.1088)
      • type of fracture not demonstrated on the radiographs obtained
      • patient positioning (e.g. supine) may reduce some malalignment
      • spasm of cervical muscles may reduce and/or stabilize the injury
      • microfractures
3. inadequate models: some findings may be judged to be stable using certain models, but in the long-run may prove to be unstable (there is no perfect model for instability)

67.3.3 Indications for additional studies

Further studies or repeat x-rays several weeks after the trauma should be considered in patients with neurologic deficit, persistent pain, significant degenerative changes when the original films were suboptimal, subluxations <3 mm, or when surgery is contemplated.14

67.4 Delayed deterioration following spinal cord injuries

Etiologies include:
1. posttraumatic syringomyelia (p.1148). Latency to symptoms: 3 mos-34 yrs
2. subacute progressive ascending myelopathy (SPAM): rare. Median time of occurrence: 13 days post injury (range: 4–86 days).15 Signal changes extending to ≥4 levels above the original injury
3. unrecognized spinal instability16: mean delay in diagnosis was 20 days
4. tethered spinal cord: may be due to scar tissue at site of injury
5. delayed spinal epidural hematoma (SEH): most symptomatic SEH occur within 72 hours of surgery, however longer delays have been reported17
6. apoptosis of neurons, oligodendrogliocytes, and astrocytes18: initiated during the acute phase, deterioration occurs during the chronic phase of SCI (months to years after SCI)
7. glial scar formation: mass effect as well as release of factors that may damage surviving neurons19 (p.43–5)
67.5 Chronic management issues with spinal cord injuries

67.5.1 Overview

Most of the following topics are treated elsewhere in this manual, but are pertinent to spinal cord injured (SCI) patients, and reference to the specific section is made.

- autonomic hyperreflexia: see below
- ectopic bone, includes para-articular heterotopic ossification: ossification of some joints that occurs in 15–20% of paralyzed patients
- osteoporosis and pathologic fracture (p. 1009)
- spasticity (p. 1528)
- syringomyelia (p. 1144)
- deep vein thrombosis (p. 952): see below
- shoulder-hand syndrome: possibly sympathetically maintained

67.5.2 Respiratory management problems in spinal cord injuries

In attempting to wean high level SCI patients from a ventilator, it may be helpful to change tube feedings to Pulmonaid® which lowers the CO$_2$ load.

Patients with cervical SCIs are more prone to pneumonia due to the fact that most of the effort in a normal cough originates in the abdominal muscles which are paralyzed.

67.5.3 Autonomic hyperreflexia

General information

**Key concepts**

- exaggerated autonomic response to normally innocuous stimuli
- in spinal cord injury, occurs only in patients with lesions above $\approx$ T6
- patients complain of pounding headache, flushing and diaphoresis above lesion
- can be life threatening, requires rapid control of hypertension and a search for an elimination of offending stimuli

AKA autonomic dysreflexia. Autonomic hyperreflexia^{20,21} (AH) is an exaggerated autonomic response (sympathetic usually dominates) secondary to stimuli that would only be mildly noxious under normal circumstances. It occurs in $\approx$ 30% of quadriplegic and high paraplegic patients (reported range is as high as 66–85%), but does not occur in patients with lesions below T6 (only patients with lesions above the origin of the splanchnic outflow are prone to develop AH, and the origin is usually T6 or below). It is rare in first 12–16 weeks post-injury.

During attacks, norepinephrine (NE) (but not epinephrine) is released. Hypersensitivity to NE may be partially due to subnormal resting levels of catecholamines. Homeostatic responses include vasodilatation (above the level of the injury) and bradycardia (however, sympathetic stimulation may also cause tachycardia).

**Stimuli sources**

Stimulus sources causing episodes of autonomic hyperreflexia:

1. bladder: 76% (distension 73% UTI 3% bladder stones…)
2. colorectal: 19% (fecal impaction 12% administering enema or suppository 4%)
3. decubitus ulcers/skin infection: 4%
4. DVT
5. miscellaneous: tight clothing or leg bag straps, procedures such as cystoscopy or debriding decubitus ulcers, case report of suprapubic tube

**Presentation**

1. paroxysmal HTN: 90%
2. anxiety
3. diaphoresis
4. piloerection
5. pounding H/A
6. ocular findings:
   a) mydriasis
   b) blurring of vision
   c) lid retraction or lid lag
7. erythema of face, neck and trunk: 25%
8. pallor of skin below the lesion (due to vasoconstriction)
9. pulse rate: tachycardia (38%) or mild elevation over baseline, bradycardia (10%)
10. "splotches" over face and neck: 3%
11. muscle fasciculations
12. increased spasticity
13. penile erection
14. Horner’s syndrome
15. triad seen in 85% cephalgia (H/A), hyperhidrosis, cutaneous vasodilatation

Evaluation
In the appropriate setting (e.g. a quadriplegic patient with an acutely distended bladder), the symptoms are fairly diagnostic. Many features are also common to pheochromocytoma. Studies of catecholamine levels have been inconsistent, however they can be mildly elevated in AH. The distinguishing feature of AH is the presence of hyperhidrosis and flushing of the face in the presence of pallor and vasoconstriction elsewhere on the body (which would be unusual for a pheochromocytoma).

Treatment
1. immediately elevate HOB (to decrease ICP), check BP q 5 min
2. treatment of choice: identify and eliminate the offending stimulus
   a) make sure bladder is empty (if catheterized check for kinks or sediment plugs). Caution: irritating bladder may exacerbate AH (consider suprapubic aspiration)
   b) check bowels (avoid rectal exam, may exacerbate). Palpate abdomen or check abdominal x-ray (AH from this usually resolves spontaneously without manual disimpaction)
   c) check skin and toenails for ulceration or infection
   d) remove tight apparel
3. HTN that is extreme or that does not respond quickly may require treatment to prevent seizures and/or cerebral hemorrhage/hypertensive encephalopathy. Caution must be used to prevent hypotension following the episode. Agents used include: sublingual nifedipine23 10 mg SL, IV phentolamine – alpha cholinergic blocker (p.655) – or nicardipine (p.126).
4. consider diazepam (Valium®) 2–5 mg IVP (@<5 mg/min). Relieves spasm of skeletal and smooth muscle (including bladder sphincter). Is also anxiolytic

Prevention
Good bowel/bladder and skin care are the best preventative measures.

Prophylaxis in patients with recurrent episodes:
- phenoxybenzamine (Dibenzyline®): an alpha blocker. Not helpful during the acute crisis. May not be as effective for alpha stimulation from sympathetic ganglia as with circulating catecholamines.23 The patient may also develop hypotension after the sympathetic outflow subsides. Thus this is used only for resistant cases (note: will not affect sweating which is mediated by acetylcholine).
  - Adult: wide range quoted in literature: average 20–30 mg PO BID
- beta-blockers: may be necessary in addition to α-blockers to avoid possible hypotension from β₂-receptor stimulation (a theoretical concern)
- phenazopyridine (Pyridium®): a topical anesthetic that is excreted in the urine. May decrease bladder wall irritation, however, the primary cause of irritation should be treated if possible.
  - Adult: 200 mg PO TID after meals. Supplied: 100, 200 mg tabs.
- "radical measures" such as sympathectomy, pelvic or pudendal nerve section, colecotomy, or intrathecal alcohol injection have been advocated in the past, but are rarely necessary and may jeopardize reflex voiding
- prophylactic treatment prior to procedures may employ use of anesthetics even in regions rendered anesthetic by the cord injury. Nifedipine 10 mg SL has also been used effective for AH during cystoscopy and prophylactically22

68 Low Back Pain and Radiculopathy

68.1 General information

Key concepts

See reference.¹
- low back pain is common, and in ≈ 85% of cases no specific diagnosis can be made
- initial assessment is geared to detecting “red flags” (indicating potentially serious pathology), and in the absence of these, imaging studies and further testing of patients is usually not helpful during the first 4 weeks of low back symptoms
- relief of discomfort is usually best achieved with nonprescription pain meds and/or spinal manipulation
- while activities may need to be modified, bed rest beyond 4 days may be more harmful than helpful, and patients are encouraged to return to work or their normal daily activities as soon as possible
- 89–90% of patients with low back problems will improve within 1 month even without treatment (including patients with sciatica from disc herniation)

Low back pain (LBP) is extremely prevalent, and is the second most common reason for people to seek medical attention.² After the common cold, it is the number two cause for loss of time at work. LBP accounts for ≈ 15% of all sick leave from work, and is the most common cause of disability for persons <45 yrs age.³ Estimates of lifetime prevalence range from 60–90% and the annual incidence is 5%.⁴ Only 1% of patients will have nerve-root symptoms, and only 1–3% have lumbar disc herniation. The prognosis for most cases of LBP is good, and improvement usually occurs with little or no medical intervention.

68.2 Intervertebral disc

68.2.1 General information

The function of the intervertebral disc is to permit stable motion of the spine while supporting and distributing loads under movement. The intervertebral disc has been characterized as the largest nonvascularized structure in the human body, which imparts some unique attributes to it.

68.2.2 Anatomy

Anulus fibrosus (anulus may alternatively be spelled annulus, but fibrosus is the only correct spelling and is distinct from fibrosis):⁵ the multilaminated ligament that encompasses the periphery of the disc space. Attaches to the end-plate cartilage and ring apophyseal bone. Blends centrally with the nucleus pulposus.

Nucleus pulposus: the central portion of the disc. A remnant of the notocord.

Capsule:⁶ combined fibers of the anulus fibrosus and the posterior longitudinal ligament (this term is useful because these 2 structures may not be distinguishable on imaging studies).

68.3 Nomenclature for disc pathology

Historically, the terminology for lumbar disc pathology has been contentious and nonstandardized. A committee tasked to standardize the nomenclature has issued version 2.0 of their recommendations.⁷ Some of these standardizations are useful primarily for consistency related to radiographic reports and for research, and may not be as useful for day-to-day clinical practice. A subset of the recommendations is shown in Table 68.1.

Degenerated disc: (see Table 68.1 for definition) some reports indicate that these can cause radicular pain possibly by an inflammatory mechanism,⁸ but this is not universally accepted.

Vacuum disc: gas in the disc space (empty space on imaging), usually indicates disc degeneration, not infection.
68.4 Vertebral body marrow changes

Associated with degenerative or inflammatory changes. Modic’s classification of MRI characteristics is shown in Table 68.2.

68.5 Clinical terms

Radiculopathy. Dysfunction of a nerve root; signs and symptoms may include: pain in the distribution of that nerve root, dermatomal sensory disturbances, weakness of muscles innervated by that nerve root, and hypoactive muscle stretch reflexes of the same muscles.
Mechanical low back pain (p.1024). AKA “musculoskeletal” back pain (both non-specific terms). The most common form of low back pain. May result from strain of the paraspinal muscles and/or ligaments, irritation of facet joints... Excludes anatomically identifiable causes (e.g. tumor, disc herniation...)

Sciatica. Pain along the course of the sciatic nerve, usually resulting from nerve root compromise (the sciatic nerve is comprised of nerve roots L1 through L5)

68.6 Disability, pain and outcome determinations

Disability scales for low back pain have been developed to assess outcomes for research purposes. Some widely used measures include:
1. visual analogue scale: used for any type of pain. The patient is asked to mark their pain level on a line divided into segments with sequential labels 0 (no pain) to 10 (the worst pain)
2. Oswestry disability index (ODI)
   a categorical ordinal scale that is used for low back pain. There are 4 English versions in wide use, version 2.0 is recommended. It consists 10 questions related to activities of daily living. Each item is scored 0–5 (5 being the most disability) and the total is multiplied by 1.0 to obtain the final score (range: 0–100%). The interpretation of the final score is shown in Table 68.3. A score >45% is essentially completely disabled. A score in the teens is very functional
3. Roland–Morris disability questionnaire
4. Short Form 36 (SF36)

68.7 Differential diagnosis of low back pain

The differential diagnosis of low back pain (p.1024) overlaps with that of myelopathy. In ≈85% of cases of LBP no specific diagnosis can be made, however, serious and/or dangerous conditions can usually be reliably ruled out.

68.8 Initial assessment of the patient with back pain

68.8.1 Background

Initial assessment consists of a history and physical exam focused on identifying serious underlying conditions such as: fracture, tumor, infection or cauda equina syndrome (p.1050). Serious conditions presenting as low back problems are relatively rare.

68.8.2 History

The following information has been found to be helpful in identifying patients with serious underlying conditions such as cancer and spinal infection. Table 68.4 shows the sensitivity and specificity of some features of the history for various conditions.
1. age
2. history of cancer (especially malignancies that are prone to skeletal metastases: prostate, breast, kidney, thyroid, lung, lymphoma/myeloma)
3. unexplained weight loss

4. immunosuppression: from steroids, organ transplant medication, or HIV
5. prolonged use of steroids
6. duration of symptoms
7. responsiveness to previous therapy
8. pain that is worse at rest
9. history of skin infection: especially furuncle
10. history of IV drug abuse
11. UTI or other infection
12. pain radiating below the knee
13. persistent numbness or weakness in the legs
14. history of significant trauma. In a young patient: usually involves MVA, a fall from a height, or a direct blow to the back. In an older patient: minor falls, heavy lifting or even a severe coughing episode can cause a fracture especially in the presence of with osteoporosis
15. findings consistent with cauda equina syndrome (p.1050):
   a) bladder dysfunction (usually urinary retention, or overflow incontinence) or fecal incontinence
   b) saddle anesthesia (p.1050)
   c) unilateral or bilateral leg weakness or pain
16. psychological and socioeconomic factors may influence the patient’s report of symptoms (p.1033), and one should inquire about:
   a) work status
   b) typical job tasks
   c) educational level

68.8.3 Physical examination

Less helpful than the history in identifying patients who may be harboring conditions such as cancer, but may be more helpful in detecting spinal infections.

1. spinal infection (p.349): findings that suggest this as a possibility (but are also common in patients without infection)
   a) fever: common in epidural abscess and vertebral osteomyelitis, less common in discitis
   b) vertebral tenderness
   c) very limited range of spinal motion

2. findings of possible neurologic compromise: the following physical findings will identify most cases of clinically significant nerve root compromise due to L4–5 or L5-S1 HLD which comprise >90% of cases of radiculopathy due to HLD; limiting the exam to the following might not detect the much less common upper lumbar disc herniations, which may be difficult to detect on PE (p.1057)
   a) dorsiflexion strength of ankle and great toe: weakness suggests L5 and some L4 dysfunction
   b) achilles reflex: diminished reflex suggests S1 root dysfunction
   c) light touch sensation of the foot:
      • diminished over medial malleolus and medial foot: suggests L4 nerve root involvement
      • diminished over dorsum of foot: suggests L5
      • diminished over lateral malleolus and lateral foot: suggests S1
   d) straight leg raising (SLR); also check for crossed SLR (p.1048)

68.8.4 “Red flags” in the history and physical exam for low back problems

Based upon the above history and physical exam, the findings in Table 68.5 would suggest the possibility of a serious underlying condition as the cause of the low back problem. Also, thoracic region pain is relatively uncommon and should raise the index of suspicion.

68.8.5 Special diagnostic tests

For patients without features suggesting a serious underlying condition, special diagnostic tests are not needed during the first month of symptoms. This covers approximately 95% of patients with low back problems.¹

68.9 Radiographic evaluation

68.9.1 General information

Diagnosing lumbar spinal stenosis or herniated intervertebral disc is usually helpful only in potential surgical candidates. This includes patients with appropriate clinical syndromes who have not responded satisfactorily to adequate non-surgical treatment over a sufficient period of time, and who have no medical contraindications to surgery. Radiologic confirmation of these diagnoses usually requires CT, myelography, MRI, or some combination (see below). NB: myelography, CT, or MRI may also show bulging or herniated lumbar discs (HLD) or spinal stenosis in asymptomatic patients (e.g. 24% of asymptomatic patients have herniated discs on MRI and 4% have spinal stenosis; these numbers become 36% and 21% respectively in patients 60–80 years old). Thus, these tests must be interpreted in light of clinical findings, and the anatomic level and side should correspond to the history, examination, and/or other physiologic data. Diagnostic radiology is of limited benefit as the initial evaluation in the majority of spinal disorders.

In the absence of red flags for serious conditions, imaging studies are not recommended in the first month of symptoms. For patients who have had previous back surgery, MRI with contrast is probably the best test. Myelography (with or without CT) is invasive and has increased risk of complications, and is therefore indicated only in situations where MRI cannot be done or is inadequate, and the possibility of surgery is anticipated.

### Patients for whom radiographic imaging is recommended are those with:

1. suspected benign conditions with symptoms persisting >4 weeks of great enough severity to consider surgery, including:
   a) back related leg symptoms and clinically specific signs of nerve root compromise
   b) a history of neurogenic claudication (p.1100) or other finding suggestive of lumbar spinal stenosis
   c) symptoms related to spinal deformity/imbalance, especially positional back pain that increases with time spent upright
2. red flags: physical examination or other test results suggesting other serious conditions affecting the spine (e.g. cauda equina syndrome, fracture, infection, tumor, or other mass lesions or defects)

Recommendations for use of MRI and discography to select patients for fusion are shown in the Practice Guideline (p.1029).

### Practice guideline: MRI and discography for patient selection for lumbar fusion*

1. Level II¹¹:
   a) MRI is recommended as the initial diagnostic test
   b) normal appearing discs on MRI should not be considered for discography or treatment
   c) lumbar discography should not be used as a stand-alone test
   d) to consider a disc level for treatment, if discography is used, there should be a concordant pain response and associated abnormalities on MRI
2. Level III²¹: discography should be reserved for equivocal MRI findings, especially at levels adjacent to unequivocally abnormal levels

Notes:
* see also recommendations on use of facet injections (p.1036)
* concordant pain response: pain identical or very similar to the patient’s usual pain complaints
  (NB: discography can produce severe LBP in patients with no prior complaints²²,²³)
* abnormal disc morphology on MRI: loss of T2WI signal intensity (“black disc”), disc space collapse, Modic changes (see Table 68.2), and high-intensity zones (these findings also frequently occur in asymptomatic patients²⁴)
68.9.2 Plain lumbosacral x-rays

General information

Unexpected findings occurred in only 1 in 2500 adults <50 years age. Diagnosis of surgical conditions of disc herniation and spinal stenosis cannot be made from plain films (although they may be inferred, further study would be required). Various congenital abnormalities of uncertain significance may be identified (e.g. spina bifida occulta), and evidence of degenerative changes (including osteophytes) are as frequent in symptomatic as in asymptomatic patients. Gonadal radiation is significant. Seldom indicated during pregnancy.

Recommendation

Not recommended for routine evaluation of patients with acute low back problems during the first month of symptoms unless a “red flag” is present (see below). Reserve LS x-rays for patients with a likelihood of having spinal malignancy, infection, inflammatory spondylitis, or clinically significant fracture. In these cases, plain x-rays are often just a starting point, and further study (CT, MRI...) may be indicated even if the plain x-rays are normal. “Red flags” for these conditions include the following:

- age >70 years, or <20 yrs
- systemically ill patients
- temp >100°F (or >38°C)
- history of malignancy
- recent infection
- patients with neurologic deficits suggesting possible cauda equina syndrome (saddle anesthesia, urinary incontinence or retention, LE weakness) (p.1050)
- heavy alcohol or IV drug abusers
- diabetics
- immunosuppressed patients (including prolonged treatment with corticosteroids)
- recent urinary tract or spinal surgery
- recent trauma: any age with significant trauma, or >50 yrs old with mild trauma
- unrelenting pain at rest
- persistent pain for more than \( \approx 4 \) weeks
- unexplained weight loss

When spine x-rays are indicated, AP and lateral views are usually adequate. Obliques and coned-down L5-S1 views more than double the radiation exposure, and add information in only 4–8% of cases, and can be obtained in specific instances where warranted (e.g. to diagnose spondylolysis when spondylolisthesis is found on the lateral film).

68.9.3 MRI

Unless contraindicated, noncontrast MRI is the initial diagnostic test of choice for diagnosing most cases of disc herniation and spinal stenosis. Specificity and sensitivity for HLD are on the same order as CT/myelography, which is better than myelography alone. Advantages:

- Provides the most information about soft tissues (intervertebral discs, spinal cord, inflammation...) of any available diagnostic test
- provides information regarding tissue outside of the spinal canal, e.g. extreme lateral disc herniation (p.1058), tumors...
- non-invasive and does not utilize ionizing radiation

Disadvantages:

- patients in severe pain or with claustrophobia may have difficulty holding still
- dose not visualize bone well
- poor for studying blood early (e.g. spinal epidural hematoma)
- expensive
- interpretation with scoliosis is more difficult, may be partially compensated by contouring visualization plane through center of canal
- a number of contraindications: see Contraindications to MRI (p.230)
Findings:
In addition to demonstrating herniated lumbar disc (HLD) outside of the disc interspace compressing nerve root or thecal sac, MRI can demonstrate signal changes within the interspace suggestive of disc degeneration\(^\text{30}\) (loss of signal intensity on T2WI, loss of disc space height) and is useful in diagnosing infections and tumors.

### 68.9.4 Lumbosacral CT

If technically adequate images can be obtained (e.g. good quality scanner, images not obscured by artifact from patient movement or obesity), CT can demonstrate most spine pathology. For HLD, sensitivity is 80–95% and specificity is 68–88%\(^\text{31,32}\). However, even some large disc herniations will be missed with plain CT. CT studies for HLD tend to be less satisfactory in the elderly. When MRI is an option, the main utility of CT is for imaging bone to assess fractures or to demonstrate details of bony anatomy for surgery.

Disc material has density (Hounsfield units) \(\approx\) twice that of the thecal sac. Associated findings with herniated disc include:
- loss of epidural fat (normally seen as low density in the anterolateral canal)
- loss of normal “convexity” of thecal sac (indentation by herniated disc)

**Advantages:**
- excellent bony detail
- non-invasive
- outpatient evaluation
- evaluates paraspinal soft tissue (e.g. to rule out tumor, paraspinal abscess...)
- advantages over MRI: faster scanning (significant in patients who have difficulty laying still for long time), less expensive, less claustrophobic, fewer contraindications, see Contraindications to MRI (p.230)

**Disadvantages:**
- involves ionizing radiation (x-rays)
- sensitivity is significantly lower than MRI or myelogram/CT

### 68.9.5 Myelography

With water soluble intrathecal contrast introduced via lumbar puncture, sensitivity (62–100%) and specificity (83–94%)\(^\text{33,34,35,36}\) are similar to CT for detection of HLD. Usually combined with post-myelographic CT scan (myelogram/CT), which increases the sensitivity and especially the specificity.\(^\text{37}\) A herniated disk in the large space between thecal sac and posterior border of vertebral bodies at L5-S1 (insensitive space) may not be seen on myelography alone (CT or MRI are usually better at demonstrating this).

**Advantages:**
1. evaluates cauda equina better than noncontrast CT
2. provides “functional” information about degree of stenosis (a high-degree block will allow flow of dye only after certain position changes)
3. when combined with CT, may demonstrate some anatomy obscured by metal artifact on MRI in patients with prior instrumentation

**Disadvantages:**
1. may miss pathology outside of the dura (including far laterally herniated disc), sensitivity is improved with post-myelographic CT
2. invasive
   a) drugs e.g. warfarin must be stopped, and sometimes bridged to heparin
   b) with occasional side effects (post LP H/A, N/V, rare seizures)
3. iodine allergic patients
   a) requires iodine allergy prep
   b) may still be risky (especially in severely iodine allergic patients)
Findings:
HLD produces extradural filling defect at the level of the intervertebral disc. Massive disc herniation or severe lumbar stenosis may produce a total or near total block. In some cases of HLD, the finding may be very subtle and may consist of a cut-off of the filling (with contrast) of the nerve root sleeve (compared to normal nerve(s) on contralateral side or at other levels). Another subtle finding may be a “dual shadow” on lateral view.

68.9.6 Bone scan
See Bone scan for low back problems (p.1032).

68.9.7 Discography
Injection of water-soluble contrast agent directly into the nucleus pulposus of the intervertebral disc being studied by percutaneous needle access through Kambin’s triangle in an awake patient. Results of the test depend on volume of dye accepted into the disc, the pressure needed to inject the dye, the configuration of the dye (including leakage from the confines of the disc space) on radiographic imaging (plain x-rays produce the so-called “discogram”, CT scan is often also be utilized), and reproduction of the patient’s pain on injection. Some of the basis for performing a discogram is to identify levels that may produce “discogenic pain” or “painful disc syndrome” (p.1032), a controversial point.

Critique:
Invasive. Interpretation is equivocal, and complications may occur (disc space infection, disc herniation, and significant radiation exposure with CT-discography). May be abnormal in asymptomatic patients (as any of the above tests may be) although the false positive rate may not be quite this high. See Practice guideline: MRI and discography for patient selection for lumbar fusion (p.1029) for recommendations.

68.10 Electrodiagnostics for low back problems
If the diagnosis of radiculopathy seems likely on clinical grounds, electrophysiologic testing is not recommended.
1. needle EMG (p.242): can assess acute and chronic nerve root dysfunction, myelopathy and myopathy, and may be useful for patients with suspicion of other conditions (e.g. neuropathy) or when a reliable strength exam is not possible. Reduced recruitment may be seen within the first several days of onset, however, spontaneous activity takes 10–21 days to develop (p.242) (less helpful in the first ≈ 3 weeks). Also, not usually helpful with normal muscle strength exam. Accuracy is highly operator dependent and improves with knowledge about imaging studies and clinical information. See findings in radiculopathy (p.243).
2. H-reflex (p.243): measures sensory conduction through nerve roots. Use is limited to assessing S1 radiculopathy. Correlates with achilles reflex.
3. SSEPs (p.239): assesses afferent fibers which travel in peripheral nerve and the posterior column of the spinal cord. May be abnormal in conditions affecting the dorsal columns with impaired joint position and proprioception (e.g. cervical spondylotic spinal myelopathy)
4. nerve conduction studies (including NCVs): helps identify acute and chronic entrapment neuropathies that may mimic radiculopathy
5. not recommended for assessing acute low back problems
   a) F-wave response (p.243): measures motor conduction through nerve roots, used to assess proximal neuropathies
   b) surface EMG: assesses acute and chronic recruitment patterns during static or dynamic tasks using surface (instead of needle) electrodes

68.11 Bone scan for low back problems
Description: injection of a radiolabeled compound (usually technetium-99m) that is taken up by metabolically active bone. A gamma camera localizes regions of uptake. Total radiation dose is ≈ to a set of lumbar spine x-rays. Contraindicated during pregnancy. Breast feeding must be briefly suspended following a bone scan due to presence of radiotracer in the breast milk.
A moderately sensitive test which may be used in evaluating low back pain when spinal tumor, infection, or occult fracture is suspected from “red flags” (see Table 68.5) on history or examination, or results of lab tests or plain x-rays. Not very specific, but may locate occult lesions and help
differentiate these conditions from degenerative changes. A positive bone scan suggesting one of these conditions usually must be confirmed by other diagnostic tests or procedures (no studies have compared bone scans to CT or MRI).

Low yield in patients with longstanding low back problems and normal plain x-rays and laboratory tests (especially ESR or CRP). SPECT scans may provide additional information to a bone scan.

68.12 Thermography for low back problems

Not recommended. Did not accurately predict absence or presence of nerve root compression seen at surgery, and may be positive in a significant percentage of asymptomatic patients.

68.13 Psychosocial factors

Although some patients with chronic LPB (>3 months duration) may have started off with a diagnosable condition, psychological and socioeconomic factors (such as depression, secondary gain...) may come to play a significant role in perpetuating or amplifying pain. Psychological factors, especially elevated hysteria or hypochondriasis scales on the Minnesota Multiphasic Personality Inventory (MMPI) were found to be a better predictor of outcome than findings on radiographic imaging in one study. A screening scale of 5 factors has been proposed (positive findings in any 3 suggests psychological distress):

1. These items are potentially reliable:
   a) pain on simulated axial loading: press on top of head
   b) inconsistent performance; e.g. difficulty tolerating straight leg raising (SLR) while supine, but no difficulty when sitting
   c) overreaction during the physical exam
2. These items may not be reliable:
   a) inappropriate tenderness that is superficial or widespread
   b) motor or sensory abnormalities not corresponding to anatomic boundaries (e.g. for sensation: dermatomes, peripheral nerve distribution...)

However, the usefulness of this information is limited, and no effective interventions have been identified to address these factors. Therefore the AHCPR panel was unable to recommend specific assessment tools or interventions.

68.14 Treatment

68.14.1 General information

An initial period of nonsurgical management (below) is indicated except in the following circumstances where urgent surgery is indicated:

- Symptoms of cauda equina syndrome: urinary retention, saddle anesthesia... (p. 1050)
- Progressive neurologic deficit, or profound motor weakness
- A relative indication for proceeding to urgent surgery without conservative management is severe pain that cannot be sufficiently controlled with adequate pain medication (rare)

If specific diagnoses such as herniated intervertebral lumbar disc or symptomatic lumbar stenosis are made, surgical treatment for these conditions may be considered if the patient fails to improve satisfactorily. In cases where no specific diagnosis can be made, management consists of conservative treatment and following the patient to rule out the possible development of symptoms suggestive of a more serious diagnosis that may not have initially been evident.

68.14.2 “Conservative” treatment

This term has regrettably come to be used for non-surgical management. With minor modification, similar approaches can be used for mechanical low back pain, as well as for acute radiculopathy from disc herniation.

Recommendations (based on AHCPR findings in the absence of “red flags”; note: some key literature citations are given here, primarily those from the better studies that support the Agency for
Health Care Policy and Research [AHCPR] panel recommendations. However, refer to Bigos et al.¹ for full analysis and list of references:

1. activity modifications: no studies were found that met the panels review criteria for adequate evidence. However, the following information was felt to be useful:
   a) bed rest: for 2–3 days maximum
      • the theoretical objective is to reduce symptoms by reducing pressure on the nerve roots and/or intradiscal pressures which is lowest in the supine semi-Fowler position,⁴⁷ and also to reduce movements which are experienced as painful by the patient
      • deactivation from prolonged bed rest (>4 days) appears to be worse for patients (producing weakness, stiffness, and increased pain) than a gradual return to normal activities⁴⁸
      • recommendations: the majority of patients with low back problems will not require bed rest. Bed rest for 2–4 days may be an option for those with severe initial radicular symptoms, however, this may be no better than watchful waiting⁴⁹ and may be harmful⁵⁰
   b) activity modification
      • the goal is to achieve a tolerable level of discomfort while continuing sufficient physical activity to minimize disruption of daily activities
      • risk factors: although there is not agreement on their exact role, the following were identified as having an increased incidence of low back problems. Jobs requiring heavy or repetitive lifting, total body vibration (from vehicles or industrial machinery), asymmetric postures, or postures sustained for long periods (including prolonged sitting)
      • recommendations: temporarily limit heavy lifting, prolonged sitting, and bending or twisting of the back. Establish activity goals to help focus attention on expected return to full functional status
   c) exercise (may be part of a physical therapy program):
      • during the 1st month of symptoms, low-stress aerobic exercise can minimize debility due to inactivity. In the first 2 weeks, utilize exercises that minimally stress the back: walking, bicycling, or swimming
      • conditioning exercises for trunk muscles (especially back extensors, and possibly abdominal muscles) are helpful if symptoms persist (during the first 2 weeks, these exercises may aggravate symptoms)
      • there is no evidence to support stretching of back muscles, or to recommend back-specific exercise machines over traditional exercise
      • recommended exercise quotas that are gradually escalated results in better outcome than having patients simply stop when pain occurs⁵¹

2. analgesics:
   a) for the initial short-term period, acetaminophen (APAP) or NSAIDs (p.137) may be used. In one study of acute LBP, NSAIDs did not add any benefit to APAP+standard education (see below)
   b) stronger analgesics – mostly opioids (p.138) – may be required for severe pain, usually severe radicular pain. For non-specific back pain, there was no earlier return to full activity than with NSAIDs or APAP.¹ Opioids should not be used >2–3 weeks, at which time NSAIDs should be instituted unless contraindicated

3. muscle relaxants
   a) the therapeutic objective is to reduce pain by relieving muscle spasm. However, muscle spasms have not been proven to cause pain, and the most commonly used muscle relaxants have no peripheral effect on muscle spasm
   b) probably more effective than placebo, but have not been shown to be more effective than NSAIDs, and their use in combination with NSAIDs has not been shown to be more effective than use of NSAIDs alone
   c) potential for side effects: drowsiness (in up to 30%). Most manufacturers recommend use for <2–3 weeks. Agents such as chlorzoxazone (Paraon Forte® and others) may be associated with risk of serious and potentially fatal hepatotoxicity⁵³

4. education: (may be provided as part of a physical therapy program)
   a) explanation of the condition to the patient⁵⁴ in understandable terms, and positive reassurance that the condition will almost certainly subside⁵⁵ have been shown to be more effective than many other forms of treatment
   b) proper posture, sleeping positions, lifting techniques… should be conveyed to the patient. Formal “back school” seems to be marginally effective.⁵⁶ There may be some early benefit, but long-term efficacy could not be shown.⁵⁷ The quality and expense of such programs varies widely¹

5. spinal manipulation therapy (SMT): defined as manual therapy in which loads are applied to the spine using long or short lever methods with the selected joint being taken to its end range of
voluntary motion, followed by application of an impulse loading (may be part of a physical therapy program)
a) may be helpful for patients with acute low back problems without radiculopathy when used in the first month of symptoms (efficacy after 1 month is unproven) for a period not to exceed 1 month. One study\textsuperscript{52} found no added benefit to APA + standard education
b) there is insufficient evidence to recommend SMT in the presence of radiculopathy
c) SMT should not be used in the face of severe or progressive neurologic deficit until serious conditions have been ruled out
d) reports of arterial dissection: especially vertebral artery (p.1325) and stroke, myelopathy & subdural hematoma with cervical SMT and cauda equina syndrome with lumbar SMT\textsuperscript{58,59,60} and the uncertainty of benefits have led to the questioning of the use of SMT\textsuperscript{58} (especially cervical)

6. epidural injections:
a) epidural (cortico)steroid injections (ESI): there is no evidence that this is effective in treating acute radiculopathy. Most studies that show benefit are retrospective and noncontrolled. Prospective studies yield varied results.\textsuperscript{62} Some improvement at 3 & 6 weeks may occur (but no functional benefit, and no change in the need for surgery), with no benefit at 3 months.\textsuperscript{53} The response in chronic back pain is poor in comparison to acute pain. ESI may be an option for short-term relief of radicular pain when control on oral medications is inadequate or for patients who are not surgical candidates
b) there is no evidence to support the use of epidural injections of steroids, local anesthetics and/or opioids for LBP without radiculopathy
c) reports on efficacy with conditions such as lumbar spinal stenosis are conflicting.\textsuperscript{62} relief is almost uniformly temporary (4–6 weeks with initial injection, shorter times with subsequent ones)

Not recommended by the AHCPR panel\textsuperscript{1} for treatment of acute low back problems in the absence of “red flags” (Table 68.5):
1. medications
a) oral steroids: no difference was found at one week and 1 year after randomization to receive 1 week therapy with oral dexamethasone or placebo\textsuperscript{64}
b) colchicine: conflicting evidence shows either some\textsuperscript{65} or no\textsuperscript{66} therapeutic benefit. Side effects of N/V and diarrhea were common\textsuperscript{1}
c) antidepressant medications: most studies of these medications were for chronic back pain. Some methodologically flawed studies failed to show benefits when compared to placebo for chronic (not acute) LBP\textsuperscript{67}

2. physical treatments
a) TENS (transcutaneous electrical nerve stimulation): not statistically significantly better than placebo, and added no benefit to exercise alone\textsuperscript{68}
b) traction (including pelvic traction): not demonstrated to be effective.\textsuperscript{69} One possible explanation for lack of benefit is that due to the sizable paraspinal muscles and ligaments (as compared to the cervical spine) the amount of weight required to distract the intervertebral disc space is approximately $\geq 2/3$ of the patient’s body weight, which is painful and/or pulls the patient to the foot of the bed
c) physical agents and modalities: including heat (including diathermy), ice, ultrasound. Benefit is insufficiently proven to justify their cost, however, self-administered home programs for application of heat or cold may be considered. Ultrasound and diathermy should not be used in pregnancy
d) lumbar corsets and support belts: not proven beneficial for acute back problems. Prophylactic use has been advocated to reduce time lost from work by individuals doing frequent lifting as part of their job, but this is controversial\textsuperscript{70}
e) biofeedback: has not been studied for acute back problems. Primarily advocated for chronic LBP, where effectiveness is controversial\textsuperscript{71}

3. injection therapy
a) trigger point and ligamentous injections: the theory that trigger points cause or perpetuate LBP is controversial and disputed by many experts. Injections of local anesthetic are of equivocal efficacy (saline may be as effective\textsuperscript{72}) and are mildly invasive
b) (zygapophyseal) facet joint injections: theoretical basis is that there exists a “facet syndrome” producing LBP which is aggravated by spine extension, with no nerve root tension signs (p.1047). No studies have adequately investigated injections for pain $\leq 3$ months duration. For chronic LBP, neither the agent nor the location (intrafacet or pericapsular) made a significant difference in outcomes\textsuperscript{73,74}
c) epidural injections in the absence of radiculopathy: see above
d) acupuncture: no studies were found that evaluated the use in acute back problems. All randomized clinical trials found were for patients with chronic LBP, and even the best studies were felt to be mediocre and contradictory. Meta-analysis found acupuncture was more effective in relieving chronic LBP than sham or no treatment, but there was no comparison to other therapies.

### Practice guideline: Injection therapy for low-back pain

**Therapeutic recommendations**
Level III: lumbar epidural injections or trigger point injections are not recommended for long-term relief of chronic LBP. These techniques or facet injections may be used to provide temporary relief in select patients.

**Diagnostic recommendations**
Level III:
- lumbar facet injections
  - may predict the response to radiofrequency facet ablation
  - not recommended as a diagnostic tool to predict the response to lumbar fusion

### 68.14.3 Surgical treatment

#### Indications for surgery for herniated lumbar disc
See the section on herniated lumbar discs (p.1049).

#### Indications for fusion for chronic LBP without stenosis or spondylolisthesis

Very controversial.

### Practice guideline: Lumbar fusion for LBP without stenosis or spondylolisthesis

Level I:
- lumbar fusion is recommended for carefully selected patients with disabling LBP due to one- or two-level degenerative disease without stenosis or spondylolisthesis (in the primary quoted study patients had chronic LBP for ≥ 2 years and had radiologic evidence of disc degeneration at L4-L5, L5-S1, or both, and had failed best medical management).
- Level III: an intensive course of PT and cognitive therapy is recommended as an option for patients with LBP in whom conventional medical management has failed.

### Practice guideline: Choice of fusion technique

Level II:
- for ALIF or TLIF + instrumentation, the addition of a posterolateral fusion is not recommended (the demonstrated benefit does not outweigh the additional time and blood loss involved).
- Level III:
  - either a posterolateral fusion or an interbody fusion (PLIF, TLIF or ALIF) are options for patients with LBP due to DDD at 1 or 2 levels
  - an interbody graft is an option to improve fusion rates and functional outcome (caution: the improvement in fusion rate and outcome is marginal, and interbody fusion is associated with an increased complication rate, especially with combined approaches, e.g. 360° fusion)

  the use of multiple approaches (anterior + posterior) is not recommended as a routine option for LBP without deformity
Surgical treatment options

The type of surgical procedure chosen is tailored to the specific condition identified. Examples are shown in Table 68.6. Discussion of some options is also provided below.

Lumbar spinal fusion

Although there is no consensus on the indications, lumbar spinal fusion (LSF) is accepted treatment for fracture/dislocation or instability resulting from tumor or infection.

For degenerative spine disease, practice parameters have been developed and are included herein. Pain associated with Modic type 1 changes (see Table 68.2) may respond to stabilization procedures, the other Modic types do not exhibit this association.

Practice guideline: Lumbar fusion for disc herniation

**Level II**

1. Lumbar fusion is not routinely recommended following disc excision in patients with HLD or 1st time recurrent HLD causing radiculopathy
2. Lumbar fusion is a potential adjunct to disc excision in cases of a HLD or recurrent HLD:
   a) with evidence of preoperative lumbar spinal deformity or instability
   b) in patients with chronic axial LBP associated with radiculopathy

Instrumentation as an adjunct to fusion

Practice guideline: Pedicle screw fixation

**Level III**

Pedicle screw fixation is recommended as a treatment option for patients with LBP treated with posterolateral fusion who are at high risk for fusion failure (routine use of pedicle screws is discouraged because of conflicting evidence of benefit, together with considerable evidence of increased cost and complications)

The use of instrumentation increases the fusion rate. Hardware used in the absence of fusion will eventually fatigue, especially in the region of the lumbar lordosis. Therefore, instrumentation must be viewed as a temporary internal stabilizing measure while awaiting the fusion process to complete.

68.15 Chronic low back pain

Rarely can an anatomic diagnosis be made in patients with chronic LBP ≥ 3 months duration. Also, see Psychosocial factors (p.1033). Patients with chronic pain syndromes (CPS) refer to their problems with affective or emotional terms with a higher frequency than those with acute pain.

amount of time that a patient has been out of work due to low back problems is related to the chances of the patient getting back to work as shown in Table 68.7.

### 68.16 Coccydynia

#### 68.16.1 General information

Pain and tenderness around the coccyx. A symptom, not a diagnosis. Typically, discomfort is experienced on sitting or on rising from sitting. More common in females, possibly due to a more prominent coccyx. The condition is unusual enough in males that in the absence of local trauma, strong consideration should be given to an underlying condition.

#### 68.16.2 Etiologies

For differential diagnosis, see Acute low back pain (p.1416). Better accepted etiologies include:

1. local trauma (may be associated with fracture or dislocation):
   a) 25% of patients give a history of a fall
   b) 12% had repetitive trauma (rowing machine, prolonged bicycle riding…)
   c) 12% started with parturition
   d) 5% started following a surgical procedure (half of which were in the lithotomy position)
2. idiopathic: excluding traumatic cases, no etiology can be identified in most cases
3. neoplasms
   a) chordoma
   b) giant cell tumor
   c) intradural schwannoma
   d) perineural cyst
   e) intra-osseous lipoma
   f) carcinoma of the rectum
   g) sacral hemangioma
   h) pelvic metastases (e.g. from prostate cancer)
4. prostatitis

Controversial etiologies include:

1. local pressure over a prominent coccyx
2. referred pain:
   a) spinal disease
      • herniated lumbosacral disc
      • cauda equina syndrome
      • arachnoiditis
   b) pelvic/visceral disease
      • pelvic inflammatory disease (PID)
      • perirectal abscess
      • perirectal fistula
      • pilonidal cyst
3. inflammation of the various ligaments attached to the coccyx
4. neurosis or frank hysteria

Histological evaluation of the coccyx has not helped delineate the cause, even though avascular necrosis has been suggested.
68.16.3 Evaluation
MR: effective for detecting soft tissue masses, including presacral masses
CT scan: no characteristic finding in coccydynia findings. Very sensitive for detecting bony pathology (fracture, destructive lesion...).
Sacrococcygeal films are often performed to rule-out a bony destructive lesion. Often, the question of a fracture will be raised, and many times cannot be definitely ruled-in or out based on this study. There may or may not be any significance of such a fracture.
Nuclear bone scans were not helpful in 50 patients with coccydynia.

68.16.4 Treatment
Numerous treatments have been proposed, and some are offered here for historical purposes and to dissuade casual attempts to effect a “new” cure that in reality has already been tried:
1. plaster jackets
2. hot baths (sitz baths), heating pads
3. massage therapy
4. XRT
5. psychotherapy

Most cases resolve within ≈ 3 months of conservative management consisting of NSAIDs, mild analgesics, and measures to reduce pressure on the coccyx (e.g. a rubber ring (“doughnut”) sitting cushion, lumbar supports to maintain sitting lumbar lordosis to shift weight from coccyx to posterior thighs).
Management recommendations for refractory cases
1. local injection: 60% respond to corticosteroid + local anesthetic (40 mg Depo-Medrol® in 10 cc of 0.25% bupivacaine). Recommended as initial treatment; response should be achieved by 2 injections
2. manipulation of the coccyx: usually under general anesthesia. ≈ 85% successful when combined with local injection
3. ± physiotherapy (diathermy & ultrasound): found to be of benefit only in ≈ 16% (may be more effective with the addition of gentle manipulation of the coccyx without general anesthesia)
4. caudal epidural steroid injection
5. blockade or neurolysis (with chemicals or by cryoablation) of the ganglion impar (AKA ganglion of Walther, the lowest ganglion of the paired paravertebral sympathetic chain, located just anterior to the sacrococcygeal junction): some success has been described with this technique (traditionally used for intractable sympathetic perineal pain of neoplastic etiology)
6. neurolytic techniques directed to S4, S5 and coccygeal nerves
7. coccygectomy (surgical removal of the mobile portion of the coccyx, followed by smoothening of the residual bony prominence on the sacrum): was required in ≈ 20% of patients in one series, with a reported success rate of 90%. However, many practitioners do not view this as a highly effective treatment and feel that great restraint should be used in considering this form of therapy

68.16.5 Recurrence
Occurs in ≈ 20% of conservatively treated cases, usually within the first year. Repeat therapy was often successful in providing permanent relief. More aggressive treatment may be considered for refractory cases.

68.17 Failed back surgery syndrome
68.17.1 General information
Definition: failure to satisfactorily improve low back pain or radiculopathy following back surgery. These patients often require analgesics and are unable to return to work. The failure rate for lumbar discectomy to provide satisfactory long-term pain relief is ≈ 8–25%. Pending legal or worker’s compensation claims were the most frequent deterrents to a good outcome.
68.17.2 Etiologies

Factors that may cause or contribute to the failed back syndrome:

1. incorrect initial diagnosis
   a) inadequate pre-op imaging
   b) clinical findings not correlated with abnormality demonstrated on imaging
   c) other causes of symptoms (sometimes in the presence of what was considered to be an appropriate lesion on imaging studies which may have been asymptomatic): e.g. trochanteric bursitis, diabetic amyotrophy...

2. continued nerve root or cauda equina compression caused by:
   a) residual compression (retained disc material, osteophytes...)
   b) recurrent pathology at same level: disc reherniation at the same level, usually have pain-free interval > 6 mos post-op (p.1061); or restenosis (over many years was more common with midline fusions)
   c) adjacent level pathology: disc herniation or stenosis97
   d) compression of nerve root by peridural scar (granulation) tissue (see below)
   e) pseudomeningocele
   f) epidural hematoma
   g) conjoined nerve roots with compression at another level or in atypical location
   h) segmental instability: 3 patterns98 1) lateral rotational instability, 2) post-op spondylolisthesis, 3) post-op scoliosis

3. permanent nerve root injury from the original disc herniation or from surgery, includes deafferentation pain which is usually constant and burning or ice cold

4. adhesive arachnoiditis: responsible for 6–16% of persistent symptoms in post-op patients99 (see below)

5. discitis (p.356): usually produces exquisite back pain 2–4 weeks post-op

6. spondylolysis

7. other causes of back pain unrelated to the original condition: paraspinal muscle spasm, myofascial syndrome... Look for trigger points, evidence of spasm

8. post-op reflex sympathetic dystrophy, RSD (p.1054)

68.17.3 Arachnoiditis (AKA adhesive arachnoiditis)

General information

Inflammatory condition of the lumbar nerve roots. Actually a misnomer, since adhesive arachnoiditis is really an inflammatory process or fibrosis that involves all three meningeal layers (pia, arachnoid, and dura).

Etiologies/risk factors

Many putative “risk factors” have been described for the development of arachnoiditis, including100:

1. spinal anesthesia: either due to the anesthetic agents or to detergent contaminants on the syringes used for same
2. spinal meningitis: pyogenic, syphilitic, tuberculous
3. neoplasms
4. myelographic contrast agents: less common with currently available nonionic water soluble contrast agents
5. trauma
   a) post-surgical: especially after multiple operations
   b) external trauma
6. hemorrhage
7. idiopathic

Radiographic findings in arachnoiditis

NB: Radiographic evidence of arachnoiditis may also be found in asymptomatic patients.100 Arachnoiditis must be differentiated from tumor: the central adhesive type (see below) may resemble CSF seeding of tumor, and myelographic block may mimic intrathecal tumor.
MRI

3 patterns on MRI\textsuperscript{101,102}:
1. central adhesion of the nerve roots into 1 or 2 central “cords”
2. “empty thecal sac” pattern: roots adhere to meninges around periphery, only CSF signal is visible intrathecaally
3. thecal sac filled with inflammatory tissue, no CSF signal. Corresponds with myelographic block and candle-dripping appearance

Enhancement: acute arachnoiditis may enhance. Chronic arachnoiditis usually does not enhance with gadolinium as much as e.g. tumor.

Myelogram

May demonstrate complete block, or clumping of nerve roots. One of many myelographic classification systems\textsuperscript{103} for arachnoiditis is shown in Table 68.8.

68.17.4 Peridural scar

General information

Although peridural scar tissue is frequently blamed for causing recurrent symptoms,\textsuperscript{104,105} there has been no proof of correlation between the two.\textsuperscript{106} Peridural fibrosis is an inevitable sequela to lumbar disc surgery just as post-op fibrosis is a consequence of any surgical procedure. Even patients who are relieved of their pain following discectomy develop some scar tissue post-op.\textsuperscript{107} Although it has been shown that if a patient has recurrent radicular pain following a lumbar discectomy there is a 70% chance that extensive peridural scar will be found on MRI,\textsuperscript{106} this study also showed that on post-op MRIs at 6 months, 43% of patients will have extensive scar, but 84% of the time this will be asymptomatic.\textsuperscript{108} Thus, one must use clinical grounds to determine if a patient with extensive scar on MRI is in the 16% minority of patients with radicular symptoms attributable to scar.\textsuperscript{108}

See a discussion of measures to reduce peridural scarring (p. 1053).

Radiologic evaluation

General information

Patients with only persistent low back or hip pain without a strong radicular component, with a neurologic exam that is normal or unchanged from pre-op, should be treated symptomatically. Patients with signs or symptoms of recurrent radiculopathy (positive SLR is a sensitive test for nerve root compression), especially if these follow a period of apparent recovery, should undergo further evaluation.

It is critical to differentiate residual/recurrent disc herniation from scar tissue and adhesive arachnoiditis as surgical treatment has generally poor results with the latter two (below).

MRI without and with IV gadolinium

Diagnostic test of choice. The best exam for detecting residual or recurrent disc herniation, and to reliably differentiate disc from scar tissue. Pre-contrast studies with T1WI and T2WI yields an accuracy of ≈ 83% comparable to IV enhanced CT.\textsuperscript{109,110} With the addition of gadolinium, using the protocol below yields 100% sensitivity, 71% specificity, and 89% accuracy.\textsuperscript{111} May also detect adhesive arachnoiditis (see above). As scar becomes more fibrotic and calcified with time, the differential enhancement with respect to disc material attenuates and may become undetectable at some point, ≈ 1–2 years post-op\textsuperscript{110} (some scar continues to enhance for >20 yrs).

Table 68.8 Myelographic classification of arachnoiditis
**Recommended MRI protocol**

See reference.\(^{111}\)

Get pre-contrast T1WI and T2WI. Give 0.1 mmol/kg gadolinium IV. Obtain T1WI images within 10 minutes (early post-contrast). No benefit from post-contrast T2WI.

**Findings on unenhanced MRI**

Signal from a HLD becomes more intense as the sequence is varied from T1WI → T2WI, whereas scar tissue becomes less intense with this transition. Indirect signs (also applicable to CT):

1. **mass effect**: a nerve root is displaced away from disc material, whereas it may be retracted toward scar tissue by adherence to it
2. **location**: disc material tends to be in contiguity with the disc interspace (best seen on sagittal MRI)

**Findings on enhanced MRI**

On early (≤ 10 mins post-contrast) T1WI images: scar enhances inhomogeneously, whereas disc does not enhance at all. A nonenhancing central area surrounded by irregular enhancing material probably represents disc wrapped in scar. Venous plexus also enhances, and may be more pronounced when it is distorted by disc material, but the morphology is easily differentiated from scar tissue in these cases.

On late (> 30 mins post-contrast) T1WI: scar enhances homogeneously, disc had variable or no enhancement. Normal nerve roots do not enhance even on late images.

**CT scan without and with IV (iodinated) contrast**

Unenhanced CT scan density measurements are unreliable in the postoperative back.\(^{112}\) Enhanced CT is only fairly good in differentiating scar (enhancing) from disc (unenhancing with possible rim enhancement). Accuracy is about equal to unenhanced MRI.

**Myelography, with post-myelographic CT**

Postoperative myelographic criteria alone are unreliable for distinguishing disc material from scar.\(^{100,113}\) With the addition of CT scan, neural compression is clearly demonstrated, but scar still cannot be reliably distinguished from disc.

Myelography (especially with post-myelographic CT) is very capable of demonstrating arachnoiditis\(^{113}\) (see above).

**Plain LS x-rays**

Generally helpful only in cases of instability, malalignment, or spondylisis.\(^{113}\) Flexion/extension views are most helpful when trying to demonstrate instability.

### 68.17.5 Treatment of failed back surgery syndrome

**Post-operative discitis**

For treatment of intervertebral disc-space infection, see Discitis (p.356).

**Symptomatic treatment**

Recommended for patients who do not have radicular signs and symptoms, or for most patients demonstrated to have scar tissue or adhesive arachnoiditis on imaging. As in other cases of non-specific LBP treatment includes: short-term bed rest, analgesics (non-narcotic in most cases), anti-inflammatory medication (non-steroidal, and occasionally a short course of steroids), and physical therapy.

**Surgery**

Generally reserved for those with recurrent or residual disc herniation, segmental instability, or patients with a pseudomeningocele. Patients with post-op spinal instability should be considered for spinal fusion (p.1037).\(^98\)

In most series with sufficient follow-up, success rates after reoperation are lower in patients with only epidural scar (as low as 1%) compared to those patients with disc and scar (still only ≈ 37%).\(^95\)
An overall success rate (>50% pain relief for >2 yrs) of ≈34% was seen in one series,\textsuperscript{105} with better results in patients that were young, female, with good results following previous surgery, a small number of previous operations, employment prior to surgery, predominantly radicular (cf axial) pain, and absence of scar requiring lysis.

In addition to the absence of disc material, factors associated with poor outcome were: sensory loss involving more than one dermatome, and patients with past or pending compensation claims.\textsuperscript{95,114}

**Arachnoiditis:**

Surgery for carefully selected patients with arachnoiditis (those with mild radiographic involvement (Types 1 & 2 in Table 68.8), and <3 previous back operations)\textsuperscript{103} has met with moderate success (although in this series, no patient returned to work). Approximate success rate in other series\textsuperscript{115,116}: 50% failure, 20% able to work but with symptoms, 10–19% with no symptoms. Surgery consists of removal of extradural scar enveloping the thecal sac, removing any herniated disc fragments, and performing foraminotomies when indicated. Intradural lysis of adhesions is not indicated since no means for preventing reformation of scar has been identified.\textsuperscript{116}

69 Lumbar and Thoracic Intervertebral Disk Herniation / Radiculopathy

69.1 Lumbar disc herniation and lumbar radiculopathy

69.1.1 General information

Key concepts

- **Radiculopathy:** pain and/or subjective sensory changes (numbness, tingling...) in the distribution of a nerve root dermatome, possibly accompanied by weakness and reflex changes of muscles innervated by that nerve root
- **typical disc herniation → radiculopathy in the nerve exiting at the level below**
- **massive disc herniations can → cauda equina syndrome (a medical emergency).** Typical symptoms: saddle anesthesia, urinary retention, LE weakness (p. 1050).
- **most patients do as well with conservative treatment as with surgery,** initial nonsurgical (conservative) treatment should be attempted for the vast majority
- **surgery indications:** cauda equina syndrome, progressive symptoms or neurologic deficits despite conservative treatment, or severe radicular pain \(\approx 6\) weeks

69.1.2 Pathophysiology

Intervertebral discs may undergo degenerative changes (p. 1096); see Table 68.1 for description: this includes desiccation and fibrosis which further leads to fissuring and tearing which in turn increases the risk of herniation of disc material outside the normal confines of the disc space (see same table for definitions).

Disc herniations may compress one or more nerve roots, producing lumbar radiculopathy or less frequently cauda equina syndrome.

69.1.3 Herniation zones

Central and paramedial disc herniations

The posterior longitudinal ligament is strongest in the midline, and the posterolateral annulus may bear a disproportionate portion of the load exerted by the weight from above. This may explain why most herniated lumbar discs (HLD) occur posteriorly, slightly off to one side within the central canal zone or in the subarticular zone as illustrated in Fig. 69.1. In the lumbar spine this characteristically compresses the nerve root en passage (that is, the nerve entering the lateral recess just before it exits through the neural foramen of the level below).
**Extreme lateral disc herniation**

Disc herniations may also occur in the foraminal zone, which typically involves the nerve root exiting at that level.

Disc herniations in the extraforaminal zone occasionally involve the nerve root exiting at that level, however disc herniation here and those herniating anterior to the spine may not result in any nerve root involvement.

### 69.1.4 Other disc herniation variants

1. intravertebral disc herniation: AKA Schmorl’s node. See Herniation through the endplate into the vertebral body (p.1060)
2. intradural disc herniation (p.1060)
3. limbus fracture: traumatic separation of a segment of bone from the edge of the vertebral ring apophysis at the site of anular attachment. May accompany HLD

### 69.1.5 Characteristic findings on the history

- **symptoms may start off with back pain, which after days or weeks gradually or sometimes suddenly yields to radicular pain often with reduction of the back pain**
- **precipitating factors:** various factors are often blamed, but are rarely identified\(^1\) with certainty
- **pain relief upon flexing the knee and thigh (e.g. lying supine with a pillow under the knees)**
- **patients generally avoid excessive movements, however, remaining in any one position (sitting, standing, or lying) too long may also exacerbate the pain, sometimes necessitating position changes at intervals that range from every few minutes to 10–20 minutes. This is distinct from constant writhing in pain e.g. with ureteral obstruction**
- **“cough effect”: ↑ pain with coughing, sneezing, or straining at the stool. Occurred in 87% of patients with HLD in one series\(^2\)**
- **bladder symptoms: the incidence of voiding dysfunction is 1–18%\(^3\)(p.966) Most common: difficulty voiding, straining, or urinary retention. Reduced bladder sensation may be the earliest finding. The possible causes of this are sensory loss, or incomplete interruption of the preganglionic parasympathetic fibers. Later it is not unusual to see “irritative” symptoms including urinary urgency, frequency (including nocturia), increased post-void residual. Less common: enuresis, and dribbling incontinence\(^4\); NB: frank urinary retention may indicate cauda equina syndrome (p.1050). Occasionally a HLD may present only with bladder symptoms which may improve after surgery.\(^5\)**

Discectomy may improve bladder function, but this cannot be assured

**Back pain per se is usually a minor component (only 1% of patients with acute low back pain have sciatica\(^6\)), and when it is the only presenting symptom, other causes should be sought; see Low back pain (p.1024). Sciatica has such a high sensitivity for disc herniation, that the likelihood of a clinically significant disc herniation\(^7\) in the absence of sciatica is \(\approx 1\) in 1000. Exceptions include a central disc herniation which may cause symptoms of lumbar stenosis (i.e. neurogenic claudication) or a cauda equina syndrome.

### 69.1.6 Physical findings in radiculopathy

**General information**

Nerve root impingement gives rise to a set of signs and symptoms present to variable degrees. Characteristic syndromes are described for the most common nerve roots involved; see Nerve root syndromes (p.1049).

In a series of patients referred to neurosurgical outpatient clinics for radiating leg pain, 28% had motor loss (yet only 12% listed motor weakness as a presenting complaint), 45% had sensory disturbance, and 51% had reflex changes.\(^8\)

Findings suggestive of nerve root impingement include the following. Table 69.1 shows the sensitivity and specificity of some findings on the exam among patients with sciatica.

1. **signs/symptoms of radiculopathy** (Table 69.1)
   a) pain radiating down LE
   b) motor weakness
   c) dermatomal sensory changes
   d) reflex changes: mental factors may influence symmetry\(^9\)
2. positive nerve root tension sign(s): including Lasègue’s sign (see below)
3. tenderness over the sciatic notch
Nerve root tension signs

Includes:
1. Lasègue’s sign: AKA straight leg raising (SLR) test. Helps differentiate sciatica from pain due to hip pathology. Test: with patient supine, raise afflicted limb by the ankle until pain is elicited (should occur at <60°, tension in nerve increases little above this angle). A positive test consists of leg pain or paresthesias in the distribution of pain (back pain alone does not qualify). The patient may also extend the hip (by lifting it off table) to reduce the angle. Although not part of Lasègue’s sign, ankle dorsiflexion with SLR usually augments pain due to nerve root compression. SLR primarily tenses L5 and S1, L4 less so, and more proximal roots very little. Nerve-root compression produces a positive Lasègue’s sign in ≈83% of cases (more likely to be positive in patients <30 yrs age with HL D). May be positive in lumbosacral plexopathy (p.544). Note: flexing both thighs with the knees extended (“long-sitting” or sitting knee extension) may be tolerated further than flexing the single symptomatic side alone
2. Cram test: with patient supine, raise the symptomatic leg with the knee slightly flexed. Then, extend the knee. Results similar to SLR
3. crossed straight leg-raising test AKA Fajersztajn’s sign: SLR on the painless leg causes contralateral limb pain (a greater degree of elevation is usually required than the painful side). More specific but less sensitive than SLR (97%of patients undergoing surgery with this sign have confirmed HL D). May correlate with a more central disc herniation
4. femoral stretch test, AKA reverse straight leg raising: patient prone, examiner’s palm at popliteal fossa, knee is maximally dorsiflexed. Often positive with L2, L3, or L4 nerve root compression (e.g. in upper lumbar disc herniation), or with extreme lateral lumbar disc herniation (may also be positive in diabetic femoral neuropathy or psoas hematoma); in these situations SLR (Lasègue’s sign) is frequently negative (since L5 & S1 not involved)
5. “bowstring sign”: once pain occurs with SLR, lower the foot to the bed by flexing knee, keeping the hip flexed. Sciatic pain ceases with this maneuver, but hip pain persists
6. sitting knee extension test: with patient seated and both hips and knees flexed 90°, slowly extend one knee. Stretches nerve roots as much as a moderate degree of SLR

Other signs useful in evaluation for lumbar radiculopathy

1. FABER: an acronym for Flexion ABlduction External-Rotation, AKA FABERE test (the trailing “e” is for extension), AKA Patrick’s-test (after Hugh Talbot Patrick). A test of hip motion. Method: the hip and knee are flexed and the lateral malleolus is placed on the contralateral knee. The ipsilateral knee is gently displaced downward towards the exam table. This stresses the hip joint and does not usually exacerbate true nerve-root compression. Often markedly positive in the presence of hip joint disease – e.g. trochanteric bursitis (p.1101) – sacroiliitis or mechanical low-back pain
2. Trendelenburg sign: examiner observes pelvis from behind while patient raises one leg while standing. Normally the pelvis remains horizontal. A positive sign occurs when the pelvis tilts down toward the side of the lifted leg indicating weakness of the contralateral thigh adductors (primarily L5 innervated).

3. Crossed adductors: in eliciting patellar reflex (knee jerk (KJ)), the contralateral thigh adductors contract. In the presence of a hyperactive ipsilateral KJ it may indicate an upper motor neuron lesion, in the presence of a hypoactive ipsilateral KJ it may be a form of pathological spread, indicating nerve root irritability.

4. Hoover sign: to distinguish unilateral functional weakness of iliopsoas from organic weakness using synergistic contraction of the contralateral gluteus medius. The supine patient is asked to lift one leg off the bed against resistance from the examiner’s hand. The examiner simultaneously places the palm of his/her other hand under the heel of the unlifted leg and gently lifts. Test 1: when the patient lifts the normal leg, if the paretic leg pushes down with more force than was exhibited on manual testing of the limb beforehand, the weakness is judged functional, if the force is equally weak the weakness is judged organic. Test 2: (the better known test) the patient is asked to lift the weak leg. If the heel on the normal side lifts passively by the examiner, it suggests the weakness is functional (i.e. the patient is not trying). Not totally reliable.

5. Abductor sign: an alternative to the Hoover test, to differentiate functional from organic weakness in the thigh abductors using synergistic contraction of the contralateral thigh abductors. With the patient supine, the examiner places a hand on the lateral aspect of both legs. The patient is asked to abduct one leg, and then the other while the examiner applies resistance with his/her hand. The examiner mentally notes the response of the non-abducting LE. The results are as noted in Table 69.2.

**Nerve root syndromes**

Due to the facts listed below, a herniated lumbar disc (HLD) usually spares the nerve root exiting at that interspace, and impinges on the nerve exiting from the neural foramen one level below (e.g. a L5-S1 HLD usually causes S1 radiculopathy). This gives rise to the characteristic lumbar nerve root syndromes shown in Table 69.3.

Important applied anatomy in lumbar disc disease:
1. in the lumbar region, the nerve root exits below and in close proximity to the pedicle of its like-numbered vertebra
2. the intervertebral disc space is located well below the pedicle
3. not all patients have 5 lumbar vertebrae; see Localizing levels in spine surgery (p.1436)

**69.1.7 Radiographic evaluation**

See Radiographic evaluation under Low back pain (p.1416). 70% of herniated discs that migrate do so inferiorly.

**69.1.8 Nonsurgical treatment**

See nonsurgical treatment measures (p.1033).

**69.1.9 Surgical treatment**

**Indications for surgery**

No predictive factors have been identified that can determine which patients are likely to improve on their own and which would be better served with surgery.

Surgical indications in patients with a radiographically identified herniated disc that correlates with findings on the history and physical exam:

1. failure of non-surgical management to control pain after 5–8 weeks: over 85% of patients with acute disc herniation will improve without surgical intervention in an average of 6 weeks (70% within 4 weeks). Most clinicians advocate waiting somewhere between 5–8 weeks from the onset of radiculopathy before considering surgery (assuming none of the items listed below applies).

2. “EMERGENT SURGERY”: (i.e. before the 5–8 weeks of symptoms have lapsed). Indications:
   a) cauda equina syndrome (CES): (see below)
   b) progressive motor deficit (e.g. foot drop). NB paresis of unknown duration is a doubtful indication for surgery (no study has documented that there is less motor deficit in surgically treated patients with this finding). However, the acute development or progression of motor weakness is considered an indication for rapid surgical decompression
   c) “urgent” surgery may be indicated for patients whose pain remains intolerable in spite of adequate narcotic pain medication

3. ± patients who do not want to invest the time in a trial of non-surgical treatment if it is possible that they will still require surgery at the end of the trial

Cauda equina syndrome

The clinical condition arising from dysfunction of multiple lumbar and sacral nerve roots within the lumbar spinal canal. Usually due to compression of the cauda equina (the bundle of nerve roots below the conus medullaris arising from the lumbar enlargement and conus). See Table 69.3 for features to help differentiate CES from a conus lesion.

Possible findings in CES:

1. sphincter disturbance:
   a) urinary retention: the most consistent finding. Sensitivity ≈ 90% at some point in time during course. To evaluate acutely: have patient empty bladder and check post-void residual (by catheterization or with bladder ultrasound). In a patient without retention, only 1 in 1000 will have a CES. Cystometrogram (when done) shows a hypotonic bladder with decreased sensation and increased capacity
   b) urinary and/or fecal incontinence: some patients with urinary retention will present with overflow incontinence
   c) anal sphincter tone: diminished in 60–80%

2. “saddle anesthesia”: the most common sensory deficit. Distribution: region of the anus, lower genitals, perineum, over the buttocks, posterior-superior thighs. Sensitivity ≈ 75% Once total perineal anesthesia develops, patients tend to have permanent bladder paralysis.
3. significant motor weakness: usually involves more than a single nerve root (if untreated, may progress to paraplegia)
4. low back pain and/or sciatica (sciatica is usually bilateral, but may be unilateral or entirely absent, prognosis may be worse when absent or bilateral\textsuperscript{26})
5. bilateral absence of Achilles reflex has been noted\textsuperscript{29}
6. sexual dysfunction (usually not detected until a later time)

Etiologies of CES includes:
1. compression of cauda equina
   a) massive herniated lumbar disc: see below
   b) tumor
      • from compression: e.g. with metastatic disease to the spine with epidural extension
      • intravascular lymphomatosis (B-cell lymphoma) (p. 711): a circulating lymphoma without solid mass. Often presents with CNS findings: dementia, enhancing meninges on MRI, lymphoma cells in CSF, and CES
   c) free fat graft following discectomy\textsuperscript{30}
   d) trauma: fracture fragments compressing cauda equina
   e) spinal epidural hematoma
2. infection: may cause neurologic deficit from
   a) compression: typically from spinal epidural abscess complicating discitis or vertebral osteomyelitis
   b) a significant number of cases of CES from infection may be due to vascular compromise resulting from local septic thrombophlebitis. This may carry a worse prognosis as surgical decompression cannot correct this mechanism
3. neuropathy:
   a) ischemic
   b) inflammatory
4. ankylosing spondylitis: etiology is often obscure (p. 1123)

CES from HLD: May be due to massive herniated disc, usually midline, most common at L4–5, often superimposed on a preexisting condition (spinal stenosis, tethered cord…).\textsuperscript{27}

Prevalence of CES
1. 0.0004 in all patients with LBP\textsuperscript{7}
2. only $\approx 1–2\%$ of HLD that come to surgery\textsuperscript{7}

Time course: CES tends to develop either acutely, or (less typically) slowly (prognosis is worse in the acute onset group, especially for return of bladder function, which occurred in only $\approx 50\%$.\textsuperscript{25} 3 patterns:\textsuperscript{31}
   • Group I – sudden onset of CES symptoms with no previous low back symptoms
   • Group II – previous history of recurrent backache and sciatica, the latest episode combined with CES
   • Group III – presentation with backache & bilateral sciatica that later develop CES

Surgical issues: some advise a bilateral laminectomy\textsuperscript{27} (but this is not mandatory). Occasionally, when it is difficult to remove a very tense midline disc, transdural removal may be helpful.\textsuperscript{29}

Timing of discectomy in CES: controversial, and the point of contention in numerous lawsuits. In spite of early reports emphasizing rapid decompression,\textsuperscript{29} other reports found no correlation between the time to surgery after presentation and the return of function.\textsuperscript{25,26} Some evidence supports the goal of performing surgery within 48 hours (although performing surgery within 24 hours is desirable if possible, there is no statistically significant proof that delaying up to 48 hrs is detrimental).\textsuperscript{32,33}

**Booking the case: Lumbar discectomy**

Also see defaults & disclaimers (p. 27).
1. position: prone
2. equipment: microscope (if used), minimally invasive retractors (if used)
3. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: through the back to go between the bones and remove the piece of disc that is pressing on the nerve(s)
b) alternatives: nonsurgical management
c) complications: usual spine surgery complications (p. 1018) plus the disc can herniate again in the same place in \( \approx 6\% \) of cases, it is possible that a fragment of disc can be missed at the time of surgery, there might not be the amount of pain relief desired (back pain does not respond as well to surgery as nerve-root pain)

Surgical options for lumbar radiculopathy

Once it is decided to treat surgically, options include:
1. trans-canal approaches
   a) standard open lumbar laminectomy and discectomy: 65–85\% reported no sciatica one year post-op compared to 36\% for conservative treatment.\(^{34}\) Long-term results (> 1 year) were similar. 10\% of patients underwent further back surgery during the first year.\(^{24}\)
b) “microdiscectomy”\(^{35,36}\): similar to standard procedure, however smaller incision is utilized. Advantages may be cosmetic, shortened hospital stay, lower blood loss. May be more difficult to retrieve some fragments.\(^{37}\) Overall efficacy is similar to standard discectomy.\(^{38}\)
c) sequestrectomy: removal of only the herniated portion of the disc without entering the disc space to remove disc material from there
2. intradiscal procedures (see below): a number of procedures have been devised over the years to percutaneously treat HLD by creating a cavity within the disc. Some have been abandoned for various reasons, not the least of which is controversy regarding the validity of the underlying premise that this can work
   a) chemonucleolysis: using chymopapain to enzymatically dissolve the disc (no longer used)
b) automated percutaneous lumbar discectomy: utilizes a nucleotome
c) percutaneous endoscopic intradiscal discectomy: see below
d) intradiscal endothermal therapy (IDET or IDTA): see below
e) laser disc decompression

Intradiscal surgical procedures (ISP)

ISPs (see below for specific procedures) are among the most controversial procedures for lumbar spine surgery. The theoretical advantage is that epidural scarring is avoided, and that a smaller incision or even just a puncture site is used. This is also purported to reduce postoperative pain and hospital stay (often performed as an outpatient procedure). The conceptual problem with ISPs is that they are directed at removing disc material from the center of the disc space (which is not producing symptoms) and rely on the reduced intradiscal pressure to decompress the herniated portion of the disc from the nerve root. Only \( \approx 10–15\% \) of patients considered for surgical treatment of disc disease are candidates for an ISP. ISPs are usually done under local anesthetic in order to permit the patient to report nerve root pain to identify impingement on a nerve root by the surgical instrument or needle. Overall, ISPs are not recommended until rigorous controlled trials prove the efficacy.\(^{10}\)

Indications utilized by proponents of intradiscal procedures:
1. type of disc herniation: appropriate only for “contained” disc herniation (i.e. outer margin of annulus fibrosus intact)
2. appropriate level: best for L4–5 HLD. May also be used at L3–4. Difficult but often workable (utilizing angled instruments or other techniques) at L5–S1 because of the angle required and interference by iliac crest
3. not recommended in presence of severe neurologic deficit\(^{40}\)

Results:
“Success” rate (\( \approx \) pain free and return to work when appropriate) reported ranges from 37–75\%\(^{41,42,43}\).

Automated percutaneous lumbar discectomy: AKA nucleoplasty. Utilizes a nucleotome to remove disc material from the center of the intervertebral disc space. 1 year success rate of 37\% Complications include cauda equina syndrome from improper nucleotome placement.\(^{45}\) In another study, nucleoplasty (with or without IDET (see below)) for HLD showed only modest reduction in pain at 9 months.\(^{46}\)

Laser disc decompression: Insertion of a needle into the disc, and introduction of a laser fiberoptic cable through the needle to allow a laser to burn a hole in the center of the disc (with or without endoscopic visualization).
The 2104 North American Spine Society Coverage Committee position statement:
“Laser spine surgery in the cervical or lumbar spine is NOT indicated at this time. Due to lack of high quality clinical trials concerning laser spine surgery with the cervical or lumbar spine, it cannot be endorsed as an adjunct to open, minimally invasive, or percutaneous surgical techniques.”

Percutaneous endoscopic lumbar discectomy (PELD): This term refers to an essentially intradiscal procedure indicated primarily for contained disc herniations, although some small “non-contained” fragments may be treatable. No large randomized study has been done to compare the technique to the accepted standard, open discectomy (with or without microscope). In one report of 326 patients with L4–5 HLD, only 8 (2.4%) met study criteria (no previous operation, failure of conservative treatment, imaging study proving disc protrusion followed by discography to R/O “disc perforation”) for PELD. Of these 8, only 3 were reported as having a good result. This study is not adequate for evaluating the technique.

Intradiscal endothermal therapy (IDET): AKA intradiscal (electro)thermal anuloplasty (IDTA). Efficacy: 23–60% at 1 year for treating “internal disc disruption” which is purported to account for 40% of patients with chronic low back pain of unknown etiology.

Adjunctive treatment in lumbar laminectomy

Epidural steroids following discectomy
Perioperative epidural steroids after routine surgery for lumbar degenerative disease may result in a small reduction of post-op pain, length of stay, and the risk of not returning to work at 1 year, but most of the evidence originates from studies not using validated outcome assessment that favor positive results, and further study is recommended (various agents, dosages, co-administered drugs, and delivery methods were reported). However, the combination of systemic steroids at the start of the case (Depo-Medrol® 160 mg IM and methylprednisolone sodium succinate (Solu-Medrol®) 250 mg IV) combined with infiltration of 30 ml of 0.25% bupivacaine (Marcaine®) into the paraspinal muscles at incision and closure, may reduce hospital stay and post-op narcotic requirements.

Methods to reduce scar formation

Epidural free fat graft
The use of an autogenous free fat graft in the epidural space has been employed in an attempt to reduce post-op epidural scar formation. Opinion varies widely as to the effectiveness, some feel it is helpful, others feel it actually exacerbates scarring. In some patients, no evidence of the graft will be found on reoperation years later. The fat graft can very rarely be a cause of nerve root compression or cauda equina syndrome within the first few days post-op, and there is a case report of compression 6 years following surgery.

Other measures
Other measures include the placement of barrier films or gels. There are numerous products available, none has been shown to have reproducible benefit.

Risks of lumbar laminectomy

General information
Overall risk of mortality in large series: 6 per 10,000 (i.e. 0.06%), most often due to septicemia, MI, or PE. Complication rates are very difficult to determine accurately, but the following is included as a guideline.

Common complications
1. Infection:
   a) Superficial wound infection: 0.9–5% (risk is increased with age, long term steroids, obesity, DM): most are caused by S. aureus; see Laminctomy wound infection (p.345) for management
   b) Deep infection: <1% (see below under Uncommon complications)
2. Increased motor deficit: 1–8% (some transient)
3. Unintended “incidental” durotomy (the term “unintended durotomy” has been recommended in preference to “dural tear”, see below): incidence is 0.3–13% (risk increases to ≈ 18% in re-do operations). Possible sequelae include those listed in Table 69.4
Table 69.4 Possible sequelae of dural opening

Well documented

1. CSF leak
   a) contained: pseudomeningocele
   b) external: CSF fistula
2. herniation of nerve roots through opening
3. associated nerve root contusion, laceration or injury to the cauda equina
4. CSF leak collapses the thecal sac and may increase blood loss from epidural bleeding

Less well documented

1. arachnoiditis
2. chronic pain
3. bladder, bowel and/or sexual dysfunction

a) CSF fistula (external CSF leak): the risk of a CSF fistula requiring operative repair is ≈ 10 per 10,000.
b) pseudomeningocele: 0.7–2% (may appear similar radiographically to spinal epidural abscess (SEA), but post-op SEA often enhances, is more irregular, and is associated with muscle edema)
4. recurrent herniated lumbar disc (same level either side) (p.1061): 4% (with 10 year follow-up)
5. Post-operative urinary retention (POUR): usually temporary, but may delay hospital discharge

Uncommon complications

1. direct injury to neural structures. For large disc herniations, consider a bilateral exposure to reduce risk
2. injury to structures anterior to the vertebral bodies (VB): injured by breaching the anterior longitudinal ligament (ALL) through the disc space, e.g. with pituitary rongeur. The depth of disc space penetration with instruments should be kept ≤ 3 cm, since 5% of lumbar discs had diameters as small as 3.3 cm. Asymptomatic perforations of the ALL occur in up to 12% of discectomies. Breach of the ALL risks potential injuries to:
   a) great vessels: risks include potentially fatal hemorrhage, and arteriovenous fistula which may present years later. Most such injuries occur with L4–5 discectomies. Only ≈ 50% bleed into the disc space intraoperatively, the rest bleed into the retroperitoneum. Emergent laparotomy or endovascular treatment is indicated, preferably by a surgeon with vascular surgical experience, if available. Mortality rate is 37–67%.
   - aorta: the aortic bifurcation is on the left side of the lower part of the L4 VB, and so the aorta may be injured above this level
   - below L4, the common iliac arteries may be injured
   - veins (more common than arterial injuries): vena cava at and above L4, common iliac veins below L4
   b) ureters
   c) bowel: at L5-S1 the ileum is the most likely viscus to be injured
   d) sympathetic trunk
3. wrong site surgery: incidence in self-reporting survey was 4.5 occurrences per 10,000 lumbar spine operations. Factors identified as potential contributors to the error: unusual patient anatomy, not performing localizing radiograph. 32% of responding neurosurgeons indicated that they removed disc material from the wrong level at some time in their career
4. rare infections:
   a) meningitis
   b) deep infection: <1% Including:
      - discitis (p.356): 0.5%
      - spinal epidural abscess (SEA) (p.349): 0.67%
5. cauda equina syndrome: may be caused by post-op spinal epidural hematoma (see below). Incidence was 0.21% in one series of 2842 lumbar discectomies and 0.14% in a series of 12,000 spine operations. Red flags: urinary retention, anesthesia that may be saddle or bilateral LE postoperative visual loss (POVL): (see below)
6. complications of positioning:
   a) compression neuropathies: ulnar, peroneal nerves. Use padding over elbows and avoid pressure on posterior popliteal fossa
h) anterior tibial compartment syndrome: due to pressure on anterior compartment of leg (reported with Andrew’s frame). An orthopedic emergency that may require emergent fasciotomy
c) pressure on the eye: corneal abrasions, damage to the anterior chamber
d) cervical spine injuries during positioning due to relaxed muscles under anesthesia
8. post-op arachnoiditis (p.1040): risk factors include epidural hematoma, patients who tend to develop hypertrophic scar, post-op discitis, and intrathecal injection anesthetic agents or steroids. Surgical treatment for this is disappointing. Intrathecal depo-medrol may provide short-term relief (in spite of the fact that steroids are a risk factor for the development of arachnoiditis).
9. thrombophlebitis and deep-vein thrombosis with risk of pulmonary embolism (PE)69: 0.1% see Thromboembolism in neurosurgery (p.167)
10. complex regional pain syndrome AKA reflex sympathetic dystrophy (RSD) (p.497): reported in up to 1.2% of cases, usually after posterior decompression with fusion, often following reoperations71 with onset 4 days to 20 weeks post-op. See also critique of RSD (p.497). Treatment includes some or all of: PT, sympathetic blocks, oral methylprednisolone, removal of hardware if any
11. very rare: Ogilvie’s syndrome (pseudo-obstruction (“ileus”) of the colon). Usually seen in hospitalized/debilitated patients. May be related to narcotics, electrolyte deficiencies, possibly from chronic constipation. Also reported following spinal surgery/trauma, spinal/epidural anesthesia, spinal metastases, & myelography72

Unintended durotomy

Unintentional opening of the dura during spinal surgery has an incidence of 0–14%73

Terminology: The terms “unintended durotomy”, “incidental durotomy”,73 or even just “dural opening”, have been recommended in preference to “dural tear” which may imply carelessness62 when none was present. Dural openings have been associated with one or more alleged complications or sequelae in medical malpractice suits involving surgery on the lumbar spine.

The injury: By itself, opening the dura intentionally or otherwise is not expected to have a deleterious effect on the patient.62,74 In fact, dural opening is often a standard part of the operation for intradural disc herniation,75 tumors, etc. Although not frequent, (for incidence, see above) unintended durotomy is not an unusual occurrence, and alone, is not considered an act of malpractice. However, it may result from an event or events that produce more serious injuries. These events and injuries should be dealt with on their own merits.

In the SPORT study, there was a 9% incidence of unintended durotomy in patients undergoing first-time open laminectomy.76 There were no long-term differences in nerve root injuries, mortality, additional operations, or outcome measures. Short-term differences included longer inpatient stay, increased blood loss, and duration of surgery.76

Possible sequelae include those listed in Table 69.4. A CSF leak may produce “spinal headache” (p.1508) with its associated symptoms and if it breaches the skin it may be a risk factor for meningitis. Pain or sensory/motor deficits may be associated with injuries to nerve roots or delayed herniation of nerve roots through the dural opening.

Etiologies: Potential causes are many, and include62: unanticipated anatomic variations, adhesion of the dura to removed bone, slippage of an instrument, an obscured fold of dura caught in a rongeur or curette, thinning of the dura in cases of longstanding stenosis, and the possibility of a delayed CSF leak caused by perforation of the dura when it expands onto a surgically created spine of bone.77 The risk may be increased with anterior decompression for OPLL, with revision surgery, and with the use of high-speed drills.73

Treatment: If the opening is recognized at the time of surgery, watertight primary closure (with or without patch graft) should be attempted with nonabsorbable suture if at all possible to prevent pseudomeningocele and/or CSF fistula. A cottonoid placed over the opening prevents aspiration of nerve roots.78 Care must be taken to avoid incorporating a nerve root into the closure. Most repairs will be accomplished with no complication or sequelae to the patient. When the opening is in the far (anterior) side of the dura, consideration may be given to intradural repair accessed through a posterior durotomy which is subsequently closed (this may risk additional injury to the nerve roots). Bio-compatible fixatives (e.g. fibrin glue73) may be used to supplement primary closure.

Primary repair may be impossible in some situations (e.g. when the opening cannot be found or accessed, as is sometimes the case when it occurs on the nerve root sleeve) and alternatives here include placement of a fat or muscle graft over the suspected leak site, use of a the patient’s own blood for a “blood patch” (one technique is to have the anesthesiologist draw ≈ 5–10 ml of the patient’s blood from an arm vein, keeping it in the syringe for several minutes until it starts to coagulate, and then to have the anesthesiologist inject the blood onto the dura), use of gelfoam, fibrin
glue... Some recommend that the wound not be drained post-op, with a water-tight closure of fascia, fat, and skin to add to the barrier. Others use a subcutaneous drain or epidural catheter. CSF diversionary procedures (e.g. through a drain inserted 1 or more levels away) may also be used.

Although bed rest × 4–7 days is often advocated to reduce symptoms and facilitate healing, when watertight closure has been achieved, normal post-op mobilization is not associated with a high failure rate (bed rest is recommended if symptoms develop). In one report of 8 patients with leaks that appeared post-op, re-operation was avoided when treated by resuturing the skin under local anesthesia, followed by bed rest in slight Trendelenburg position (to reduce pressure on the leakage site), broad spectrum antibiotics and antibiotic ointment over the skin incision, and daily puncture and drainage of the subcutaneous collection.

See other treatment measures for H/A associated with CSF leak (p. 1049).

Postoperative visual loss

1. ischemic optic neuropathy: the most common cause of the very uncommon post-operative loss of vision. Often bilateral. Usually associated with significant blood loss (median: 2 L), and/or prolonged operative time (≥6 hrs). All cases had anesthetic time > 5 hrs or blood loss > 1 L. Blood loss can cause hypotension (may cause release of endogenous vasoconstrictors in addition to reduced blood flow due to low hemodynamic pressure) and increased platelet aggregation. Is not due to direct pressure on the globe in most cases, and can occur at any age and even in otherwise healthy patients. No association with age, HTN, atherosclerosis, smoking or DM.

The blindness can be extensive and is often permanent. Prevention is critical since there is no known effective treatment.

a) posterior ischemic optic neuropathy (PION): may follow surgery (surgical PION). Risk factors as above, plus:
   - surgery in the prone position (can cause periorbital edema, and rarely, direct pressure on the orbit)
   - lack of tight glycemic control
   - use of Trendelenburg position
   - hemodilution or overuse of crystalloid vs. colloid (blood) fluid replacement
   - prolonged hypotension
   - cellular hypoxia
   - decreased renal perfusion

b) 6 independent risk factors for POVL:
   - male gender: odds ratio (OR) = 2.53
   - obesity: by clinical assessment or BMI ≥ 30 OR = 2.83
   - use of Wilson frame: OR = 4.36
   - length of anesthesia: OR = 1.39 per hour
   - EBL: OR = 1.34 per Liter
   - use of colloid as a percentage of nonblood replacement: less certain (small difference). OR = 0.67 per 5% colloid

c) anterior ischemic optic neuropathy (AION): divided into arteritic (as with GCA) and nonarteritic (common with DM)

2. central retinal artery occlusion

3. cortical blindness: from occipital lobe infarction possibly due to embolism

Post-op care

Post-op orders

The following are guidelines for post-operative orders for a lumbar laminectomy without intra-operative complications; variations between surgeons and institutions must be taken into consideration:

1. admit post-anesthesia care unit (PACU)
2. vital signs on the nursing unit: q 2° × 4 hrs, q 4° × 24°, then q 8°
3. activity: up with assist, advance as tolerated
4. nursing care
   - Ts & Os
   - intermittent catheterization q 4–6° PRN no void
   - optional: TED hose (may reduce risk of DVT) or PCB
   - optional (if drain used): empty drain q 8° and PRN
5. diet: clear liquids, advance as tolerated
6. IV: D5 1/2 NS + 20 mEq KCl/l @ 75 ml/hr, D/C when tolerating PO well (after antibiotics D/Cd if prophylactic antibiotics are used)
7. meds
   - laxative of choice (LOC) PRN
   - sodium docusate (e.g. Colace®) 100 mg PO BID when tolerating PO (stool softener, does not substitute for LOC)
   - optional: prophylactic antibiotics if used at your institution
   - acetaminophen (Tylenol®) 325 mg 1–2 PO or PR q 6° PRN
   - narcotic analgesic
   - optional: steroids are used by some surgeons to reduce nerve-root irritation from surgical manipulation

8. labs
   - optional (if significant blood loss during surgery): CBC

Post-op check
In addition to routine, the following should be checked:
1. strength of lower extremities, especially muscles relevant to nerve root, e.g. gastrocnemius for L5-S1 surgery, EHL for L4–5 surgery...
2. appearance of dressing: look for signs of excessive bleeding, CSF leak...
3. signs of cauda equina syndrome (p.1050), e.g. by post-op spinal epidural hematoma
   a) loss of perineal sensation (“saddle anesthesia”)
   b) inability to void: may not be not unusual after lumbar laminectomy, more concerning if accompanied by loss of perineal sensation
   c) pain out of the ordinary for the post-op period
   d) weakness of multiple muscle groups

Any new neurologic deficit should prompt rapid evaluation for spinal epidural hematoma⁰⁹ (EDH). Delayed deficits may be due to EDH or epidural abscess. Post-op films in the recovery room can rule out graft or hardware malposition for fusions or instrumentation procedures, or changes in alignment. The diagnostic test of choice is MRI. If contraindicated or not available, CT/myelography may be indicated. An extradural defect immediately post-op suggests EDH.

Outcome of surgical treatment
In a series of 100 patients undergoing discectomy, at 1 year post-op 73% had complete relief of leg pain and 63% had complete relief of back pain; at 5–10 years the numbers were 62% for each category. At 5–10 years post-op, only 14% felt that the pain was the same or worse than pre-op (i.e. 86% felt improved), and 5% qualified as having a failed back surgery syndrome (a heterogeneous not-precisely defined term, here meaning not returned to work, requiring analgesics, receiving worker’s compensation, see Failed back surgery syndrome (p.1039)).

Attempts to measure relative merits of conservative treatment vs. surgery have failed. The recent SPORT study⁸²,⁸³ suffered from significant selection bias since patients were allowed to crossover to the other arm of the study and thus more nearly approximated the current methodology of surgical selection than an actual RCT.⁸⁴ Earlier attempts at randomized trials also suffered from methodological flaws.⁸⁵ Conclusions that can be drawn from these studies⁸⁴: most patients with manageable or improving pain and less disability typically choose conservative treatment and most have improvement in symptoms, whereas patients with severe, persistent or worsening pain and/or neurologic deficit are more likely to choose surgery with a resultant excellent outcome.

In patients with a diminished knee-jerk or ankle-jerk pre-op, 35% and 43% (respectively) still had reduced reflexes 1 year post-op⁶; reflexes were lost post-op in 3% and 10% respectively. The same study found that motor loss was improved in 80% aggrivated in 3% and was newly present in 5% post-op; and that sensory loss was improved in 69% and was worsened in 15% post-op.

Foot drop: severe or complete paralysis of ankle dorsiflexion occurs in 5–10% of HLD, and about 50% of cases recover with or without treatment. Discectomy does not improve the outcome, especially in cases of painless foot drop.⁸⁶

See Recurrent disc herniation (p.1061).

69.1.10 Herniated upper lumbar discs (levels L1–2, L2–3, and L3–4)

General information
L4–5 & L5-S1 herniated lumbar discs (HLD) account for most cases of HLD (realistically ≈ 90% possibly as high as 98%). 24% of patients with HLD at L3–4 have a past history of a HLD at L4–5 or L5-S1, suggesting a generalized tendency towards disc herniation. In a series of 1,395 HLDs, there were 4 at L1–2 (0.28% incidence), 18 at L2–3 (1.3%), and 51 at L3–4 (3.6%).⁸⁵
Presentation

Typically presents with LBP, onset following trauma or strain in 51% With progression, paresthesias and pain in the anterior thigh occur, with complaints of leg weakness (especially on ascending stairs).

Signs

Quadriceps femoris was the most common muscle involved, demonstrating weakness and sometimes atrophy.

Straight leg raising was positive in only 40% Psoas stretch test was positive in 27% Femoral stretch test may be positive (p.1048).

50% had reduced or absent knee jerk; 18% had ankle jerk abnormalities; reflex changes were more common with L3–4 HLD (81%) than L1–2 (none) or L2–3 (44%).

69.1.11 Extreme lateral lumbar disc herniations

General information

Definition: herniation of a disc at (foraminal disc herniation) or distal to (extraforaminal disc herniation) the facet (some authors do not consider foraminal disc herniation to be “extreme lateral”). See Fig. 69.1.

Incidence (Table 69.5): 3–10% of herniated lumbar discs (HLD) (series with higher numbers include some HLD that are not truly extreme lateral).

Occurs most commonly at L4–5 and next at L3–4 (see Table 69.5), thus L4 is the most common nerve involved and L3 is next. With a clinical picture of an upper lumbar nerve root compression (i.e. radiculopathy with negative SLR), chances are ∝ 3 to 1 that it is an extremely lateral HLD rather than an upper lumbar disc herniation.

Differs from the more common central and subarticular HLD in that:

• the nerve root involved is usually the one exiting at that level (c.f. the root exiting at the level below)
• straight leg raising (SLR) (p.1048) is negative in 85–90% of cases ≥1 week after onset (excluding double herniations; ∝ 65% will be negative if double herniations are included); may have positive femoral stretch test
• pain is reproduced by lateral bending to the side of herniation in 75%
• higher incidence of extruded fragments (60%)
• higher incidence of double herniations on the same side at the same level (15%)
• pain tends to be more severe (may be due to fact that the dorsal root ganglion may be compressed directly) and often has more of a burning dysesthetic quality

Presentation

Quadriceps weakness, reduction of patellar reflex, and diminished sensation in the L3 or L4 dermatome are the most common findings.

Differential diagnosis

1. lateral recess stenosis or superior articular facet hypertrophy
2. retroperitoneal hematoma or tumor

3. diabetic neuropathy (amyotrophy) (p.545)
4. spinal tumor
   a) benign (schwannoma or neurofibroma)
   b) malignant tumors
   c) lymphoma
5. infection
   a) localized (spinal epidural abscess)
   b) psoas muscle abscess
   c) granulomatous disease
6. spondylolisthesis (with pars defect)
7. compression of conjoined nerve root
8. on MRI, enlarged foraminal veins may mimic extreme lateral disc herniation

Radiographic diagnosis

NB: if actively sought, many asymptomatic far-lateral disc herniations may be demonstrated on MRI or CT. Careful clinical correlation is usually required.

MRI: diagnostic test of choice. Sagittal views through the neural foramen may help demonstrate the disc herniation. MRI may have ≈8% false positive rate due to presence of enlarged foraminal veins that mimic extreme lateral HLD. Myelography: myelography alone is rarely diagnostic (usually requires post myelo CT). Myelography alone is rarely diagnostic (usually requires post myelo CT). Fails to disclose the pathology in 87% of cases due to the fact that the nerve root compression occurs distal to the nerve root sleeve (and therefore beyond the reach of the dye). CT scan reveals a mass displacing epidural fat and encroaching on the intervertebral foramen or lateral recess, compromising the emerging root. Or, may be lateral to foramen. Sensitivity is ≈50% and is similar with post-myelographic CT. Post-discography CT has also been able to demonstrate.

Surgical treatment

NB: compression of the dorsal root ganglion may result in a slower recovery from discectomy and overall less satisfying outcome than with the more commonplace paramedian disc herniation.

Foraminal discs

Usually requires mesial facetectomy to gain access to the region lateral to the dural sac without undue retraction on nerve root or cauda equina. Caution: total facetectomy combined with discectomy may result in a high incidence of instability (total facetectomy alone causes ≥10% rate of slip-page), although other series found this risk to be lower (∼1 in 3). An alternative technique is to remove just the lateral portion of the superior articular facet below. Endoscopic techniques may be well suited for herniated discs in this location.

Discs herniated beyond (lateral to) the foramen

Numerous approaches are used, including:
1. traditional midline hemilaminectomy: the ipsilateral facet must be partially or completely removed. The safest way to find the exiting nerve root is take the laminectomy of the inferior portion of the upper vertebral level (e.g. L4 for a L4–5 HLD) high enough to expose the nerve root axilla, and then follow the nerve laterally through the neural foramen by removing facet until the HLD is identified
2. lateral approach (i.e. extra-canal) through a paramedian incision. Advantages: the facet joint is preserved (facet removal combined with discectomy may lead to instability), muscle retraction is easier. Disadvantages: unfamiliar approach for most surgeons and the nerve cannot be followed medial to lateral. A localizing x-ray is taken with a spinal needle. A 4–5 cm vertical skin incision is made 3–4 cm lateral to the midline on the side of the disc herniation. The incision is taken down to the thoracolumbar fascia and the subcutaneous tissue is dissected off the fascia. Above L4, one may palpate the groove between multifidus (medial) and longissimus (lateral), where the fascia is incised. The facet joint is palpated, and blunt dissection is used to gain access to the lateral facet joint and transverse processes above and below the level of the disc herniation. The correct level is confirmed on x-ray using a probe as a marker. The intertransversarius muscle and fascia are divided. Care must be taken to avoid mechanical and electrocautery injury to the nerve and dorsal root ganglion (which lies immediately beneath the intertransverse ligament). The radicular artery, vein, and nerve root are located just beneath the transverse processes, usually slightly
medi al to thi s posi ti on.  T he nerv e root hugs the pedi cl e of  the l ev el  above as i t exi ts the neural foramen (palpating this e.g. with a dental dissector helps locate it), and it may be splayed over the herniated disc fragment. If more medial exposure is necessary, the lateral facet joint may be resected. The HLD is removed. Additional removal of disc material from the disc space may be performed with down-biting pituitary rongeurs. Extracanal approach to L5-S1 requires removal of part of the sacral ala in order to access the space caudal to the L5 transverse process.

69.1.12 Lumbar disc herniations in pediatrics

Less than one percent of surgery for herniated lumbar disc is performed on patients between the ages of 10 and 20 yrs (one series at Mayo found 0.4% of operated HLD in patients <17 yrs age). These patients often have few neurologic findings except for a consistently positive straight leg raising test. Herniated disc material in youths tends to be firm, fibrous and strongly attached to the cartilaginous end-plate unlike the degenerated material usually extruded in adult disc herniation. Plain radiographs disclosed an unusually high frequency of congenital spine anomalies (transitional vertebra, hyperlordosis, spondylolisthesis, spina bifida...). 78% did well after their first operation.

69.1.13 Intradural disc herniation

Herniation of a fragment of disc into the thecal sac, or into the nerve root sleeve (the latter sometimes referred to as “intraradicular” disc herniation) has been recognized with a reported incidence of 0.04–1.1% of disc herniations. Although it may be suspected on the basis of pre-op MRI or myelography, the diagnosis is rarely made preoperatively. Intraoperatively, it may be suggested by the appreciation of a tense firm mass within the nerve root sleeve or by the negative exploration of a level with obvious clinical signs and clear cut radiographic abnormalities (after verifying that the correct level is exposed).

Surgical treatment:

Although a surgical dural opening may be utilized, others have found this to be necessary in a minority of cases.

69.1.14 Intravertebral disc herniation

General information

AKA Schmorl’s node or nodule. Named for German pathologist Christian Georg Schmorl (1861–1932) the term was first used in 1971. AKA Schmor’s (no “l”) nodule AKA Geipel hernia. Disc herniation through the cartilaginous end-plate into the cancellous bone of the vertebral body (VB) (AKA intraspongious disc herniation). Often an incidental finding on x-ray or MRI. Clinical significance is controversial. May produce low back pain initially that lasts ≈ 3–4 months after onset. Diffuse displacement (as may be seen in osteoporosis) is sometimes referred to as a balloon disc.

Clinical findings

During the acute (symptomatic) phase, patients may exhibit LBP that is aggravated by weight bearing and movement. There may be tenderness to percussion or manual compression over the involved segment.

Radiographic findings

MRI: the extrusion of disc material into the VB is easily appreciated on sagittal images. It has been suggested that acute (symptomatic) lesions may appear differentiated from chronic (asymptomatic) lesions by the presence of MRI findings of inflammation in the bone marrow immediately surrounding the node as outlined in Table 69.6.

CT: demonstrates defect in endplate and vertebral body since disc material has a significantly lower density than bone.

Plain x-ray: ≤ 33% may be seen on plain x-rays. They may not be detectable acutely until sclerotic osseous bone casting develops.

Treatment

Conservative treatment is indicated, usually consisting of non-steroidal anti-inflammatory drugs (NSAIDs). Occasionally stronger pain medication and/or lumbar bracing may be required. Surgery is rarely indicated.
Outcome

With conservative treatment, symptoms generally resolve within 3–4 months of onset (as with most vertebral body fractures).

69.1.15 Recurrent herniated lumbar disc

General information

Rates quoted in the literature range from 3–19% with the higher rates usually in series with longer follow-up. In an individual series with 10 year mean F/U, the rate of recurrent disc herniation was 4% (same level, either side), one third of which occurred during the 1st year post-op (mean: 4.3 yrs). A second recurrence at the same site occurred in 1% in another series with mean F/U of 4.5 yrs. In this series, patients presenting for a second time with disc herniation had a recurrence at the same level in 74% but 26% had a HLD at another level. Recurrent HLD occurred at L4–5 more than twice as often as L5–S1.

It is often possible for a smaller amount of recurrent herniated disc to cause symptoms than in a “virgin back”, due to the fact that the nerve root is often fixated by scar tissue and has little ability to deviate away from the fragment.

Treatment

Initial recommended treatment is as with a first time HLD. Nonsurgical treatment should be utilized in the absence of progressive neurologic deficit, cauda equina syndrome (CES) or intractable pain.

69.1.16 Surgical treatment

Disagreement occurs regarding optimal treatment. See Practice guideline: Lumbar fusion for disc herniation (p.1037).

Surgical outcome:

As with first time HLD, the outcome from surgical treatment is worse in worker’s compensation cases and in patients undertaking litigation, only 40% of these patients benefit. A worse prognosis is also associated with: patients with <6 mos relief after their first operation, cases where fibrosis without recurrent HLD is found at operation.

69.1.17 Spinal cord stimulation

One study actually showed a better response rate to spinal cord stimulation than to reoperation. Since surgery for recurrent HLD carries a higher risk of dural and nerve root injury, and a lower success rate than first time operations, this may be a viable option for some patients.

69.2 Thoracic disc herniation

69.2.1 General information

<table>
<thead>
<tr>
<th>Key concepts</th>
</tr>
</thead>
<tbody>
<tr>
<td>• comprise only 0.25% of herniated discs, and &lt;4% of operations for herniated disc</td>
</tr>
<tr>
<td>• usually occur at or below T8 (the more mobile portion of the thoracic spine)</td>
</tr>
<tr>
<td>• frequently calcified get CT through disc (may affect choice of surgical approach)</td>
</tr>
</tbody>
</table>
- primary indications for surgery: refractory pain, progressive myelopathy
- surgical treatment: laminectomy is usually not appropriate

Account for 0.25–0.75% of all protruded discs.\textsuperscript{110} 80% occur between the 3rd and 5th decades. 75% are below T8 (the more mobile portion of the thoracic spine), with a peak of 26% at T11–12. 94% were centrolateral and 6% were lateral.\textsuperscript{111} A history of trauma may be elicited in 25% of cases.

Most common symptoms: pain (60%), sensory changes (23%), motor changes (18%). With thoracic radiculopathy, pain and sensory disturbance is in a band-like distribution radiating anteriorly and inferiorly along the involved root’s dermatome. Motor involvement is difficult to document.

69.2.2 Evaluation
MRI is the mainstay of diagnosis. However, it is almost mandatory to also obtain a CT scan to determine if the disc is soft or calcified (“hard disc”) which can have a profound effect on the approach. The CT is also useful to demonstrate bony detail if instrumentation is needed.

69.2.3 Indications for surgery
Herniated thoracic discs requiring surgery are rare.\textsuperscript{111} Indications: refractory pain (usually radicular, bandlike) or progressive myelopathy. Uncommon: symptomatic syringomyelia originating at level of disc herniation.

69.2.4 Surgical approaches
Surgery for thoracic disc disease is problematic because of: the difficulty of anterior approaches, the proportionately tighter space between cord and canal compared to the cervical and lumbar regions, and the watershed blood supply which creates a significant risk of cord injury with attempts to manipulate the cord when trying to work anteriorly to it from a posterior approach. Herniated thoracic discs are calcified in 65% of patients considered for surgery\textsuperscript{111} (more difficult to remove from a posterior or lateral approach than non-calcified discs).

Open surgical approaches\textsuperscript{111,112}:
1. posterior (midline laminectomy): primary indication is for decompression of posteriorly situated intracanalicular pathology (e.g. metastatic tumor) especially over multiple levels. There is a high failure and complication rate when used for single-level anterior pathology (e.g. midline disc herniation)
2. posterolateral
   a) lateral gutter: laminectomy plus removal of pedicle.
   b) transpedicular approach\textsuperscript{113}
   c) costotransversectomy (see below)
   d) transfacet pedicle sparing
3. anterolateral (transthoracic): usually through the pleural space
4. lateral extracavitary (retrocolic)\textsuperscript{114} staying external to the pleural space

Thoracoscopic surgery is an alternative to open surgery.

69.2.5 Choosing the approach
General information
See anterior approaches to the thoracic spine (p. 1489).
Intraoperative SSEPs and MEPs may be helpful for patients with myelopathy.
For a laterally herniated thoracic disc without myelopathy: posterolateral approach with medial facetectomy is technically simple, and has generally good results. For a central disc herniation, or when myelopathy is present: transthoracic approach has the lowest incidence of cord injury with the best operative results (Table 69.7). For anterior access, unless pathology is predominantly left-sided, a right-sided thoracotomy is preferred because the heart does not impede access.

Costotransversectomy
Indications: in the past this was often used to drain tuberculous spine abscess. It may be used for lateral disc herniation, biopsy of VB or pedicle, limited unilateral decompression of spinal cord from
tumor or bone fragments, or sympathectomy. Can be used at any T-spine level. Limitations: difficult to visualize anterior canal to access midline anterior pathology. Better for soft disc than for calcified central disc.

Involves resection of the transverse process and at least 4–5 cm of the posterior rib. A serious risk of this approach is interruption of a significant radicular artery which may compromise spinal cord blood supply; see Spinal cord vasculature (p. 87). There is also a risk of pneumothorax which is less grave.

**Booking the case: Costotransversectomy**

Also see defaults & disclaimers (p. 27).
1. position: prone, usually on chest rolls
2. equipment:
   a) microscope (not used for all cases)
   b) C-arm
3. implants: if post-op instability is anticipated, thoracic pedicle screws and possibly a cage (e.g. for fracture or tumor, not typically for disc herniation)
4. neuromonitoring: SSEP/MEP
5. blood availability: type and cross 2 U PRBC
6. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery through the back of the chest to remove a small piece of rib to permit removal of the herniated/calcified disc
   b) alternatives: nonsurgical management, surgery from the side through the chest
   c) complications: spinal cord injury with paralysis, lung complications including pneumothorax or hemothorax (blood or air outside lungs), possible seizures with MEPs

**69.2.6 Surgical technique**

The approach can be somewhat difficult due to the infrequent encounter with the anatomy by most neurosurgeons. Be prepared for a “deep, red hole, where everything initially looks the same and the bony anatomy is not easy to define.” With patience and persistence and the help of an anatomic model in the O.R., the surgeon can get his/her bearings. One of the most helpful landmarks is following the NVB (or just the nerve root) medially to the neural foramen.

In the O.R., before the prep and skin incision, localizing x-rays are obtained; a spinal needle inserted between 2 spinous processes may be used as a marker.

Patient position: the approach is from the side of the pathology/symptoms; for central disc herniations a right-sided approach reduces risk of injury to artery of Adamkiewicz (located on the left in 80% (p. 87)). Options:
1. lateral oblique, ≈ 30° elevated from straight prone, a “bean-bag” is good for stabilization. For a thin patient, the surgeon may stand in front of the patient (gives more horizontal angle of view – does not work as well with heavier patients due to mass of skin/muscle in the way laterally)

---

</tbody>
</table>
2. prone on chest rolls; the chest roll on the side of the pathology should be more medial to allow the shoulder and scapula to fall forward out of the way

Skin incision options:
1. curved paramedian skin incision: apex oriented away from the midline along the slight depression demarcating the junction of the lateral border of the paraspinal muscles with the ribs (= 6–7 cm lateral to midline) centered over the interspace of interest extending ≈ 3 vertebral bodies (VB) above and below. The incision is carried through the skin, subcutaneous fat, trapezius, and (for lower 6 thoracic levels, where most thoracic disc herniations occur) the latissimus dorsi, down to the ribs, and this musculocutaneous flap can be reflected medially as a unit.
2. midline incision: need to extend 3–4 levels above and below the level of pathology to get an angle low enough to visualize posterior to the facet in order to access the posterior vertebral body. The inferior aspect can be curved laterally towards the side of pathology. Advantage: a laminectomy can more easily be performed if needed (if the angle does not provide adequate visualization, as a “bail-out” contingency, a facetectomy may be performed, and pedicle may even be removed to access inferior to the disc space. This usually permits easy decompression of the entire thecal sac. In the thoracic spine, stabilization is optional, and if chosen, unilateral pedicle screws and fusion are usually adequate)

Rib removal and thoracic exposure: for a simple biopsy or drainage of a small abscess, removal of only 1 rib may suffice. The rib to be removed is from the level inferior to the disc space to be accessed (e.g. remove the T5 rib to access T4–5 disc space). For most other pathologies, 2 or 3 ribs are often removed. To access a VB, the like-numbered rib and the rib below are removed.

There are a number of ligaments attached to the rib: the intercostal neurovascular bundle (NVB) courses medial to the superior costotransverse ligament which extends from the superior aspect of the rib to the transverse process of the level above. This ligament and the lateral costotransverse ligament are divided and the transverse process is rongeured off (the base of which lies on the lamina directly posterior to the pedicle). This exposes the rib anterior to the transverse process. The periosteum is incised on the rib from the angle of the rib to the costovertebral articulation, and by subperiosteal dissection around its circumference the pleura is dissected off the anterior surface of the rib. The NVB is dissected from the deep-inferior surface along with the periosteum. The rib is then transected laterally at the angle (= 5 cm lateral to the rib head) with rib shears, it is gripped with a clamp, and is rotated while the ligaments (including the radiate ligaments which attach the rib to the both the VB above and the VB below the disc space at the superior and inferior costal facet, respectively, except T1, 11 & 12 which only articulate with their like-numbered VB) are sharply dissected off the rib which is then removed. The removed rib material may be used for fusion substrate except in cases of tumor or infection. The pleura is then dissected from the deep surface of the adjacent ribs and VB (taking care not to injure the segmental vessels and to dissect the sympathetic trunk off the VB with the pleura). The pleura is then retracted laterally with a malleable ribbon or Deaver retractor.

The intervertebral foramen of interest may be located by following the NVB of the rib above proximally, the intercostal nerve (the ventral ramus of the nerve root at that level) enters between the two pedicles. The dura may then be exposed by enlarging the neural foramen by removing part of the pedicles with a high-speed drill and Kerrison rongeers.

Instrumentation/fusion are rarely required for simple discectomy. Instability due to fracture, tumor, or extensive resection (e.g. with total facet takedown) necessitates surgical stabilization, typically with pedicle screws/rods extending 2 levels above and 2 levels below. Prior to closure, check for air leak by filling the opening with saline and having the anesthesiologist apply a valsalva maneuver. If an air leak is identified, a Cook catheter may be placed into the pleural space through the surgical exposure, or alternatively a chest tube is placed through a separate intercostal incision after the laminectomy wound is closed. A post-op CXR is obtained regardless of whether an air leak is identified.

Transpedicular approach
Drilling down the pedicle and removing a small amount of bone from the vertebral body, then pushing material from the epidural space into the defect created and removing it. Requires removal of just the rib head. Advantages: minimal risk of pneumothorax, more familiar anatomy. Disadvantages: requires instrumentation especially if done bilaterally, the angle is not very obliques so visualization of epidural space is minimal, may need to be done bilaterally if there are extensive bilateral components to the pathology.
Booking the case: Transpedicular approach

Same as for costotransversectomy (p. 1062).

Transthoracic approach

Indications: thoracic disc disease with central fragment or calcified disc, burst fractures of the thoracic spine, etc.

Advantages:
- excellent anterior exposure (especially advantageous for multiple levels)
- little compromise of stability (due to supporting effect of rib cage)
- low risk of mechanical cord injury

Disadvantages:
- requires thoracic surgeon (or familiarity with thoracic surgery)
- some risk of vascular cord injury (due to sacrifice of intercostal arteries)
- definitive diagnosis may not be possible if it is uncertain prior to procedure

Possible complications:
- pulmonary complications: pleural effusion, atelectasis, pneumonia, empyema, hypoventilation
- CSF-pleural fistula

Booking the case: Transthoracic spine surgery

Also see defaults & disclaimers (p. 27).
1. position: typically on the side, often on a beanbag
2. equipment:
   a) microscope (not used for all cases)
   b) C-arm
3. anesthesia: double lumen tube
4. implants: if post-op instability is anticipated, thoracic pedicle screws and possibly a cage (e.g. for fracture or tumor, not typically for disc herniation)
5. neuromonitoring: SSEP/MEP
6. blood availability: type and cross 2 U PRBC
7. some surgeons use chest surgeon for the approach, closure and for follow-up
8. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery through the chest with removal of a small piece of rib to permit removal of the herniated/calcified disc
   b) alternatives: nonsurgical management, surgery from the side or through the back
   c) complications: spinal cord injury with paralysis, pneumothorax, possible seizures with MEPs

Key technical points

1. the services of an experienced thoracic surgeon are usually engaged
2. position: true lateral (facilitates intra-op localizing x-rays); approached from the more involved side. For the upper thoracic midline region, some prefer right-side-up to eliminate thoracic aorta from obstructing exposure and to reduce the possibility of encountering the artery of Adamkiewicz, others prefer left-side-up to use the aorta as a landmark (for levels below the cardiophrenic angle, a left-sided approach is preferred because the inferior vena cava is difficult to mobilize)
3. usually one rib is resected; most often the rib of the vertebra immediately above the disc space desired (facilitates exposure). Multiple ribs may be resected to increase exposure
4. when removing the vertebral body (VB) (corpectomy, e.g. for osteomyelitis, especially Pott’s disease or for kyphoscoliosis)
a) the posterior cortex of the VB must be pulled anteriorly (e.g. with angled curettes) to avoid mechanical cord trauma
b) anterior fusion may be performed using the removed rib. If inadequate, fibula or iliac crest may be used

5. sizeable radicular arteries are spared. The intercostal nerve is used as a guide to the intervertebral foramen (nerve enters foramen superiorly and posteriorly)
6. the disc space is situated off the caudal aspect of the intervertebral foramen for most thoracic levels
7. one or two intervertebral arteries and veins usually have to be sacrificed; to minimize the risk of ischemic cord injury, cut them as close to the midline of the spine as possible (collaterals tend to lie on the lateral aspect of the spine)
8. the sympathetic chain is dissected off the VBs and is pushed posteriorly

Lateral (retrocolic) approach

See reference.14

The same instrumentation used for lateral lumbar interbody fusion (p.1498) may be used to access the lateral thoracic bodies for thoracic disc herniation.

Check the pre-op MRI for the location of the aorta and to rule-out aortic aneurysm. Above T11, enter on the right side. The access retractor is "reversed" so that the center blade is positioned anteriorly and the shim is place so that as the retractor is expanded in the AP direction, the lateral blades move posteriorly, giving more access to the posterior disc space. In general, do not penetrate the contralateral annulus because of proximity of aorta. At or just below L1–L2, the diaphragm attaches to the VB. A dual lumen endotracheal tube is not required. A chest tube is mandatory if there is an air leak, otherwise it is optional (a pigtail catheter may suffice).

70 Cervical Disc Herniation

70.1 General information

Important applied anatomy in herniated cervical disc (HCD):
1. in the cervical region, the nerve root exits above the pedicle of its like-numbered vertebra (opposite to the situation in the lumbar spine, due to the fact that there are 8 cervical nerve roots and only 7 cervical vertebrae)
2. each root exits passes through its neural foramen in close relation to the undersurface of the pedicle
3. the intervertebral disc space is located close to the inferior portion of the pedicle (unlike the lumbar region)

70.2 Cervical nerve root syndromes (cervical radiculopathy)

70.2.1 General information

Due to the facts listed above, a HCD usually impinges on the nerve exiting from the neural foramen at the level of the herniation (e.g. a C6–7 HCD usually causes C7 radiculopathy). This gives rise to the characteristic cervical nerve root syndromes shown in Table 70.1.

70.2.2 Miscellaneous clinical facts

C4 radiculopathy is not common, and may produce nonradiating axial neck pain.
Left C6 radiculopathy (e.g. from C5–6 HCD) occasionally presents with pain simulating an MI (pseudo-angina).
C8 and T1 nerve root involvement may produce a partial Horner's syndrome.
The most common scenario for patients with herniated cervical disc is that the symptoms were present upon awakening in the morning, without identifiable trauma or stress.¹

70.3 Cervical myelopathy and SCI due to cervical disc herniation

Acute cord compression presenting with myelopathy or spinal cord injury (SCI) (including complete SCI and incomplete syndromes, especially central cord syndrome (p.944) and sometimes Brown-Sequard syndrome (p.947) is well described in association with traumatic cervical disc herniation.² Less commonly, these findings may occur in non-traumatic cervical disc herniation.

*not everyone has a finger flexor reflex. Description: gently lift the fingertips of the patient’s pronated hand and tap the underside of the fingers with a reflex hammer. When present, fingers flex in response
70.4 Differential diagnosis
See Differential diagnosis (p.1420).

70.5 Physical exam for cervical disc herniation

70.5.1 Overview
1. evaluation for radiculopathy
   a) lower motor neuron findings
      ● weakness usually in one myotome group on one side
      ● muscle bulk and tone: atrophy and fasciculations, may be present
   b) sensation: with nerve root compression, sensory loss will follow a dermatomal pattern and
      will be in the same nerve root distribution as the weakness
   c) muscle stretch reflexes
   d) mechanical signs: reproduction of radicular symptoms with axial loading of the head
2. evidence of spinal cord involvement (myelopathy)
   a) upper motor neuron findings, usually in the lower extremities
      ● weakness may occur without atrophy or fasciculations
      ● spasticity: poor control of the legs when walking, scissoring of the legs
   b) sensation: any loss below the level of involvement will follow spinal cord patterns
      ● complete loss
      ● Brown-Sequard pattern: unilateral loss of pinprick with contralateral vibratory and position
        sense loss
      ● Central cord syndrome: suspended sensory loss in upper extremities, less impaired below
      ● Pathologic reflexes: Hoffmann’s reflex, Babinski sign, ankle clonus

70.5.2 Signs useful in evaluating cervical radiculopathy

General information
Almost all herniated cervical discs cause painful limitation of neck motion. Neck extension usually
aggravates pain when cervical disc disease is present (a minority of patients instead exhibit pain
with flexion). Some patients find relief in elevating the arm and cupping the back or the top of the
head with the hand (abduction relief sign, see below for shoulder abduction test). Lhermitte’s sign
(electrical shock-like sensation radiating down the spine) may be present; see DDx (p.1421).

Miscellaneous
The following tests were found to be specific, but not particularly sensitive in detecting cervical root
compression⁴:
1. Spurling’s sign⁵: radicular pain reproduced when the examiner exerts downward pressure on
   vertebra while tilting head towards symptomatic side (sometimes adding neck extension). Causes
   narrowing of the intervertebral foramen and possibly increases disc bulge. Used as a “mechanical
   sign” analogous to SLR for lumbar disc herniation
2. axial manual traction: 10–15 kg of axial traction is applied to a supine patient with radicular
   symptoms (pull up on patient’s mandible and occiput). The reduction or disappearance of radicular
   symptoms is a positive finding
3. shoulder abduction test⁶: a sitting patient with radicular symptoms lifts their hand above their
   head. The reduction or disappearance of radicular symptoms is a positive finding. Moderately
   sensitive, fairly specific⁷

70.6 Radiologic evaluation

70.6.1 MRI
The study of choice for initial evaluation for herniated cervical disc (HCD). Accuracy is less than water
soluble contrast myelogram/CT (≈ 85–90% accuracy for MRI because of only fair to good imaging of
neural foramen), but is non-invasive. For myelopathy, MRI is >95% effective in diagnosing.
Protocol:
1. sagittal T1WI
2. multiple echo cardiac gated sagittal images (T₁ = 1560, Tₑ = 25, 4th echo)
3. GRASS image: axial partial flip-angle fast scan (Tr = 25, Te = 13, angle = 8°). Dark material adjacent to disc space is bone, disc is higher signal, CSF and flowing blood are high signal.

70.6.2 CT and myelogram/CT

Indications: when MRI cannot be done or when more bony detail than what MRI provides is required. Evaluates for ossification of the posterior longitudinal ligament (OPLL) when suspected.

Plain CT: is usually good at C5–6, is variable at C6–7 (due to artifact from patient’s shoulders, depending on body habitus), and is usually poor at C7-T1.

Myelogram/CT (water soluble intrathecal contrast): invasive, on rare occasions requires overnight hospitalization. Accuracy is ≈ 98% for cervical disc disease.

70.6.3 Electrodiagnostics (EMG and NCV)

Compression may occur at the level of the dorsal (pre-ganglionic) sensory root (which, if occurs alone, produces a sensory-only radiculopathy) and/or at the ventral (motor) root. When motor exam is normal, EMG is unlikely to show abnormality. The AANEM practice parameter for cervical radiculopathy reports sensitivity of 50-71% for the needle EMG examination and correlation between positive needle EMG and radiologic findings of 65-85%.

EMG can also be normal in sensory only radiculopathy, which occasionally occurs in cervical spine, but not in lumbar spine. Since most muscles have at least dual innervation this poses a particular challenge for proximal cervical radiculopathies in which many muscles have the same shared innervation, e.g. biceps, deltoïd, brachioradialis, infraspinatus and supraspinatus are all innervated by C5-C6.

For both cervical and lumbar radiculopathy, screening 6 muscles representing all root levels to include paraspinal muscles yield consistently high identification rates.

For muscles to demonstrate fibrillations and positive waves there must be axonal loss in the motor nerve axons which innervates a muscle. Muscle demonstrates fibr and positive waves within 1 to 2 weeks following loss of innervation depending on the distance from the nerve to the muscle.

NCV is helpful to assess for peripheral neuropathies which may have symptoms similar to radiculopathy (e.g. carpal tunnel syndrome vs. C6 radiculopathy; ulnar neuropathy vs. C8 radiculopathy). A good physical exam can differentiate these entities in most cases.

Practice guideline: EDX guidelines for cervical radiculopathy

See reference.

1. Guideline: EMG needle examination:
   a) needle examination of at least 1 muscle innervated by C5, C6, C7, C8 and T1 spinal roots in a symptomatic limb
   b) cervical paraspinal muscles at 1 or more levels (except in patients with prior posterior approach cervical surgery
   c) if abnormalities are identified, perform studies of 1 or 2 additional muscles innervated by the suspected root and different peripheral nerve

2. Guideline: At least 1 motor and 1 sensory nerve conduction study (NCS) in the clinically involved limb to determine if there is concomitant polyneuropathy or nerve entrapment. Motor and sensory NCS of median and ulnar nerves if symptoms and signs suggest CTS or ulnar neuropathy. If 1 or more NCS are abnormal or if clinical features suggest polyneuropathy, further evaluation may include NCS of other nerves in the ipsilateral and contralateral limb

70.7 Treatment

70.7.1 General information

Over 90% of patients with acute cervical radiculopathy due to cervical disc herniation can improve without surgery, and regression of an extruded cervical disc has been demonstrated radiographically by CT and MRI. The recovery period may be made more tolerable by adequate pain medication, anti-inflammatory medication (NSAIDs or short-course tapering steroids) and intermittent cervical traction (e.g. gradually escalating up to 10–15 lbs for 10–15 minutes, 2–3 × daily).
Surgery is indicated for those that fail to improve or those with progressive neurologic deficit while undergoing non-surgical management. Management of myelopathy/central cord syndrome associated with acute cervical disc herniation is controversial, since the natural history is favorable in most cases. However, some patients have poor recovery and experience permanent deficits even with emergency surgery.\textsuperscript{16}

### 70.7.2 Conservative management

Modalities include:

1. Physical therapy, which may also include cervical traction.
2. Interventional pain management
   a) Trigger point injections
   b) Facet blocks
   c) Epidural steroid injection: not used as often and with lumbar spine

### 70.7.3 Surgery

**Surgical options**

1. Anterior cervical discectomy: see below
   a) without any prosthesis or fusion: rarely used today
   b) combined with interbody fusion: the most common approach
      • without anterior cervical plating
      • with anterior cervical plating or with zero profile
   c) with artificial disc AKA cervical disc arthroplasty

2. Posterior approaches
   a) Cervical laminectomy: not typically used for a herniated cervical disc, more common for cervical spinal stenosis, OPLL
      • without posterior fusion
      • with lateral mass fusion
   b) Keyhole laminotomy: sometimes permits removal of disc fragment

For practice guidelines regarding intra-op electrophysiologic, see monitoring for surgery for cervical radiculopathy (p. 1090).

**Anterior cervical discectomy with fusion (ACDF)**

Without special modifications, a routine anterior approach is usually able to access levels C3–7. In patients with short thick necks, access may be even more limited. In some cases, with long thin necks, up to C2–3 or as low as C7–T1 can be approached anteriorly.

**Advantages over posterior (nonfused) approach:**

1. Safe removal of anterior osteophytes
2. Fusion of disc space affords immobility (up to 10% incidence of subluxation with extensive posterior approach)
3. Only viable means of directly dealing with centrally herniated disc

**Disadvantages over posterior approach:** Immobility at fused level may increase stress on adjacent disc spaces. If a fusion is performed, some surgeons prescribe a rigid collar (e.g., Philadelphia collar) for 6–12 weeks. Multiple level ACDF can devascularize the vertebral body (or bodies) between discectomies.

**Booking the case: ACDF**

Also see defaults & disclaimers (p. 27).
1. Position: supine, some use halter traction with this
2. Equipment:
   a) Microscope (not used by all surgeons)
   b) C-arm
3. Implants: graft (e.g., PEEK, cadaver bone, titanium cage...) and anterior cervical plate (optional, especially on single level ACDF)
4. neuromonitoring: (optional) some surgeons used SSEP/MEP
5. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery through the front of the neck to remove the degenerated disc and bone spurs, and to place a graft where the disc was, and possibly place a metal plate on the front of the spine. Some surgeons take bone from the hip to replace the removed disc
   b) alternatives: nonsurgical management, surgery from the back of the neck, artificial disc (in some cases)
   c) complications: swallowing difficulties are common but usually resolve, hoarseness of the voice (<4% chance of it being permanent), injury to: foodpipe (esophagus), windpipe (trachea), arteries to the brain (carotid), spinal cord with paralysis, nerve root with paralysis, possible seizures with MEPs

Technique

A summary of the steps involved is included here. For C5–6, the skin incision is made at level of cricoid cartilage, for other levels, appropriate adjustments up or down may be made, sometimes with the assistance of fluoroscopy. The incision is approximately 4–5 cm horizontally, centered on the SCM. Many right handed surgeons prefer operating from the right side of the neck, although the risk to the recurrent laryngeal nerve (RLN) is lower with a left sided approach (the RLN lies in a groove between the esophagus and trachea). The skin may be undermined off the platysma to permit a vertical incision in the platysma in the same orientation as its muscle fibers. Alternatively, some incise the platysma horizontally with scissors horizontally.

Dissect in tissue plane medial to SCM. For the C5–6 interspace, angle slightly cranially during dissection. For the C6–7 disc, proceed almost straight down to spine. Sweep omohyoid medially (to stay out of it and to protect the RLN). The trachea + esophagus are retracted medially. The carotid sheath + SCM are retracted laterally.

After verification of level with lateral C-spine x-ray with spinal needle in the interspace, bipolar the prevertebral fascia and medial edges of the longus coli muscles longitudinally in the midline. Self-retaining retractor blades are inserted underneath the fascia to retract the longus coli muscles laterally. The anesthesiologist is asked to deflate the cuff on the endotracheal tube and then to re-inflate it using minimal leak technique to reduce the risk of compression injury from the retractor.

The disc space is incised with a 15 scalpel blade. The discectomy is performed with curettes and pituitary rongeurs; a vertebral body spreader aids the exposure. The posterior longitudinal ligament is incised, one technique is to elevate it with a sharp nerve hook and then incise it with a #11 scalpel. The subligamentous space is probed with a blunt nerve hook. The posterior lip of the VB above and below are removed with a Kerrison rongeur with a small foot-plate. Decompression of the roots is verified with the blunt nerve hook. Fusion is performed at this time if desired by placing the graft in the interspace.

For redo operations (same or different levels): approach is usually from the same side as previous operation(s) since many patients have swelling issues post-op, and some may be due to partial recurrent laryngeal nerve injury (which can be subclinical) and which could result in a permanent need for a feeding tube if a contralateral injury occurs. If for some reason it is desired to go to the opposite side, an evaluation by an ENT physician is recommended, and should include scoping the patient to rule out subclinical problems that could turn into major difficulties if bilateral.

Choice of graft material

Autologous bone (usually from iliac crest), non-autologous bone (cadaveric), bone substitutes (e.g. hydroxyapatite or synthetics (e.g. PEEK or titanium cage) filled with osteogenic material. Substitutes for autologous bone eliminate problems with the donor site (p.1075), but may have a higher rate of absorption. There were also cases of HIV transmission from cadaveric bone grafts in 1985, however, as a result of the heightened awareness of AIDS since that time together with significant improvements in antibody testing and careful screening of donors, no further cases have been reported.

Anterior cervical plating

Recommendations for plating following ACDF are shown in Practice guideline: Anterior cervical plating (p.1074).
Practice guideline: Anterior cervical plating

1 level A DCF: The addition of an anterior plate to an ACDF is recommended to reduce the pseudarthrosis rate and graft problems (Level D Class III) and to maintain lordosis (Level C Class II) but it does not improve clinical outcome alone (Level B Class II)\textsuperscript{18}

2 level A DCF: Plating is recommended to improve arm pain. Plating does not improve other outcome parameters (Level C Class II)

Use of bone morphogenic proteins (BMP)

Practice guideline: Use of BMP in cervical interbody grafting

Current evidence does not support the routine use of rhBMP-2 for cervical arthrodesis (Level C Class II)\textsuperscript{19} (note: italics added. Use with precautions (see text) may be indicated in cases with high risk of nonunion).

Use of BMP in anterior cervical discectomies is not FDA approved, but has been used off-label. Complication rates as high as 23–27% have been reported (including post-op swallowing or respiratory difficulties as a result of edema which is usually temporary) compared to 3% without BMP.\textsuperscript{19} If used, it is recommended that a smaller dose be employed than in the lumbar spine (25% has been advocated) and to avoid contact of BMP with soft tissues in the neck.

Post-op check

In addition to routine, the following should be checked

1. evidence of airway obstruction – post-op wound hematoma: should be first consideration. Wound may need to be emergently opened at bedside (before getting to the OR) if airway is compromised, see Carotid endarterectomy, disruption of arteriotomy closure, management (p.1294). Also consider swelling from IJV thrombosis (rare) in differential diagnosis (see below)
   a) respiratory distress
   b) extreme difficulty swallowing: alternatively may indicate anterior extrusion of bone graft impinging upon esophagus (check lateral C-spine x-ray)
   c) tracheal deviation: may be visible or may be seen on AP C-spine x-ray

2. weakness of nerve root of level operated: e.g. biceps for C5–6, triceps for C6–7

3. long tract signs (Babinski sign…) which may indicate cord compression by spinal epidural hematoma

4. hoarseness: may indicate vocal cord paresis from recurrent laryngeal nerve injury: hold oral feeding until this can be further assessed

ACDF complications

General information

Common ones listed below, see references\textsuperscript{20,21} for more details. The most common complication following ACDFs: swallowing difficulties (may be multifactorial).

1. exposure injuries
   a) perforation of viscus: minimize risk by blunt retraction until longus colli is separated from its attachment to vertebrae
      • pharynx
      • esophagus: difficult to manage, and require multidisciplinary effort including ENT involvement.\textsuperscript{22} The incidence may be higher with use of anterior cervical plate, and injury may not manifest until years after the fusion (may be due to repetitive motion of esophagus over the plate). Treatment of esophageal perforation is usually facilitated by plate removal
      • trachea
   b) vocal cord paresis: due to injury of the recurrent laryngeal nerve (RLN) or vagus. Incidence: 11% temporary, 4% permanent paresis. Symptoms include: hoarseness, breathiness, cough, aspiration, mass sensation, dysphagia, and vocal cord fatigue.\textsuperscript{23} Avoid sharp dissection in parapharyngeal space. Some cases may be due to prolonged retraction against trachea and not to nerve division; to reduce this risk, after the self-retaining retractor is placed, have the
anesthesiologist deflate the cuff on the ET tube and then inflate it to minimal leak pressure. More common with right sided approaches, primarily in the lower cervical spine (C5–6 and below) where the RLN is more vulnerable.

c) vertebral artery injury: thrombosis or laceration. 0.3% incidence. Treatment alternatives include: packing, direct repair by temporary clipping with aneurysms clips and repair with 8–0 prolene and endovascular trapping. Risks of treating hemorrhagic complications with packing include: recurrent bleeding, AV fistula, pseudoaneurysm, arterial thrombosis, distal embolic stroke (primarily in cerebellum).

d) carotid injury: thrombosis, occlusion, or laceration (usually by retraction)

e) CSF fistula: usually difficult to repair directly. Place fascial graft beneath bone plug. Keep HOB elevated post-op. Consider: dural sealant (fibrin glue, DuraSeal®,...), lumbar drain

f) Horner’s syndrome: sympathetic plexus lies within longus coli, thus do not extend dissection far laterally into these muscles

g) thoracic duct injury: in exposing lower cervical spine, primarily on left

h) thrombosis of internal jugular vein: rare. Carries 2–3% risk of PE.

2. spinal cord or nerve root injuries

a) spinal cord injury: especially risky in myelopathy due to narrowed canal. Minimize risk by penetrating the osteophyte at the lateral margin of interspace (however, this increases risk to nerve root)

b) avoid hyperextension during intubation: anesthesiologist may need to determine patient’s tolerance pre-op. Consider fiberoptic guided or awake nasotracheal intubation in extreme stenosis

c) bone graft must be shorter than interspace depth. Exercise caution in tapping graft into position

d) sleep induced apnea: rare but serious complications of C3–4 level operations. May be associated with bradycardia & cardiorespiratory instability. Possibly due to disruption of the afferent component of the central respiratory control mechanism.

3. bone fusion problems

a) failure of fusion (pseudarthrosis): see below

b) anterior (kyphotic) angulation deformity: may be as high as 60% with Cloward technique (may be reduced by collar immobilization). May develop in Hirsch technique with excessive bone removal

c) graft extrusion: 2% incidence (rarely requires re-operation unless compression of cord posteriorly, or esophagus or trachea anteriorly occurs)

d) donor site complications: hematoma-seroma, infection, fracture of ilium, injury to lateral femoral cutaneous nerve, persistent pain due to scar, bowel perforation

4. miscellaneous

a) wound infection: incidence <1%

b) post-op hematoma: see above. Placing cervical collar in O.R. may delay recognition
c) dysphagia and hoarseness: common. Usually transient (see below)

d) adjacent level degeneration: controversial whether this represents a sequelae to altered biomechanics from surgery, or a predisposition to cervical spondylosis. Many (~70%) are asymptomatic.

e) postoperative discomfort:
   • globus: the sensation of a lump in throat (see below)
   • nagging discomfort in neck, shoulder, and very commonly in interscapular regions (may last several months). May correlate with amount of distraction of the disc space

f) complex regional pain syndrome (CRPS) AKA reflex sympathetic dystrophy (RSD): rarely described in the literature, possibly due to stellate ganglion injury; see discussion of RSD (p.497)

g) angioedema: massive edema of the tongue and neck. A dramatic hypersensitivity reaction (not really a direct complication of ACDF, but superficially can mimic some findings of post-op hematoma). If limited to the tongue, the airway is not compromised. See treatment (p.222)

h) pneumothorax or hemothorax: accessing C7-T1 or lower may expose the pleural apex

Dysphagia following ACDF

Symptoms: Include: difficulty swallowing (solids, liquids including saliva), pain with swallowing (odynophagia), globus (sensation of a lump in throat) and compromise of ability to protect against aspiration. Food may stick in the throat (or feel as if it is) and there may be coughing or choking.
Incidence: Early dysphagia is common. Incidence: 60% in retrospective survey after noninstrumented fusion (dysphagia occurred in 23% in a control group undergoing unrelated lumbar spine surgery), 50% in prospective study. At 6 months, only ~5% reported moderate or severe dysphagia. Surgery at multiple levels increased the risk at 1 & 2 months. Decreases significantly in most cases by 6 months.

Etiologies: Etiologies of post-op dysphagia include:
1. post-op hematoma. If severe, may cause tracheal obstruction (see above)
2. post-op edema, due in part to retraction of esophagus
3. effects of general anesthesia: e.g. irritation from ET tube. Accounts for up to 23% of early symptoms (dysphagia occurred in 23% in a control group undergoing unrelated lumbar spine surgery). Usually subsides within ~24–72 hours
4. recurrent laryngeal nerve dysfunction:
   a) temporary: usually due to traction on the nerve
   b) permanent: 1.3% at 12 months
5. esophageal injury
   a) at time of surgery
   b) delayed: possibly from repetitive abrasion on surgical site/hardware or from unrecognized esophageal injury at time of surgery
6. cervical collar
   a) prevents patient from lowering jaw during swallow phase, which compromises effective glottic closure of airway
   b) may be too tight thereby directly squeezing the throat
7. protrusion of graft/hardware anterior to the vertebral bodies
   a) some protrusion is present with most anterior hardware. This may be minimized with “zero profile” instrumentation
   b) hardware failure (screw-pullout/backout/breakage, plate pullout)
   c) interbody graft migration: without anterior plate, or in conjunction with anterior plate displacement
8. excessive adhesions
9. denervation of the pharyngeal plexus
10. rare conditions: swelling from IJV thrombosis, angioedema

Management:
1. initial management: rule-out emergent/serious conditions (severe edema, hematoma with airway compromise, risk of aspiration)
   a) if there is significant stridor or dysphonia, especially if tracheal deviation is obvious, someone must stay with the patient as efforts are made to emergently take the patient to the O.R. for wound exploration evacuation. Consider opening the wound at the bedside if delays occur or if symptoms are severe; see Carotid endarterectomy, disruption of arteriotomy closure, management (p.1294). Emergent anesthesia consultation for airway protection – alert them to the likelihood of deviated trachea which challenges even the most expert at intubating
2. once emergent conditions are ruled out, early management is geared towards amelioration of symptoms
   a) advise patient to eat softer foods (temporarily avoiding steak or bread), to chew food well, to wash down dry foods with a drink. Reassure patient that most cases largely resolve with 6 months
   b) if significant symptoms persist >2 weeks
      ● refer patient to ENT for laryngoscopy to rule out vocal cord paralysis (from RLN injury) or other etiologies. For RLN, see below
      ● modified barium swallow
3. persistent symptoms may be amenable to surgical intervention, including hardware removal and lysing of adhesions, management of esophageal perforation usually requires consultation with ENT

Management of esophageal perforation:
There is no consensus on optimal management. A multidisciplinary approach with head and neck surgeons together with the spine surgeon is suggested with the following:
- Closure with a sternocleidomastoid muscle flap, or possibly a pedicle flap
- Removal of all anterior hardware. If there is evidence that the fusion is not solid, posterior instrumentation may be necessary
Recurrent laryngeal nerve paralysis

Heralded by breathy voice, hoarseness, or aspiration. Refer to ENT to have patient scoped to determine if cord is paralyzed and its position. 4 possible positions: 1) median, 2) paramedian, 3) intermediate, 4) lateral (cadaveric). Many patients can compensate for median or paramedian position. Patients requiring intervention usually are treated with medialization technique, either 1) injection, or 2) medialization thyroplasty using an implant. For injections, different materials may be selected for desired duration of effect (Teflon used to be the only available agent, and was essentially permanent) and so early intervention may be employed with temporary materials (instead of waiting 1 year, which was the previous paradigm).

Pseudarthrosis (or pseudoarthrosis) following ACDF

Pseudarthrosis may occur with or without supplemental anterior cervical plating.

**Practice guideline: Assessment of subaxial fusion**

>2 mm movement between spinous processes on dynamic (flexion-extension) cervical spine x-rays is recommended as a criteria for pseudarthrosis (Level B Class II), this measurement is unreliable when performed by the treating surgeon (level C Class II).

Visualization of bone trabeculation across the fusion on static films is a less reliable marker for fusion (Level D Class III) (2D reformatted CT increases the accuracy (Level D Class III)).

In incidence: Difficult to assess because of lack of validated criteria. Estimate: 2–20% Higher with dowel technique (Cloward) than with keystone technique of Bailey & Badgley or with interbody method of Smith-Robinson (10% or with non-fusion advocated by Hirsch. One criteria: motion >2 mm between the tips of the spinous processes on lateral flexion/extension x-rays. Other criteria: lucencies around the screws of an anterior plate, toggling of the screws on flexion/extension x-rays.

Presentation: Not uniformly associated with symptoms or problems. Some patients may have chronic or recurrent neck pain, some may present with radicular symptoms. (NB: when DePalma’s data is analyzed with patients reclassified as failures if neck and/or arm symptoms persist, the success rate of surgery is lower with pseudarthrosis).

Management: Guidelines are shown in Practice guideline: Management of anterior cervical pseudarthrosis (p.1077). No treatment is required for asymptomatic pseudarthrosis. Options for symptomatic patients include re-resection of the bone graft with repeat fusion (some recommend using autologous bone if allograft was used, a plate may be considered if one was not used previously), cervical corpectomy with fusion, or posterior cervical fusion.

**Practice guideline: Management of anterior cervical pseudarthrosis**

Revision of symptomatic pseudarthrosis should be considered (Level D Class III). Posterior approaches may be associated with higher fusion rates on revision than anterior approaches (Level D Class III).

Cervical disc arthroplasty

An alternative to fusion. Uses an artificial disc to preserve motion at the level of the discectomy. Some of the available cervical disc replacement (CDR) models are shown in Table 70.2.

Contraindications described by the FDA have included: isolated axial neck pain, ankylosing spondylitis or pregnancy, rheumatoid arthritis, autoimmune disease, diffuse idiopathic skeletal hyperostosis, severe spondylolisthesis with bridging osteophytes or ossification of the posterior longitudinal ligament, disc height loss > 50% spinal infection, metal allergy to components of the prosthesis, severe osteoporosis/osteopenia, active malignancy, metabolic bone disease, trauma, segmental instability, 3 or more levels requiring treatment, insulin dependent diabetes mellitus, human immunodeficiency virus, hepatitis B/C, morbid obesity, absence of motion (<2 degrees), and posterior facet arthrosis.
Cervical disc arthroplasty is a recommended alternative to ACDF in selected patients for control of arm and neck pain (Level B Class II)\(^\text{18}\).

**Booking the case: Cervical disc arthroplasty**

Also see defaults & disclaimers and/or more significant (p. 27).

1. **position:** supine, some use halter traction with this
2. **equipment:**
   a) microscope (not used by all surgeons)
   b) C-arm
3. **implants:** schedule vendor to provide desired artificial disc
4. **neuromonitoring:** (optional) some surgeons used SSEP/MEP
5. **consent** (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery through the front of the neck to remove the degenerated disc and bone spurs, and to place an artificial disc
   b) alternatives: nonsurgical management, surgical fusion (from the front or the back of the neck)
   c) complications: swallowing difficulties are common but usually resolve, hoarseness of the voice (<4% chance of it being permanent), injury to: foodpipe (esophagus), windpipe (trachea), arteries to the brain (carotid) with stroke, spinal cord with paralysis, nerve root with paralysis, possible seizures with MEPs (if used). The disc may eventually wear out and further surgery may be needed

**Post-op orders:**
1. no cervical collar (the goal is to preserve motion at the operated level)
2. NSAIDs around the clock for \(\approx\) 2 weeks (this inhibits bone growth which theoretically helps avoid undesirable fusion at the operated level)

**Posterior cervical decompression (cervical laminectomy)**

Not necessary for unilateral radiculopathy (use either ACD or keyhole laminotomy). Consists of removal of cervical lamina (laminectomy) and spinous processes in order to convert the spinal canal from a “tube” to a “trough.”
Usually reserved for the following conditions:

1. multiple cervical discs or osteophytes (anterior cervical discectomy (ACD) is usually used to treat only 2, or possibly 3, levels without) with myelopathy
2. where the anterior pathology is superimposed on cervical stenosis, and the latter is more diffuse and/or more significant (p. 1083)
3. in professional speakers or singers where the 4% risk of permanent voice change due to recurrent laryngeal nerve injury with ACD may be unacceptable

**Booking the case: Cervical laminectomy**

Also see defaults & disclaimers (p. 27).

1. position: prone, some use pin headholder
2. equipment:
   a) C-arm
   b) high-speed drill
3. implants: cervical lateral mass screws and rods if fusion is being done
4. neuromonitoring: some surgeons used SSEP/MEP
5. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery through the back of the neck to remove the bone over the compressed spinal cord and nerves and possibly to place screws and rods to fuse the boned together
   b) alternatives: nonsurgical management, surgery from the front of the neck, posterior surgery without fusion, laminoplasty
   c) complications: nerve root injury (C5 nerve root is the most common), may not relieve symptoms necessitating further surgery, possible seizures with MEPs. If fusion is not done, risk of progressive bone slippage which would require further surgery

**Posterior keyhole laminotomy**

AKA “keyhole foraminotomy.” First described in 1951. A technique to decompress only individual nerve roots (but not the spinal cord) by creating a small “keyhole” in the lamina to access the nerve root.

**Practice guideline: Cervical laminoforaminotomy**

Cervical laminoforaminotomy is recommended as a surgical treatment option for symptomatic cervical radiculopathy caused by disc herniation or lateral recess narrowing (Level D Class III).

Indications for keyhole approach (as opposed to anterior discectomy):

1. monoradiculopathy with posterolateral soft disc sequestration (small lateral osteophytic spurs may also be addressed). This approach does not provide adequate decompression with central or broad-based disc herniation or with stenosis of the spinal canal
2. radiculopathy in patients who are professional speakers or singers where the risk of recurrent laryngeal nerve injury is untenable (see above)
3. for lower (e.g. C7, C8 or T1) or upper (e.g. C3 or C4) cervical nerve root compression, especially in a patient with a short thick neck, making an anterior approach more difficult
4. in patients with a herniated disc when it is desired to avoid a fusion (as would be done with an anterior approach)

**Booking the case: Cervical keyhole laminectomy**

Also see defaults & disclaimers (p. 27).

1. position: prone, some use pin headholder
2. equipment:
   a) microscope (not used by all surgeons)
   b) C-arm
3. instrumentation: some surgeons use a tube retractor system
4. neuromonitoring: some surgeons used SSEP/MEP
5. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery through the back of the neck to remove the bone over the compressed nerve root and possibly remove fragment of herniated disc
   b) alternatives: nonsurgical management, surgery from the front of the neck, posterior surgery with fusion
   c) complications: nerve root injury, may not relieve symptoms necessitating further surgery, possible seizures with MEPs

Technique
See references 49,50,51
Position:
   a) prone, on chest rolls. Adhesive tape is used to retract shoulders down for any level below about C4–5. The head is stabilized on a horse-shoe headrest or in a Mayfield head holder.
   b) sitting position: generally abandoned. However, may be used with proper precautions (p.1445)

“Open” keyhole foraminotomy
The desired level is localized with intra-op fluoroscopy before making the skin incision, a 2–3 cm midline incision is adequate. A unilateral exposure suffices. Periosteal elevators are used to dissect muscles off the lamina and facet joint in the sub-periosteal plane. A Kocher clamp may be placed on the spinous process to permit confirmation of the correct level on intra-operative x-ray. A Scoville retractor or equivalent is employed.

A high-speed drill (e.g. with diamond burr) is used to make an opening in the medial one-third to one-half of the inferior facet of the vertebra above the desired disc space, extending slightly medially into the junction with the lamina. Once the inferior facet is penetrated, the superior facet of the inferior vertebral level will be visualized. This is also thinned with the drill (it is critical to remove the bone of the superior facet of the level below caudally to where it meets the pedicle). A small Kerrison rongeur may be used to slightly enlarge the laminectomy. An opening is made in the ligamentum flavum overlying the lateral aspect of the spinal cord dura. The nerve root can be identified as it exits from the thecal sac, and can be followed as it travels between the pedicles of the vertebrae above and below. Soft tissues (including ligamentum flavum) form fibrous bands across the dorsum of the nerve, and are removed to further expose the dura of the nerve root. The venous plexus around the nerve root is coagulated with bipolar cautery and then divided to mobilize the nerve. The nerve may then be gently moved a few millimeters rostrally using a micro nerve hook. The dura overlying the spinal cord should not be manipulated, and the disc space need not be entered. Inspection for free disc fragments should begin in the nerve root axilla using a probe (e.g. blunt nerve hook). Next, the space anterior to the root (the region of the disc) may be palpated. Any disc fragments that are dislodged are removed with a small pituitary rongeur. If the disc fragment is contained anterior to the posterior longitudinal ligament (PLL), the PLL may be incised in the region of the nerve root axilla with a #11 scalpel blade in a motion that is directed downward and laterally, away from the nerve root and spinal cord. The foraminotomy may be extended slightly laterally if the foramen still feels tight when probed. Small osteophytes can potentially be reduced using a small reversed-angled curette, although some surgeons believe that the need for this is obviated by the decompression provided by the keyhole opening. In some cases, simple posterior decompression of the nerve root (without removing a disc fragment) may be adequate to relieve compression. Spinal stability is usually preserved if less than half the facet joint is removed.

MIS keyhole foraminotomy
Positioning as described above.
1. skin incision
   a) use fluoro to locate the correct level for the incision
   b) incision 1 cm off midline on the side of the pathology at the level of the disc space
   c) remove adhesive plastic barrier (e.g. Ioban®) from around the opening to prevent pieces from being dragged into the incision
2. avoid using a guidewire to reduce the risk of penetrating the interlaminar space. STAY LATERAL
and insert the thinnest dilator. Dock the dilator on the lateral mass and insert progressively sized
dilators
3. use Bovie to expose lateral lamina and medial facet joint. Start laterally where bone is more easily
felt and there is little danger of penetrating the interlaminar space and injuring the spinal cord
4. use a straight curette to expose the inferior edge of the superior lateral lamina and the medial
facet joint
5. drill off the medial inferior facet, to expose the superior facet of the level below
6. drill the medial superior facet until you are flush with the superior aspect of the pedicle below
7. this completes the bony work, the soft tissue work proceeds as above under open keyhole
foraminotomy

Outcome
A number of large series have reported good or excellent outcome in the range of 90–96%.

References

71 Degenerative Cervical Disc Disease and Cervical Myelopathy

71.1 General information

Cervical degenerative disc disease is generally discussed in terms of “cervical spondylosis”, a term which is sometimes used synonymously with “cervical spinal stenosis.” Spondylosis usually implies a more widespread age-related degenerative condition of the cervical spine including various combinations of the following:

1. congenital spinal stenosis (the “shallow cervical canal”)
2. degeneration of the intervertebral disc producing a focal stenosis due to a “cervical bar” which is usually a combination of:
   a) osteophytic spurs (“hard disc” in neurosurgical jargon)
   b) and/or protrusion of intervertebral disc material (“soft disc”)
3. hypertrophy of any of the following (which also contributes to canal stenosis):
   a) lamina
   b) dura
   c) articular facets
   d) ligaments, including
      • increased stenosis in extension is more common than with flexion (based on MRI studies and cadaver studies), largely due to posterior inbuckling of ligamentum flavum
      • posterior longitudinal ligament: may include ossification of the posterior longitudinal ligament (OPLL) (p. 1127). May be segmental or diffuse. Often adherent to dura
      • ossification of the ligamentum flavum (yellow ligament)
4. subluxation: due to disc and facet joint degeneration
5. altered mobility: severely spondylotic levels may be fused and are usually stable, however there is often hypermobility at adjacent or other segments
6. telescoping of the spine due to loss of height of VBs → “shingling” of laminae
7. alteration of the normal lordotic curvature (NB: the amount of abnormal curvature did not correlate with the degree of myelopathy)
   a) reduction of lordosis: including
      • straightening
      • reversal of the curvature (kyphosis): may cause “bowstringing” of the spinal cord across osteophytes
   b) exaggerated lordosis (hyperlordosis): the least common variant (may also cause bowstringing)

Although the majority of individuals > 50 yrs old have radiologic evidence of significant degenerative disease of the cervical spine, only a small percentage will experience neurologic symptoms.

71.2 Pathophysiology

Pathogenesis is controversial. Theories include the following alone or in combination:

1. direct cord compression between osteophytic bars and hypertrophy or infolding of the ligamentum flavum, especially if superimposed on congenital narrowing or cervical subluxations
2. ischemia due to compression of vascular structures (arterial deprivation and/or venous stasis)
3. repeated local cord trauma by normal movements in the presence of protruded discs and/or osteophytic (spondylotic) bars (cord and root injuries)
   a) cephalad/caudad movement with flexion extension
   b) anterior/posterior traction on the cord by dentate ligaments & nerve roots
   c) diameter of spinal canal varies during flexion and extension
      • increased stenosis is more common in extension (see above)
      • unstable segments may sublux (so-called pincer mechanism)

Histologically, there is degeneration of the central grey matter at the level of compression, degeneration of the posterior columns above the lesion (particularly in the anteromedial portion), and demyelination in the lateral columns (especially the corticospinal tracts) below the lesion. Anterior spinal tracts are relatively spared. There may be atrophic changes in the ventral and dorsal roots and neurophagia of anterior horn cells.
71.3 Clinical

71.3.1 General information

Cervical spondylosis condition may produce several types of clinical problems:\n
1. Myeloradiculopathy: some combination of\n   a) Radiculopathy: nerve root compression may cause nerve-root (radicular) complaints\n   b) spinal cord compression may cause myelopathy. Some stereotypical syndromes are presented below (see Cervical spondylotic myelopathy (CSM) below)\n2. pain and paresthesias in the head, neck and shoulders with little or no suggestion of radiculopathy nor abnormal physical findings. This group is the most difficult to diagnose and treat, and often requires a good physician-patient relationship to decide if surgical treatment should be undertaken in an attempt to provide relief\n
Cervical spondylosis is the most common cause of myelopathy in patients >55 yrs of age.17 CSM is rare in patients <40 years of age.\n
Cervical spondylotic myelopathy (CSM) develops in almost all patients with ≥ 30% narrowing of the cross-sectional area of the cervical spinal canal18 (although some patients with more severe cord compression do not have myelopathy19,20).

Gait disturbance, often with LE weakness or stiffness, is a common early finding in CSM.21 Ataxia may result from spinocerebellar tract compression. Early on, patients may experience difficulty running. Cervical pain and mechanical signs are uncommon in cases of pure myelopathy. See Table 71.1 for the frequency of symptoms in CSM in one series. In most cases the disability is mild, and the prognosis for these is good.

71.3.2 Motor

Findings can be due to cord (UMN) and/or root (LMN) compression. The earliest motor findings are typically weakness in the triceps and hand intrinsics.23 There may be wasting of the hand muscles.24 Slow, stiff opening and closing of the fists may occur.25 Clumsiness with fine motor skills (writing, buttoning buttons…) is common.

There is often proximal weakness of the lower extremities (mild to moderate iliopsoas weakness occurs in 54%) and spasticity of the LES.

71.3.3 Sensory

Sensory disturbance may be minimal, and when present are often not radicular in distribution. There may be a glove-distribution sensory loss in the hands.26 A sensory level may occur a number of levels below the area of cord compression.

LES often exhibit loss of vibratory sense (in as many as 82%), and occasionally have reduced pin-prick sensation (9%) (almost always restricted to below the ankle). Compression of the spinocerebellar tract may cause difficulty running. Hermitte’s sign was present in only 2 of 37 cases. Some patients may present with a prominence of posterior column dysfunction (impaired joint position sense and 2 point discrimination).27

71.3.4 Reflexes

In 72–87% reflexes are hyperactive at a varying distance below the level of stenosis. Clonus, Babinski’s sign (p.90) or Hoffman’s sign (p.90) may also be present. Dynamic Hoffman’s sign28 may be more sensitive: test for Hoffman’s sign during multiple cervical flexion and extension movements as tolerated by the patient. 94% of asymptomatic individuals with Hoffman’s reflex will have significant spinal cord compression on MRI.29 Inverted radial reflex: flexion of the fingers in response to eliciting the brachioradialis reflex, said to be pathognomonic of CSM.10

A hyperactive jaw jerk indicates upper motor neuron lesion above the midpons, and distinguishes long tract findings due to pathology above the foramen magnum from those below (e.g. cervical myelopathy): not helpful if absent (a normal variant). Primitive reflexes (grasp, snout, rooting) are not reliable localizing signs (except perhaps the grasp reflex) of frontal lobe pathology.

71.3.5 Sphincter

Urinary urgency and frequency are common in CSM, however these complaints are also protean in the aging population. Urinary incontinence is rare. Anal sphincter disturbances are uncommon.
71.3.6 Syndromes

Clustering of CSM into these 5 clinical syndromes has been described:

1. **transverse lesion syndrome**: involvement of corticospinal and spinothalamic tracts and posterior columns, with anterior horn cells segmentally involved. Most frequent syndrome, possibly an “end-stage” of the disease process.

2. **motor system syndrome**: primarily corticospinal tract and anterior horn involvement with minimal or no sensory deficit. This creates a mixture of lower motor neuron findings in the upper extremities and upper motor neuron findings (myelopathy) in the lower extremities which can mimic ALS (see below). Reflexes may be hyperactive below the area of maximal stenosis (including the upper extremities), occasionally beginning several levels below the stenosis.

3. **central cord syndrome**: motor and sensory deficit affecting the UEs more than the LEs. This syndrome is characterized by dysfunction of the watershed areas located centrally within the cord.

</table>
which may be responsible for prominence of hand symptoms\(^3\) (results in “numb-clumsy hands”). \(\)\(^{31}\) Lhermitte’s sign may be more common in this group

4. Brown-Séquard syndrome: often with asymmetric narrowing of the canal with the side of greater narrowing producing ipsilateral corticospinal tract (upper motor neuron weakness) and posterior column dysfunction with contralateral loss of pain and temperature sensation

5. brachialgia and cord syndrome: radicular UE pain with lower motor neuron weakness, and some associated long tract involvement (motor and/or sensory)

71.3.7 Grading

1. the modified Japanese Orthopaedic Association scale (mJOA) (\(\)Table 71.2) is a valid and reliable grading system, although it is non-specific

2. Neck Disability Index\(^3\): a 10 question survey similar to the Oswestry Disability Index for the lumbar spine (see \(\)Table 68.3). Mild disability is defined as a score of 10–28%, moderate = 30–48% severe = 50–68%, complete ≥ 72%

3. other commonly used scales (not tested for validity or reliability):
   a) Nurick\(^3\) (see \(\)Table 74.2)
   b) Harsh

71.3.8 Natural history

The time course of symptoms is highly variable and unpredictable. In ≈ 75% of cases of CSM, there is progression either in a stepwise fashion (in one–third) or gradually progressive (two–thirds).\(^3\) In some series, the most common pattern was that of an initial phase of deterioration followed by a stabilization that typically lasts for years and may not change thereafter.\(^3\) In these cases, the degree of disability may be established early in the course of CSM. Others disagree with such a “benign” outlook and cite that over 50% of cases continue to deteriorate with conservative treatment. Sustained spontaneous improvement is probably rare.\(^1\)

In patients <75 years age and mJOA score > 12 (mild myelopathy), the clinical condition remained stable in 3-years of follow-up (Class I)\(^3\) (however, these patients can still have significant disability that can respond to surgery). Patients with stenosis without myelopathy who have electrodiagnostic abnormalities or clinical radiculopathy are at risk of developing myelopathy (Class I).\(^3\) Longstanding severe stenosis over many years may cause irreversible deficit due to necrosis in gray and white matter (Class III).\(^3\)

71.4 Differential diagnosis

71.4.1 General information

See Myelopathy (p. 1407) for other possible causes. Some of these (e.g. spinal cord tumor, OPLL) may be demonstrated radiographically. Asymptomatic cervical spondylosis is very common, and ≈ 12% of cases of cervical myelopathy attributed to spondylosis are later found to be due to another disease process including:

1. ALS: see below
2. multiple sclerosis (MS): spinal cord demyelination may mimic CSM. With MS, remissions and exacerbations are common, and patients tend to be younger
3. herniated cervical disc (soft disc): patients tend to be younger than with CSM. Course is more rapid
4. subacute combined system disease: abnormal vitamin B12 level and possibly macrocytic anemia (p. 1409)
5. hereditary spastic paraplegia: family history is key. Diagnosis of exclusion\(^3\)
6. (spontaneous) intracranial hypotension (p. 178)

71.4.2 Amyotrophic lateral sclerosis (ALS)

AKA (anterior horn) motor neuron disease; also see Amyotrophic lateral sclerosis (p. 183). Can mimic the motor system syndrome of CSM (see above), and spinal cord compression may be seen on MRI in >60% of patients with ALS.\(^4\)

“Triad” of ALS:
1. atrophic weakness of hands and forearms (early) – LMN finding
2. mild LE spasticity – UMN finding
3. diffuse hyperreflexia – UMN finding
Inevitably, some cases of demyelinating disease will be misdiagnosed initially as CSM until some features suggestive of ALS occur (in one series of 1500 ALS patients, 4% underwent spine surgery (56% cervical, 42% lumbar, 2% thoracic) before ALS was correctly diagnosed).

Features that may help differentiate ALS from CSM:
1. ALS: sensory changes are conspicuously absent
2. ALS: bulbar symptoms (dysarthria, hyperactive jaw-jerk...)

*total score ranges from 0 to 17 (normal)
3. ALS: extensive weakness/muscle atrophy of hands, usually with fasciculations.

4. ALS: lower-motor neuron (LMN) findings in the tongue (visible fasciculations, or positive sharp waves on EMG) or in the LES (e.g., fasciculations and atrophy) favors the diagnosis of ALS over CSM (however, LMN findings in the LES may occur in CSM if there is coincidental lumbar radiculopathy).

5. CSM or herniated cervical disc: usually includes neck and shoulder pain, limitation of neck movement, sensory changes, and LMN findings restricted to 1 or 2 spinal cord segments.

### 71.5 Evaluation

#### 71.5.1 Plain x-rays

**General information**

Minimum evaluation consists of AP, lateral (neutral position), and open-mouth odontoid views. If desired, flexion-extension views and/or oblique views may be obtained but requires specific orders. When MRI is available, the additional information provided by plain cervical spine x-rays in patients with CSM is limited. In this setting, x-rays may be best for:

1. Demonstrating dynamic instability with flexion-extension views (see below)
2. Sagittal balance measured on standing lateral cervical spine x-rays may provide prognostic information.
3. X-rays may be able to compensate for the following MRI deficiencies, but cervical CT is much better.
   a) Differentiating calcified discs or bone spurs from “soft discs”
   b) Differentiating OPLL from a thickened posterior longitudinal ligament
   c) Bone abnormalities: fractures, bony lytic lesions

**Cervical spinal stenosis**

Cervical spinal stenosis can be inferred from plain x-rays. NB: Canal diameters measured on x-rays are actually surrogate markers for the entity of interest: viz. spinal canal narrowing sufficient to produce spinal cord compression and thereby spinal cord symptoms. This can be directly demonstrated on MRI or CT/myelo, and MRI can also detect intrinsic spinal cord signal abnormalities.

See Canal diameter (p. 214) for normal dimensions and measurement techniques. Patients with CSM have an average minimal AP canal diameter of 11.8 mm, and values ≤ 10 mm were likely to be associated with myelopathy. Patients with an AP diameter < 14 mm may be at increased risk, and CSM is rare in patients with a diameter > 16 mm, even with significant spur(s).

Cervical spinal stenosis is also suggested on plain films when the spinolaminar line is close to the posterior margin of the lateral masses.

Pavlov ratio (AKA Torg ratio): the ratio of the AP diameter of the spinal canal at the mid VB level to the VB at the same location. A ratio < 0.8 is sensitive for transient neuropraxia, but has been shown to have poor positive predictive value for CSM.

**Oblique views**

Oblique views can delineate foraminal compromise caused by osteophytic spurs.

**Flexion-extension views**

Lateral flexion(extension) x-rays may provide valuable information by detecting dynamic instability (abnormalities that manifest with movement) that cannot be appreciated on (static) CT or MRI, including widening of the atlanto-dental interval on flexion (p. 213).

### 71.5.2 MRI

MRI provides information about the spinal canal, and can also show intrinsic cord abnormalities (demyelination, syringomyelia, spinal cord atrophy, edema...). MRI also rules out other diagnostic possibilities (Chiari malformation, spinal cord tumor...).

Bone structures and calcified ligaments are poorly imaged. These shortcoming and the difficulties in differentiating osteophytes from herniated discs on MRI are overcome with the addition of plain cervical spine films or to better advantage with thin-section CT bone windows.

Findings that correlate with poor outcome (Class III):
1. multilevel T2WI hyperintensity within the spinal cord parenchyma
2. single level T2WI hyperintensity with corresponding T1WI hypointensity (single level T2WI hyperintensity without T1WI changes are of uncertain prognostic significance)
3. spinal cord atrophy (transverse area <45 mm²)

Other MRI findings seen with CSM:
1. reduced transverse area of the spinal cord (TASC) at the level of maximum compression. A “banana” shaped cord on axial images has a high correlation with the presence of CSM. There is conflicting evidence whether the degree of canal stenosis predicts outcome. Sagittal T2WIs tend to exaggerate the magnitude of spinal cord compression by osteophytes and/or discs, and therefore axial images and T1WIs also need to be considered in the evaluation. Narrowing is not specific for CSM: ~26% of asymptomatic individuals >64 years of age have spinal cord compression on MRI
2. “snake eyes” (AKA “owl’s eyes”) within the spinal cord on axial T2WI (Fig. 71.1) may be related to cystic necrosis of the cord and may correlate with poor outcome (Class III)

71.5.3 CT and CT/myelogram
Plain CT scans may demonstrate a narrow canal, but do not provide adequate information regarding soft tissues (discs, ligaments, spinal cord and nerve roots). However, bony detail may prove invaluable in the surgical treatment of CSM.
Cervical myelography followed by high-resolution CT scanning provides sagittal and axial information (including spinal cord atrophy), and delineates bony detail better than MRI. Unlike MRI, CT/myelogram is invasive (requires LP) and involves ionizing radiation and does not provide information about changes within the spinal cord parenchyma.

71.5.4 EMG
Not routinely useful in CSM. EMG has poor sensitivity in cervical radiculopathy and is not reliable in predicting outcome from surgery for CSM (Class III). EMG is most helpful in suspicious cases to eliminate etiologies such as peripheral neuropathy or ALS.

71.5.5 Sensory evoked potentials (SEPs)
SEPs are of limited usefulness, although a normal pre-op SEP or normalization of SEPs in the early post-op period are associated with better outcome.

Practice guideline: Pre-op SEPs in CSM
Pre-op SEPs should be considered if the additional prognostic information would help treatment decisions (Level B Class II)

Fig. 71.1 Snake eyes (two foci of high signal) within a slightly flattened and mildly atrophic spinal cord on axial T2WI MRI
71.6 Treatment

71.6.1 Nonoperative management

Measures include: prolonged immobilization with rigid cervical bracing in an attempt to reduce motion and hence the cumulative effects of trauma on the spinal cord, modified activity to eliminate “high-risk” activities or bed rest, and anti-inflammatory medications.\(^{34}\)

71.6.2 Surgical treatment

Indications for surgery

See Practice guideline: Surgical vs. nonsurgical management (p.1090).

**Practice guideline: Surgical vs. nonsurgical management**

Mild myelopathy (mJOA score >12): in the short-term (3 years) patients may be offered the option of surgical decompression or nonoperative management (prolonged immobilization in a rigid cervical collar, anti-inflammatory medications, and “low-risk” activities or bed rest (Level C Class II)).\(^{55}\) Note: patients with mJOA scores >12 (see Table 71.2) may not always be mildly impaired, they may derive significant improvement from surgery, and deterioration from this point may be ominous.

More severe myelopathy: should be treated with surgical decompression with benefits maintained at 5 and 15 years post-op (Level D Class III)\(^{53}\)

Level B Class I\(^{56}\) Degenerative cervical radiculopathy: patients do better with anterior decompression ± fusion (compared to conservative management) for

- rapid relief (within 3–4 months) of arm & neck pain and sensory loss
- relief of longer term (≥12 months) symptoms of weakness of wrist extension, elbow extension, shoulder abduction and internal rotation

**Intraoperative electrophysiologic monitoring**

**Practice guideline: Intra-operative electrophysiologic monitoring during surgery for CSM or radiculopathy**

Use of intra-op EP monitoring during routine surgery for CSM or cervical radiculopathy is not recommended as an indication to alter the surgical plan or administer steroids since this paradigm has not been observed to reduce the incidence of neurologic injury (Level D Class III)\(^{57}\)

**Choice of approach**

General information

The debate between anterior approaches (anterior cervical discectomy or corpectomy) and posterior approaches (decompressive cervical laminectomy or laminoplasty) dates back to the time that both became widely practiced.\(^{16}\) General sentiment is to treat anterior disease at the disc level (e.g. osteophytic bar, herniated disc...) usually limited to ≤3 levels (or occasionally 4) with an anterior approach, and to use a posterior approach as the initial procedure in the situations outlined below. Considerations of spinal curvature may need to enter into the decision process.

**Practice guideline: Choice of surgical approach for CSM**

There was not enough evidence to recommend any of the following techniques over the other (in terms of short-term success in treating CSM): ACDF, anterior corpectomy and fusion, laminectomy (with or without fusion) and laminoplasty (Level D Class III)\(^{58}\)

Laminectomy without fusion, however, is associated with a higher incidence of late kyphotic deformity (Level D Class III; incidence 14–47% not all cases are symptomatic, not all cases need treatment: see text)\(^{58}\)
Posterior approach
Options include:
1. laminectomy alone laminectomy/arthrodesis (i.e. laminectomy + lateral mass fusion): Class III (this procedure was found to be effective, the class shows the strength of the evidence)\(^5\)
2. laminoplasty (Class III; this procedure was found to be effective, the class shows the strength of the evidence): methods include unilateral (“open door”) and midline enlargement (“French door”)
3. multilevel foraminotomies: usually not adequate for central canal stenosis

Situations where a posterior approach would generally be the initial approach:
1. congenital cervical stenosis where removing osteophytes will still not provide at least \(\approx 12\) mm of AP canal diameter
2. disease over \(\geq 3\) levels (although up to 4 may occasionally be dealt with anteriorly)
3. primary posterior pathology (e.g. infolding of ligamentum flavum)
4. some cases of OPLL (anterior approach has higher risk of dural tear)

Disadvantages of the posterior approach:
1. laminectomy without fusion
   a) degeneration and osteophytes continue to progress following surgery
   b) risk of subsequent subluxation or progressive kyphotic angulation (“swan neck” deformity) (facetiously dubbed “spina bifida neurosurgica”)
   - quoted incidence: 14–47%\(^6,62,63\) (risk may be minimized by careful preservation of facet joints)
   - not all cases need to be treated: in one series, 31% (18/58) developed post-op kyphosis, and 16% of these (3/18) required surgical stabilization\(^64\)
   - the development of kyphotic deformity does not appear to diminish the clinical outcome\(^63\) and does not correlate with neurologic deterioration when deterioration occurs\(^65\)
2. more painful initially post-op and sometimes more prolonged rehabilitation
3. long-term complaints of a heaviness of the head possibly associated with atrophy of the paraspinal muscles
4. contraindicated with pre-existing swan neck deformity, and not recommended in the presence of reversal of the normal cervical lordosis (i.e. kyphotic curve)\(^66\) where the spinal cord won’t tend to move away from the anterior compression or in the presence of \(\geq 3.5\) mm subluxation or \(>20^\circ\) rotation in the sagittal plane\(^46\) and caution must be exercised in hyperlordosis (see below)

Anterior approach
Also shown to be effective (Class III\(^5\)).

Instrumentation options: in terms of fusion rates for 2-level anterior operations (i.e. 2 disc spaces) (Class III)\(^58\):

\[
\begin{align*}
2\text{-level ACDF} & \quad < \quad 1\text{-level corpectomy} & < \quad 1\text{-level corpectomy} & > \quad 2\text{-level ACDF} \\
\text{with anterior plate} & \quad \frac{1}{2} \quad \text{with plate} & \quad \text{without plate} & < \quad \text{without plate*}
\end{align*}
\]

* however; the graft extrusion rate is higher for corpectomy than ACDF

Worsening of myelopathy has been reported in 2–5% of patients after anterior decompression\(^67,68\) (intraoperative SSEP monitoring may reduce this rate\(^68\)) and C5 radiculopathy may occur (see below).

Anterior cervical plating
Many systems are available, with more similarities than differences. All include some method of preventing screw back out. Some general pointers:
1. for single level fusion, typical plate length is 22–24 mm
2. screw length: rule of thumb is 12 mm for females, 14 mm for males
3. do not completely tighten a single screw (to avoid kicking up plate) until the diagonally opposite screws are placed and loosely tightened
4. most systems have fixed and variable angle screws. Variable angle screws allow for load sharing with the graft (here is where a derivative of Wolff’s law is often invoked: the weight sharing helps stimulate fusion). Avoid over-angling screws which may prevent the locking mechanism from properly engaging
5. optimal plate placement allows for contact of the plate with the VB at the screw locations. This may require
   a) contouring of plate to follow the lordosis of the c-spine
   b) reduction of anterior osteophytes

Posterior approach
For decompression, some recommend cervical laminectomy extending one or two levels beyond the stenosis above and below.\textsuperscript{69,70} A C3–6 laminectomy is often considered a “standard” laminectomy. An “extended laminectomy” includes C7 and/or C2.

Curvature considerations: extending the laminectomy to include C2 and sometimes C1 has been recommended for patients with straightening of the cervical curvature.\textsuperscript{6} In cases of hyperlordosis, posterior migration of the spinal cord following an extensive laminectomy may put increased tension on the nerve roots and blood vessels (with possible neurologic worsening), and a limited laminectomy just where the cord is compressed is often recommended (below).

“Keyhole foraminotomies” or medial facetectomy with undercutting of the facets may be performed at levels involved with radiculopathy.

Position: choices are primarily: prone, lateral oblique, or sitting. The prone position has a major disadvantage of difficulty elevating the head above the heart, resulting in venous engorgement with significant operative bleeding. The sitting position has a number of inherent risks (p. 1445), including cord hypoperfusion\textsuperscript{68} and air embolism. The lateral oblique position may introduce some distortion to the anatomy due to asymmetrical positioning.

The reported rate of post-op spinal deformity is 25–42% Neurologic worsening has been reported in 2% in some series, higher in others. C5 radiculopathy may occur (see below).

To avoid significant destabilization of the cervical spine:
1. during the dissection, do not remove soft tissue overlying the facet joints (to preserve their blood supply)
2. take the laminectomy only as far lateral as the extent of the spinal canal, carefully preserving the facet joints\textsuperscript{7} (use keyhole laminotomies where necessary)
3. avoid removing a total of one facet at any given level

Outcome
General information
Even excluding cases that are later proven to have demyelinating disease, the outcome from surgery for CSM is often disappointing. Once CSM is clinically apparent, complete remission almost never occurs. The prognosis with surgery is worse with increasing severity of involvement at the time of presentation\textsuperscript{69} and with longer duration of symptoms (48% showed clinical improvement or cure if operated within 1 yr of onset, whereas only 16% responded after 1 yr). The success of surgery is also lower in patients with other degenerative diseases of the CNS (ALS, MS...).

Progression of myelopathy may be arrested by surgical decompression. This is not always borne out, and some early series\textsuperscript{34,37} showed similar results with conservative treatment as with laminectomy which yielded improvement in 56% no change in 25% and worsening in 19% Also as discussed earlier some cases of CSM develop most of the deficit early and then stabilize (p. 1086).

Some series show good results, with 64–75% patients having improvement in CSM post-op.\textsuperscript{22} However, other authors remain less enthusiastic. Utilizing a questionnaire in 32 post-op patients operated anteriorly, 66% had relief from radicular pain, while only 33% had improvement in sensory or motor complaints.\textsuperscript{23} In one series, half the patients had improvement in fine motor function of the hands, but the other half worsened postoperatively.\textsuperscript{71} Spinal cord atrophy as a result of continued pressure or ischemia may be partly responsible for poor recovery. Bedridden patients with severe myelopathy rarely recover useful function.

Post-op C5 palsy
Criteria: weakness of deltoid and/or biceps with no worsening of myelopathy. Follows 3–5% of extensive anterior or posterior decompression (including laminoplasty).\textsuperscript{67,72} 50% have motor involvement only (deltoid > biceps), 50% also have C5 dermatomal sensory loss and/or C5 dermatomal pain (shoulder). Most occur <1 week post-op.\textsuperscript{72} 92% are unilateral.\textsuperscript{72} No pre-op risk factors have been identified.\textsuperscript{72} Etiology: unproven, may be related to traction on the nerve root from posterior migration of the cord after decompression or to bone graft displacement. Prognosis for spontaneous recovery is generally good; more severe deficits take longer to recover.\textsuperscript{72}
Late developments
Some patients who show early improvement will develop late deterioration (7–12 yrs after reaching a plateau), with no radiographically apparent explanation in up to 20% of these cases. In others, degeneration at levels adjacent to the operated segments may be demonstrated.

Adjacent segment disease (ASD): degeneration that develops at a motion segment adjacent to a previous fusion. Findings include: disc degeneration, stenosis, facet hypertrophy, scoliosis, listhesis and instability. After ACDF, ASD occurred at a rate of 2.9% per year over 10 years observation. Estimate: 25% of patients will develop symptomatic adjacent level changes within 10 years of surgery. This rate was higher with single level fusion at C5–6 or C6–7 than it was with multilevel fusion, and natural progression of the disease was felt to be a significant contributor (i.e. it was not all attributable to the fusion). Most cases of ASD observed radiographically are asymptomatic.

71.7 Coincident cervical and lumbar spinal stenosis
In 5% lumbar and cervical stenoses are symptomatic simultaneously. Coincident symptomatic lumbar and cervical spinal stenosis is usually managed by first decompressing the cervical region, and later operating on the lumbar region (unless severe neurogenic claudication dominates the picture). It is also possible, in selected cases, to operate on both in a single sitting.

References

72 Thoracic and Lumbar Degenerative Disc Disease

72.1 General information about degenerative disc disease (DDD)

Since structures outside of the disc are usually also involved, the term degenerative spine disease (DSD) may be preferable to degenerative disc disease. Spondylosis is a non-specific term which may include degenerative spine disease. “Cervical spondylosis” is occasionally used synonymously with cervical stenosis (p.1083).

Symptomatic spinal stenosis in the thoracic region is rare, and is generally seen in the setting of a calcified disc. The majority of this chapter deals with lumbar DSD. For the cervical region, see that chapter (p. 1083).

72.2 Anatomic substrate

72.2.1 General information

DSD is a progressive deterioration of the structures of the spine including:
1. disc abnormalities:
   a) the proteoglycan content of the disc nucleus decreases with age
   b) disc desiccation (loss of hydration) occurs
   c) tears develop in the disc annulus and progress to internal disruption of the lamellar architecture. Herniation of the nucleus may occur from increased nuclear pressure under mechanical loads
   d) mucoid degeneration and ingrowth of fibrous tissue ensues (disc fibrosis)
   e) subsequently disc resorption occurs
   f) there is a loss of disc space height and increased susceptibility to injury
2. facet joint abnormalities: hypertrophy and capsular laxity
3. osteophytes often form on the edges of the VB bordering the degenerated disc
4. spondylolisthesis: subluxation of one VB on another (see Spondylolisthesis below)
5. hypertrophy of the ligamentum flavum

Neurologic involvement in lumbar spinal stenosis may occur in one or more of the following 3 sites:
1. central canal stenosis: narrowing of the AP dimension of the spinal canal below a critical value. The reduction in canal size may cause local neural compression and/or compromise of the blood supply to the spinal cord (cervical) or the cauda equina (lumbar)
   a) Congenital (as in the achondroplastic dwarf)
   b) Acquired: as with hypertrophy of facets and ligamentum flavum
   c) Most commonly – acquired superimposed on congenital narrowing.
2. foraminal stenosis: narrowing of the neural foramen. May be the result of any combination of: foraminal disc protrusion, spondylolisthesis, facet hypertrophy, disc space collapse, hypertrophy of uncovertebral joints (cervical), synovial cyst
3. lateral recess stenosis; lumbar spine only (p. 1097)

72.2.2 Lumbar spinal stenosis

Key concepts

- caused by hypertrophy of facets and ligamentum flavum, may be exacerbated by disc bulging or spondylolisthesis, may be superimposed on congenital narrowing
- most common at L4–5 and then at L3–4
- symptomatic stenosis produces gradually progressive back and leg pain with standing and walking that is relieved by sitting or lying (neurogenic claudication)
- symptoms differentiated from vascular claudication which is usually relieved at rest regardless of position
- usually responds to decompressive surgery (sometimes with fusion) or interspinous spacer
Symptomatic lumbar stenosis is most common at L4–5, then L3–4, L2–3 and lastly L5–S1. It is rare at L1–2. Generally occurs in patients with congenitally shallow lumbar canal – see Normal LS spine measurements (p.1102) – with superimposed acquired degeneration in the form of some combination of facet hypertrophy, hypertrophy of the ligamentum flavum, protruding (and often calcified) intervertebral discs, and spondylolisthesis. First recognized as a distinct clinical entity producing characteristic symptoms in the 1950’s and 60’s. May be classified as:

1. stable form of lumbar spinal stenosis: hypertrophy of facets and ligamentum flavum accompanied by disc degeneration and collapse
2. unstable: have the above with superimposed
   a) degenerative spondylolisthesis (p.1098), the unisegmental form
   b) degenerative scoliosis: the multisegmental form

72.2.3 Central canal stenosis

The central canal may be narrowed by a combination of any of the following:
- Hypertrophy of the ligamentum flavum
- Hypertrophy of the facet joints
- Congenitally short pedicles
- Bulging intervertebral discs
- Osteophytes arising from the posterior VB
- Juxtafacet cysts
- Spondylolisthesis

72.2.4 Lateral recess syndrome

The lateral recess is the “gutter” alongside the pedicle which the nerve root enters just proximal to its exit through the neural foramen (Fig. 72.1). It is bordered anteriorly by the vertebral body, laterally by the pedicle, and posteriorly by the superior articular facet of the inferior vertebral body. Hypertrophy of this superior articular facet compresses the nerve root. Narrowing of the lateral recess is present in essentially all cases of central canal stenosis, but it can be symptomatic by itself. L4–5 is the most commonly involved facet.

Fig. 72.1 Schematic axial CT through the L4-5 facet joint showing the lateral recesses (normal on patient’s right, stenotic on left)
72.2.5 Spondylolisthesis

General information

Anterior subluxation of one vertebral body (VB) on another, most commonly the upper VB is anterior to the inferior one. Usually L5 on S1, the next most common is L4 on L5.

Disc herniation and nerve root compression with spondylolisthesis: It is rare for a herniated lumbar disc to occur at the level of the listhesis, however the disc may “roll” out as it is uncovered and produce findings on MRI that may resemble a herniated disc which has been termed a “pseudodisc.” It is more common to see a herniated disc at the level above the listhesis.

If the listhesis causes nerve root compression, it tends to involve the nerve exiting below the pedicle of the anteriorly subluxed upper vertebra (e.g. if an L4–5 spondylolisthesis causes nerve root compression, it will generally involve the L4 root). The compression is usually due to upward displacement of the superior articular facet of the level below together with disc material, and symptoms typically resemble neurogenic claudication, although true radiculopathy may sometimes occur. There also may be a contribution from a fibrous/inflammatory mass from the nonunion.

Isthmic spondylolisthesis rarely produces central canal stenosis since only the anterior part of the vertebral body shifts forward. May present with radiculopathy or neurogenic claudication from compression in the neural foramen, with the nerve exiting under the pedicle at that level being the most vulnerable. May also present with low back pain. Many cases are asymptomatic.

Adolescent spondylolisthesis

In adolescents and teens, spondylolisthesis usually occurs in athletes subject to repetitive hyperextension of the lumbar spine. In girls, this is frequently encountered in gymnasts and softball pitching. In boys, football is common.

In these youngsters, cessation of sports for several months usually produces resolution. Surgery is sometimes performed for patients who are unwilling to discontinue athletics.

Grading spondylolisthesis

The Meyerding grading in the sagittal plane is shown in Table 72.1.

Types of spondylolisthesis

1. Type 1: dysplastic: congenital. Upper sacrum or arch of L5 permits the spondylolisthesis. No pars defect. 94% are associated with spinal bifida occulta. Some of these may progress (no way to accurately identify those that will progress)

2. Type 2: isthmic spondylolisthesis AKA spondylolysis: a failure of the neural arch as a result of a defect in the pars interarticularis (identifiable as a discontinuity in the neck of the “Scotty dog” on oblique LS-spine x-ray). May be seen in 5–20% of spine x-rays. Rarely produces central canal stenosis since only the anterior part of the vertebral body shifts forward. May cause narrowing of the neural foramen. Three subtypes:
   a) lytic: fatigue fracture or insufficiency fracture of pars. In the pediatric age group may occur in athletes (especially gymnasts or football players); in some this may be an exacerbation of a pre-existing defect, in others it may be a result of repetitive trauma
   b) elongated but intact pars: possibly due to repetitive fractures and healing
   c) acute fracture of pars

</table>

*% of the AP diameter of the VB
3. Type 3: degenerative: due to long-standing intersegmental instability. Usually at L4–5. No break in the pars. Found in 5.8% of men and 9.1% of women (many of whom are asymptomatic)\(^9\)

4. Type 4: traumatic: due to fractures usually in areas other than the pars

5. Type 5: pathologic: generalized or local bone disease, e.g. osteogenesis imperfecta

**Natural history**

Progression of spondylolisthesis may occur without surgical intervention, but is more common following surgery.\(^10\)

### 72.2.6 Degenerative scoliosis

One of the main differentiating features from juvenile scoliosis is that in degenerative scoliosis, the disc spaces are asymmetrically narrowed in the coronal plane and the vertebral bodies tend to maintain a more normal configuration.

### 72.3 Risk factors

1. The risk of developing DSD is multifactorial and includes:
2. The most powerful determinant in developing DSD in a study of twins was genetic influence, and possibly other unidentified factors.\(^11\) Environmental factors studied (including sedentary vs. active lifestyles, occupation, cigarette smoking…) exerted only a modest influence, which may explain why conflicting findings for these have been reported
3. cumulative effects of microtrauma and macrotrauma to the spine
4. osteoporosis
5. cigarette smoking: several epidemiologic studies have shown that the incidence of back pain, sciatica and spinal degenerative disease is higher among cigarette smokers than among non-smokers\(^12,13\)
6. in the lumbar spine:
   a) stresses on the spine including effects of excess body weight
   b) loss of muscle tone (primarily abdominals and paraspinals) resulting in increased dependence on the bony spine for structural support

### 72.4 Associated conditions

1. congenital:
   a) achondroplasia
   b) congenitally narrowed canal
2. acquired:
   a) spondylolisthesis
   b) acromegaly
   c) post-traumatic
   d) Paget’s disease (p. 1120)
   e) ankylosing spondylitis (p. 1123)
   f) ossification of the ligamentum flavum: more common in East Asians, rare in Caucasians.\(^14\)

   Often, but not always, associated with OPLL\(^15\)

### 72.5 Clinical presentation

#### 72.5.1 General information

1. the degenerative abnormalities may produce spinal stenosis which can lead to neural compromise producing the following symptoms
   a) radicular symptoms (more common in cervical spine than lumbar)
   b) neurogenic claudication (lumbar) or spinal myelopathy (cervical)
2. Sagittal imbalance and scoliosis as a result of degenerative changes can place focal stress on specific spine structures which may be painful. Also, muscles used to compensate for the imbalance can cause pain from overuse fatigue
3. discogenic pain (controversial) may be less prevalent in the late stages of DSD. May contribute to “musculoskeletal low back pain” but the actual pain generators here are not definitively identified
4. Many cases of DSD (including spinal stenosis and spondylolisthesis) are asymptomatic, and the degenerative changes are discovered incidentally.

72.5.2 Neurogenic claudication

Lumbar spinal stenosis often presents as neurogenic claudication (NC), (claudicate: from Latin, claudico, to limp) AKA pseudoclaudication. To be differentiated from vascular claudication (AKA intermittent claudication) which results from ischemia of exercising muscles (see Table 72.2 for distinguishing characteristics).

NC characteristics: unilateral or bilateral buttock, hip, thigh or leg discomfort that is precipitated by standing or walking and characteristically relieved by a change in posture (usually sitting with the waist flexed, squatting, or lying in the fetal position). Painful burning paresthesias of the lower extremities are also described. Valsalva maneuvers usually do not exacerbate the pain. Many patients report increased pain first thing in the morning that improves once they have been out of bed for varying periods (usually an hour more or less).

The time course is usually gradually progressive over many months to years. As the condition progresses, the ability to get relief from position changes tends to decrease. However, presenting with acute, unrelenting pain is not characteristic and other causes should be sought.

In comparison, a HLD usually causes increased pain on sitting, has a more abrupt onset, has pain on straight leg raising, and is worsened by Valsalva maneuvers.

NC is thought to arise from ischemia of lumbar nerve roots, as a result of increased metabolic demands from exercise together with vascular compromise of the nerve root due to pressure from surrounding structures. NC is only moderately sensitive (≈ 60%) but is highly specific for spinal stenosis. Pain may not be the major complaint, instead, some patients may develop paresthesias or LE weakness with walking. Some may complain of muscle cramping, especially in the calves.

Relief from symptoms: occurs with positions that decrease the lumbar lordosis which increases the diameter of the central canal (by reducing inward buckling of the ligamentum flavum) and distracting the facet joints (which enlarges the neural foramina. Favorable positions include sitting, squatting and recumbency. Patients may develop "anthropoid posture" (exaggerated waist flexion). "Shopping cart sign" patients often can walk farther if they can lean forward e.g. as on a grocery cart. Riding a bicycle is also often well tolerated.

| Table 72.2 Clinical features distinguishing neurogenic from vascular claudication⁶⁶ |
|-----------------------------|---------------------------------|-----------------------------|
| Feature                    | Neurogenic claudication         | Vascular claudication       |
| distribution of pain        | in distribution of nerve (dermatomal) | in distribution of muscle group with common vascular supply (sclerotomal) |
| sensory loss                | dermatomal distribution         | stocking distribution       |
| inciting factors            | variable amounts of exercise, also with prolonged maintenance of a given posture (65% have pain on standing at rest); coughing produces pain in 38% | reliably reproduced with fixed amount of exercise (e.g. distance ambulated) that decreases as disease progresses; rare at rest (27% have pain on standing at rest) |
| relief with rest            | slow (often > 30 min), variable, usually positional (stooped posture or sitting often required, standing and resting is usually not sufficient) | almost immediate; not dependent on posture (relief of walking induced symptoms with standing is a key differentiating feature) |
| claudicating distance       | variable day-to-day in 62%       | constant day-to-day in 88%   |
| discomfort on lifting or bending | common (67%)                  | infrequent (15%)            |
| foot pallor on elevation    | none                            | marked                      |
| peripheral pulses           | normal; or if ↓ usually reduced only unequally | ↓ or absent; femoral bruits are common |
| skin temp of feet           | normal                          | decreased                   |
72.5.3 Neurologic exam

The neurologic exam is normal in ≈ 18% of cases (including normal muscle stretch reflexes and negative straight leg raising). Weakness in the anterior tibialis and/or extensor hallucis longus may occur in some cases of central canal stenosis at L4–5, or with foraminal stenosis of L5-S1. Absent or reduced ankle jerks and diminished knee jerks are common, however this is also prevalent in the aged population. Pain may be reproduced by lumbar extension.

72.6 Differential diagnosis

72.6.1 General considerations

1. vascular insufficiency: (AKA vascular or intermittent claudication) see above
2. hip disease: trochanteric bursitis (see below), degenerative joint disease
3. disc herniation (lumbar or thoracic)
4. facet joint pain (controversial): may respond to medial branch block (therapeutic & diagnostic)
5. Baastrup's syndrome: AKA arthrosis interspinosa. Radiographically: contact of adjacent spinous processes (“kissing spines”) with enlargement, flattening and reactive sclerosis of apposing interspinous surfaces. Produces localized midline lumbar pain & tenderness on back extension relieved by flexion, local anesthetic injection or partial excision of the involved spinous processes
6. juxtafacet cyst: (p.1143)
7. arachnoiditis
8. intraspinal tumor
9. Type I spinal AVM (spinal dural AVM) (p.1140)
10. diabetic neuritis: with this, the sole of the foot is usually very tender to pressure from the examiner’s thumb
11. delayed onset muscle soreness (DOMS): onset usually 12–48 hours after beginning a new activity or changing activities (NC occurs during the activity). Symptoms typically peak within 2 days and subside over several days
12. inguinal hernia: typically produces groin pain
13. functional etiologies

Degenerative hip disease

Trochanteric bursitis (TBS) and degenerative arthritis of the hip are also included in the differential diagnosis of NC. Although TBS may be primary, it can also be secondary to other conditions including lumbar stenosis, degenerative arthritis of the lumbar spine or knee, and leg length discrepancy. TBS produces intermittent aching pain over the lateral aspect of the hip. Although usually chronic, it occasionally may have acute or subacute onset. Pain radiates to lateral aspect of thigh in 20–40% (so called “pseudoradiculopathy”), but rarely extends to the posterior thigh or as far distally as the knee. There may be numbness and paresthesia-like symptoms in the upper thigh which are usually not dermatomal in distribution. Like NC, the pain may be triggered by prolonged standing, walking and climbing, but unlike NC it is also painful to lie on the affected side. Localized tenderness over the greater trochanter can be elicited in virtually all patients, with maximal tenderness at the junction of the upper thigh and greater trochanter. Pain increases with weight bearing (and is often present from the very first step, unlike NC) and with certain hip movements, especially external rotation (over half the patients have a positive Patrick-FABERE test (p.1048), and rarely with hip flexion/extension. Treatment includes NSAIDs, local injection of glucocorticoid (usually with local anesthetic), physical therapy (with stretching and muscle strengthening exercises) and local application of ice. No controlled studies have compared these modalities.

72.7 Diagnostic evaluation

72.7.1 Radiographic evaluation

Comparison of modalities

MRI: demonstrates impingement on neural structures and loss of CSF signal on T2WI due to central canal stenosis, lateral recess stenosis, foraminal stenosis as well as juxtafacet cysts. Increased fluid in the facet joint and vacuum disc MRI is poor for visualizing bone which contributes significantly to the pathology. Asymptomatic abnormalities are demonstrated in up to 33% of patients 50–70 years old without back-related symptoms.
Lumbosacral spine x-rays: may disclose spondylolisthesis. AP diameter of canal is usually narrowed (congenitally or acquired) (below) whereas the interpediculate distance (IPD) may be normal. Oblique films may demonstrate pars defects. Adding flexion/extension views can assess "dynamic" instability.

Standing scoliosis x-rays: provide information about scoliosis and sagittal balance. See Adult degenerative scoliosis for technique and measurements.

CT scan (either routine, or following water-soluble myelography): classically shows "trefoil" canal (cloverleaf shaped, with 3 leaflets). CT also demonstrates AP canal diameter, hypertrophied ligaments, facet arthropathy, pars fractures and occasionally may show bulging annulus or herniated disc.

Myelogram: lateral films often show "washboard pattern" (multiple anterior defects), AP films often show "wasp-waisting" (narrowing of dye column), may also show partial or complete (especially in prone position) block. May be difficult to perform LP if stenosis is severe (poor CSF flow and difficulty avoiding nerve roots the LP needle).

Normal LS spine measurements

Normal dimensions of the lumbar spine are shown in Table 72.3 for plain film and Table 72.4 for CT.

72.7.2 Adjuncts to radiographic evaluation

"Bicycle test": patients with NC can usually tolerate longer periods of exercise on a bicycle than patients with intermittent (vascular) claudication because the position in bicycling flexes the waist.

Noninvasive studies to rule-out vascular insufficiency: Ratio of ankle to brachial blood pressure (A:B ratio): > 1.0 is normal; mean of 0.59 in patients with intermittent claudication; 0.26 in patients with rest pain; < 0.05 indicates impending gangrene.

EMG with NCV may show multiple nerve-root abnormalities bilaterally.

72.8 Treatment

72.8.1 General information

In one study of 27 unoperated patients, 19 remain unchanged, 4 improved, and 4 worsened (mean follow-up: 49 months; range: 10–103 months).24

NSAIDs (acetaminophen may be as effective) and physical therapy are usually the initial measures of nonsurgical management. Unlike the cervical spine, traction is not usually helpful. Brace therapy, e.g. with an LSO may be attempted. Guidelines are shown below.

Practice guideline: Brace therapy

Level II:
- short-term use (1–3 weeks) of a rigid lumbar support is recommended for treatment of LBP of relatively short duration (<6 months)
- bracing in patients with LBP>6 months duration is not recommended because it has not been shown to have long-term benefit

Level III:
- lumbar braces may reduce the number of sick days due to LBP among workers with a previous lumbar injury. Braces are not recommended for LBP in the general working population
- the use of pre-op bracing or transpedicular external fixation as tools to predict outcome for lumbar fusion is not recommended

Interventional pain management is an option for persistent pain. Epidural steroids may provide temporary relief (usually days to weeks at most). Facet blocks and, if helpful, rhizotomies (for longer relief), may be employed.

72.8.2 Management of isthmic spondylolisthesis

See reference.9

Some special management considerations for isthmic spondylolisthesis as a subset of spinal stenosis.
1. lesions with sclerotic borders are usually well established with little chance of healing.
2. Surgery is reserved for patients with neurologic deficit or incapacitating symptoms or progression of spondylolisthesis
3. lesions without sclerosis that show increased uptake on bone scan (indicating active lesion with potential for healing) or MRI high signal changes on T2WI or STIR may heal in a rigid orthosis such as the Boston brace for ≥3 months
4. management of symptoms:
   a) LBP only: treat with NSAIDs, PT
   b) LBP with myelopathy, radiculopathy, or neurogenic claudication: surgical treatment27 (see Table 72.6 for surgical options)

5. in pediatrics: may be managed with TLSO and long course of PT (e.g. 6–9 months) for symptoms. Resumption of sports may be considered when symptoms subside, but recurrence should prompt elimination of athletics or consideration of surgery.

72.8.3 Indications for surgery
Surgical intervention is undertaken when symptoms become severe in spite of conservative management. The goals of surgery are pain relief, halting progression of symptoms, and possibly reversal of some existing neurologic deficit. Most authors do not consider surgery unless the symptoms have been present >3 months, and most patients who have surgery for this have symptoms of >1 year duration.

72.8.4 Surgery
Surgical options
1. laminectomy: posterior (direct) decompression of central canal and neural foramina without or with fusion. Fusion options:
   a) posterolateral fusion ± pedicle screw/rod fixation
   b) interbody fusion: generally not done as a “stand-alone” (i.e. usually requires additional stabilization, options here include: pedicle screws, facet screws, facet dowels, spinous process clamp…)
   • posterior lumbar interbody fusion (PLIF) (p.1497): usually bilateral graft placement
   • transforaminal lumbar interbody fusion (TLIF) (p.1497): unilateral graft placement though a facet take-down on that side
2. procedures to increase disc space height and thereby indirectly decompress neural foramina without direct decompression
   a) anterior lumbar interbody fusion (ALIF) (p.1493): through laparotomy
   b) lateral lumbar interbody fusion (p.1498): some techniques trademarked as extreme lateral interbody fusion (XLIF™ or direct-lateral (DLIF™)
   c) axial lumbar interbody fusion (Ax-LIF): L5-S1 only
3. limitation of extension by interspinous spacer: e.g. X-Stop® (see below)

Choosing which procedure to use
Items that factor into consideration when choosing which procedure to use include:
1. consider indirect decompression (lateral interbody fusion (e.g. XLIF® or DLIF®), ALIF, interspinous decompression (e.g. X-Stop):
   a) when foraminal stenosis appears to be the dominant problem (e.g. with loss of disc space height, facet hypertrophy, on the concave side of a scoliotic curve)
   b) previous spine surgery that might make exposure of the nerves more difficult or risky
   c) when the disc space is compressed (more difficult to distract an already tall disc space with normal disc)
2. consider direct decompression (e.g. laminectomy)
   a) “pinpoint” central canal stenosis especially when disc height and neural foramina are well preserved
   b) where a significant contributor to the compression is a focal, correctable lesion, e.g. herniated disc, synovial cyst, intraspinal tumor
   c) to avoid a fusion (in select cases)
3. consider motion-preservation surgery when a fusion is undertaken at a level and the adjacent level is already starting to show some degenerative changes that have not yet reached a surgical magnitude. Motion preservation at this adjacent segment theoretically shields it from some of the transmitted stresses from the fused level
4. situations where a fusion should be considered in addition to direct or indirect decompression of the nerves:
   a) spondylolisthesis (especially > Grade I)
   b) symptomatic sagittal imbalance or degenerative scoliosis
   c) dynamic instability on flexion/extension lateral lumbar spine x-rays
   d) expectation that the decompression will destabilize the spine (e.g. facet takedown for a TLIF)
   e) multiply recurrent herniated disc (when this is the third or more operation for the same disc)
   f) controversial: “black disc” on MRI with positive concordant discogram at this level: fusion without decompression has been advocated when there is no neural compression
When spondylolisthesis is present

May occur without decompression, but is more common following surgery. However, lumbar instability following decompressive laminectomy is rare (only \( \approx 1\% \) of all laminectomies for stenosis will develop progressive subluxation). Fusion is rarely required to prevent progression of subluxation with degenerative stenosis.

For Grade I and low Grade II spondylolisthesis, laminectomy without fusion may be considered. Stability (without need for instrumentation) is thought to be maintained if \( > 50-66\% \) of the facets are preserved during surgery and the disc space is not violated (maintains integrity of anterior and middle column). Younger or more active patients are at higher risk of subluxing. Patients with a tall (normal) disc space are at higher risk of subluxing than those with collapsed disc space.

One approach is to obtain flexion/extension x-rays pre-op, and follow patients after decompression. Those who develop symptomatic slippage post-op are treated by fusion, possibly in conjunction with spinal instrumentation.

When surgery is indicated, Table 72.6 serves as a guide to the type of procedure.

Laminectomy/laminotomy – surgical technique

Posterior approach with removal of the spines and lamina of affected levels (surgical “unroofing”), along with the associated ligamentum flavum. Individual nerve roots are palpated for compression within their neural foramen, with foraminotomies performed at appropriate levels. Doing a total L4 laminectomy for stenosis allows access to the L4–5 foramen, and the upper part of the L5-S1 foramen. If, in addition, the lower part of L3 is also removed, access is gained to the inferior pedicle of L3 and thus the L3–4 neural foramen. Undercutting the superior articular facet is often necessary to decompress the nerves in the lateral recess and neural foramen (p.1097). Treatment of moderate stenosis at adjacent levels appears warranted as these levels have been shown to have a significant likelihood of becoming symptomatic later.

Alternatively, laminotomies (as opposed to laminectomies) may be performed in cases where the central canal has a normal AP diameter, but the lateral canal gutter is stenotic. Multilevel subarticular fenestrations are another slight variation on this theme.

Position: either of the following is acceptable
1. prone: on a frame or chest rolls or knee-chest position to decompress the abdomen to decrease venous pressure and thus reduce bleeding
2. lateral decubitus position: if there is no laterality to symptoms, right lateral decubitus (left-side-up) is easier for most right-handed surgeons to use angled Kerrison rongeur parallel to nerve roots

Booking the case: Lumbar laminectomy

Also see defaults & disclaimers (p.27).
1. position: prone
2. implants: for fusions, schedule with the vendor for the desired implants and associated instrumentation
3. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: through the back to remove bone, ligament and any other tissue that is pressing on the nerve(s). If a fusion is to be done, then typically this will be accomplished using screws, rods and small cages, as required
   b) alternatives: nonsurgical management
   c) complications: usual spine surgery complications (p. 28), plus there might not be the amount of pain relief desired (back pain does not respond as well to surgery as nerve-root pain. The surgery slightly weaken the spine, and as a result, about 15% people will need a fusion at a later date

Minimally invasive spine surgery (MISS) decompression

Usually using \( \approx 1\” \) incisions and expandable retractors.
1. options include bilateral laminotomies (see above)
2. bilateral decompression through a unilateral laminotomy
   a) entry site: 3.5–4 cm off the midline to permit the needed angle
b) when using a retractor with an “open side” orient the retractor with the open side facing laterally (e.g. with the Nuvasive Maxcess® place the handles medially) to permit the angle needed for contralateral decompression
c) the laminectomy and facet takedown (usually for a TLIF) are done
d) open the ligamentum flavum on the side you’re working on, to visualize the posterior extent of the spinal canal, to permit finding the plane between the posterior part of the ligamentum flavum and the undersurface of the bone
e) the ligamentum flavum is left in place on the contralateral side to protect the dura during drilling
f) complete the decompression and disc removal on the side you’re working on
g) the undersurface of the bone (spinous process and contralateral lamina) are then drilled to decompress the contralateral side
h) once the undersurface of the contralateral posterior canal has been drilled, the ligamentum flavum is removed with pituitary rongeurs. It is possible to even do a contralateral foraminotomy at this point (curved Kerrison rongeurs are very helpful for this)
i) pedicle screws are placed through the open side, and then percutaneously through the contralateral side
j) this is generally followed by a transforaminal lumbar interbody fusion (TLIF)

**Interspinous process decompression/stabilization/fusion**

Interspinous spacers (e.g. X-Stop™ (Medtronic)) limit extension at 1 or 2 levels (without fusion), preventing narrowing of the associated neural foramen, and may also off-load the facet joints and even the disc. “Success rate”: 63% at 2 years. This device may be used as a standalone.

Interspinous plates (e.g. Aspen® (Lanx), Affix™ (Nuvasive), Spire® (Medtronic)) clamp across two spinous processes to fixate them (unlike X-Stop™ which just limits extension). The Aspen® clamps have a space for a graft which may optionally be used to promote fusion between the spinous processes. Interspinous plates may be used to augment other constructs e.g. lateral interbody fusion, but are not intended for standalone use. Biomechanical stability is reported to be similar to bilateral pedicle screws in flexion, and unilateral pedicle screws in lateral bending.

**Contraindications** (includes exclusionary criteria from the IDE study):
1. instability at level considered for procedure: spondylolisthesis > Grade 1 or scoliosis with Cobb angle ≥ 25°
2. cauda equina syndrome
3. acute fracture of the spinous process
4. bilateral pars defects (disconnects spinous process from the anterior elements)
5. osteoporosis. Contraindications per the IDE: DEXA scan (p.1009) with spine or hip T-score < −2.5 (i.e. more than 2.5 SD below the mean for normal adults) in the presence of ≥ 1 fragility fractures. Concerns: spinous process fracture at the time of insertion, or late subsidence due to microfractures. However, Kondrashov36 interprets a T-score < −2.5 anywhere as indicative of osteoporosis (even without fragility fractures). Options here include:
   a) augmenting the spinous processes by injecting ≈ 0.5–1 cc of PMMA into each spinous process (SP) with a 13 Ga needle inserted ≈ halfway into the SP on lateral fluoro prior to dilating the interspace or placing the X-Stop. Verify central position within SP on AP fluoro, and monitor injection on fluoro
   b) X-Stop® made of titanium and PEEK (the modulus of elasticity of PEEK is closer to bone than titanium is)
6. ankylosed level (i.e. already fused)
7. L5-S1 level: the spinous process of S1 is usually too small (not usually an issue since symptomatic stenosis at L5-S1 is rare)
8. age < 50 years: not studied in IDE investigation

**Surgical pointers:**
1. it is critical that the spacer sit in the anterior third of the spinous process
2. results may be better with the patient awake, under local anesthesia, lying on their side in a position that they feel is relieving their pain (thus opening up the critical levels). This may reduce the risk of undersizing the prosthesis
Post-op (based on manufacturer’s recommendations):
1. to avoid spinous process stress fracture: build-up physical activity gradually
2. 1st 6 weeks post-op: no spine hyperextension, no heavy lifting. Minimize stair climbing
3. initially, walking (for <1 hour) is recommended as long as it is comfortable
4. at 2 weeks post-op: cycling (stationary or bicycle) may be added
5. 6 months post-op: may add sports such as swimming, golf, racquetball, tennis, running or jogging

Gill procedure
This procedure, and its modifications, consist of radical decompression of nerve roots including removal of the loose posterior elements and total facetectomy. This is most usually followed by fusion (posterolateral or interbody). Fusion rate may be enhanced with the use of internal fixation (e.g. transpedicular screw-rod fixation).

Reduction of spondylolisthesis
Reduction of spondylolisthesis can be accomplished with instrumentation, and requires a fusion.

The risk of nerve root injury with reduction of grade I or II spondylolisthesis is low.
Reduction of high-grade (grade III or IV) spondylolisthesis carries a risk of radiculopathy (e.g. L5 radiculopathy in cases of L5-S1 spondylolisthesis) in 50%of cases (some permanent) and may produce a cauda equina syndrome, probably from stretching nerve roots by distraction. Some have recommended intraoperative stimulation of nerve while performing EMG recording as the listhesis is gradually reduced, and stopping if the current required for stimulation increases 50%above baseline.

Isthmic spondylolisthesis (spondylolysis) – pars interarticularis defect
Instrumentation and/or fusion

Practice guideline: Fusion in patients with lumbar stenosis without spondylolisthesis

Level III:
- in situ posterolateral fusion is not recommended following decompression in patients with lumbar stenosis in whom there is no evidence of preexisting spinal instability or likely iatrogenic instability due to facetectomy
- in situ posterolateral fusion is recommended in patients with lumbar stenosis in whom there is evidence of spinal instability
- the addition of pedicle-screw instrumentation is not recommended in conjunction with posterolateral fusion following decompression

Practice guideline: Fusion in patients with lumbar stenosis and spondylolisthesis

Level II:
- posterolateral fusion is recommended for patients with stenosis and associated degenerative spondylolisthesis who require decompression

Level III:
- pedicle screw fixation as an adjunct to posterolateral fusion should be considered in patients with stenosis and spondylolisthesis in cases where there is pre-op evidence of spinal instability or kyphosis at the level of the spondylolisthesis or when iatrogenic instability is anticipated (note: the definition of “instability” and “kyphosis” varies, and has not been standardized).

Fusion may accelerate degenerative changes at adjacent levels. Some surgeons recommend fusion at levels of spondylolisthetic stenosis. Patients with combined degenerative spondylolisthesis, stenosis, and radiculopathy may be reasonable candidates for fusion.
Booking the case: Lumbar lamí + fusion for stenosis

Also see defaults & disclaimers (p. 27).
1. position: prone
2. implants: for fusions, schedule with the vendor for the desired implants and associated instrumentation
3. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: through the back to remove bone, ligament and any other tissue that is pressing on the nerve(s). If a fusion is to be done, then typically this will be accomplished using screws, rods and small cages, as required
   b) alternatives: nonsurgical management
   c) complications: usual spine surgery complications (p. 28), plus there might not be the amount of pain relief desired (back pain does not respond as well to surgery as nerve-root pain). There can be problems with the implants, including breakage, migration (slippage), or undesirable positioning which may require further surgery.

72.9 Outcome

72.9.1 Morbidity/mortality
Risk of in-hospital mortality is 0.32%\textsuperscript{17} Other risks include: unintended durotomy (p. 1055) (0.32%\textsuperscript{7} to \(\approx 13\%\textsuperscript{28,42}\)), deep infection (5.9%), superficial infection (2.3%), and DVT (2.8%); see also Risks of lumbar laminectomy (p. 1053).

72.9.2 Nonunion
Risk factors for nonunion in fusion operations (does not necessarily correlate with success of operation):
1. cigarette smoking delays bone healing and increases the risk of pseudoarthrosis following spinal fusion procedures, especially in the lumbar spine\textsuperscript{12}
2. number of levels: in lumbar fusions, fusing 2 levels resulted in increased nonunion rates compared to fusing 1 level\textsuperscript{43}
3. NSAIDs: controversial
   a) short-term (\(\leq 5\) days) post-op use: high-dose ketorolac (120–240 mg/d) was associated with increased risk of nonunion, but low-dose ketorolac (\(\leq 110\) mg/d), and celecoxib (200–600 mg/d) or rofecoxib (50 mg/d) were not\textsuperscript{43}
   b) some feel that long-term NSAID use does lower fusion rate\textsuperscript{44}

72.9.3 Success of operation
General information
Patients with a postural component to their pain had much better results (96% good result) than those without a postural component (50% good results), and the relief of leg pain was much more successful than relief of back pain.\textsuperscript{45} Surgery is most likely to reduce LE pain and improve walking tolerance.\textsuperscript{41}

Outcome studies
SPORT study
There have been many attempts to ascertain the benefit of surgery, including the $13.5 million SPORT study. Shortcomings of the study include: patients were allowed to decline randomization and were then entered into an observational cohort which may introduce bias into the groups, crossovers were allowed between patients randomized to surgery and those randomized to nonsurgical treatment (degrading the “intention to treat” analysis), no standardized surgical or nonsurgical technique, relatively low long-term follow-up (52% at 8 years), change in paradigm from analyzing intention-to-treat to an as-treated analysis.

Results indicated a strong benefit of surgery at 4-years follow-up\textsuperscript{46} that appeared to diminish by 8-years in the randomized cohort but persisted in the observational cohort.\textsuperscript{47}
Other long-term outcome studies

The literature review with long-term follow-up found good or excellent outcome after surgery with a mean of 64% (range: 26–100%). A patient satisfaction survey indicated that 37% were much improved and 29% somewhat improved (total: 66%) post-op. A prospective study found a success rate of 78–88% at 6 wks and 6 months, which dropped to ≈70% at 1 year and 5 yrs. Success rates were slightly lower for lateral recess syndrome.

Reasons for surgical failure

Surgical failure may be divided into two groups:

1. patients with initial improvement who develop recurrent difficulties. Although short-term improvement after surgery is common, many patients progressively deteriorate over time. One study found a 27% recurrence of symptoms after 5 years follow-up (30% due to restenosis at the operated level, 30% due to stenosis at a new level ("adjacent segment failure"); 75% of these patients respond to further surgery). Other etiologies include: development of herniated lumbar disc, development of late instability including kyphosis ("proximal junction kyphosis" – PJK), coexisting medical conditions

2. patients who fail to have any post-op pain relief (early treatment failures). In one series of 45 such patients:
   a) the most common finding was a lack of solid clinical and radiographic indications for surgery (e.g. non-radicular LBP coupled with modest stenosis)
   b) technical factors of surgery had less influence on outcome, with the most common finding being failure to decompress the lateral recess (which, in non-fusion cases, requires judicious medial facetectomy or undercutting the superior articular facet)
   c) other diagnoses (e.g. arachnoiditis), missed diagnosis (e.g. spinal AVM)

References

73 Adult Spinal Deformity and Degenerative Scoliosis

73.1 General information

**Key concepts**

- Adult spinal deformity (ASD) encompasses scoliosis and sagittal imbalance
- Sagittal balance correlates with quality of life measures
- Basic spine measurements needed: LL, PI, PT, ± SVA
- Major alignment objectives: LL = PI ± 9°, PT < 20°, SVA < 5 cm

Adult spinal deformity (ASD) is a broad term that refers to a wide spectrum of structural abnormalities of a mature spine. ASD encompasses abnormalities in the coronal plane (scoliosis) as well as abnormalities in the sagittal plane.

The term “adult degenerative scoliosis” (ADS) (as distinguished from idiopathic juvenile scoliosis (IJS)) is often used interchangeably with ASD. Definition of adult degenerative scoliosis: spinal deformity with Cobb angle >10° in a skeletally mature individual. ADS may be the result of childhood idiopathic scoliosis persisting into adulthood, or may be de novo.

Deformity in ASD can be primarily due to asymmetric disc degeneration or secondary to hip pathology, osteoporosis and asymmetric loads. It subsequently involves posterior elements (including facet joints) and thereafter axial rotation, lateralolisthesis and ligamentous laxity. Progressive facet and discogenic degeneration may lead to segmental instability and subsequent central/foraminal stenosis secondary to ligamentum flavum hypertrophy and osteophyte formation and well as spondylolisthesis.

While treatment goals include reduction of pain, symptomatic neural compression and disability due to deformity, the methodology and biomechanics of ADS treatment differ greatly from treating IJS in the adolescent.

ADS tends to progress at an average rate of 3° per year (range: 1–6°). Factors associated with higher rates of progression: Cobb angle >30°, apical rotation >Grade II (on the Nash-Moe system, which is falling into disuse), lateral listhesis >6 mm, and an intercrest line through L5. Factors not correlated with rate of progression: age and gender. Controversial associations: osteopenia.

73.2 Epidemiology

ASD is more prevalent in patients age >60 years, however true prevalence is not well defined. >50% of adults hospitalized with spinal deformity are >65 years. Incidence of asymptomatic scoliosis ranges from 1.4%–32% and up to 68% in patients >60.

73.3 Clinical evaluation

Location, time and duration pain (leg vs. axial back) are important factors in evaluation of a patient with ASD. These patients may also have symptoms of spinal stenosis (central or radicular), which may require concomitant decompression. The patient’s ability to perform activities of daily living and medical co-morbidities (e.g. cardiac, osteoporosis etc.) need be taken into consideration for treatment planning.

Some patients present with obvious spinal deformity (scoliosis, forward flexion at the waist, walking with knees bent).

As with neurogenic claudication, patients tend to be more symptomatic when up on their feet. A significant amount of pain may be generated by attempting to correct for spinal imbalance by using paraspinal muscles as well as retroverting the pelvis (rotating it backward at the hips) and not fully extending the knees. All this extra muscle activity is fatiguing and begins to produce muscle pain in the back and thighs. Patients with ASD tends to be better in the morning when they are rested.

Unlike lumbar spinal stenosis in the absence of scoliosis, symptoms may not relieved by flexion. There may be some relief when supporting the trunk with the arms.

73.4 Diagnostic testing

CT / MRI. Both are recommended for the evaluation of symptomatic spondylosis and ASD to determine extent of neural compression.
DEXA (dual-energy x-ray absorptiometry). Patients should be evaluated for osteopenia/osteoporosis prior to surgical planning. Medical treatment may be beneficial in the peri-operative period.

Some surgeons use Forteo for 3 months (off-label use – controversial) in an effort to try and quickly increase osteoporotic bone strength for surgery.

Standing scoliosis x-rays. Recommended for the evaluation of global and regional spinal balance. Pre and postoperative plain films help confirm that alignment objectives are achieved.

Measurements related to sagittal balance are taken from standing scoliosis x-rays (CT & MRI are obtained supine and are not equivalent). Technical requirements for the lateral image:
- x-ray must image from C7 down to the femoral heads
- the patient needs to try to keep the knees straight (extended)
- arms should be folded in front of the chest (and they should not lean or hold on to anything)

Dynamic scoliosis x-rays (“lateral bending films”) help determine the degree of curve rigidity preoperatively.

73.5 Pertinent spine measurements

73.5.1 General information

Quantification of severity of spinal deformity and classification helps guide appropriate treatment paradigms.3,10

73.5.2 Scoliosis nomenclature

Scoliosis is measured using Cobb angles. On an AP x-ray, the “end vertebrae” are identified at the top and bottom of the scoliotic curve and are defined as the vertebrae with the greatest angle relative to the horizontal plane. One horizontal line is drawn through the superior endplate of the superior “end vertebra”, and a second is drawn through the inferior endplate of the inferior “end vertebra.” The Cobb angle is the angle between these 2 lines. Curves are named for the convex side (dextroscoliosis = convex to right, leftscoliosis = convex to left).

A non-structural curve can correct on side bending. A structural curve is not flexible.

The major curve is the largest structural curve. A fractional curve is the curve below the major curve.

73.5.3 Spino-pelvic parameters

Measurement methodology and pertinent information are shown in Table 73.1 and illustrated in Fig. 73.1 and Fig. 73.2. Basic measurements that can be correlated with pain reduction and quality of life measures:
- LL (lumbar lordosis)
- PI (pelvic incidence)
- PT (pelvic tilt)
- ± SVA (sagittal vertical alignment): while this can be helpful at times, it also appears to be subject to variability depending on how much pain the patient has with standing up straight

With the exception of CSVL, the measurements shown in Table 73.1 are all taken from a lateral standing x-ray (Fig. 73.1 and Fig. 73.2).

73.6 SRS-Schwab classification of adult spinal deformity

Adult scoliosis has been classified by the Scoliosis Research Society (SRS)16 based on its regional/global radiographic features (a modification of previously established adolescent King/Moe and Lenke classifications) and most recently by spino-pelvic parameters as it relates to health-related quality of life17,18,19 is shown here.

- Coronal Curve types
  - T: Thoracic only (with lumbar curve <30°)
  - L: Thoracolumbar/Lumbar only (with thoracic curve <30°)
  - D: Double curve (both T and T/L curves >30°)
  - N: No major coronal deformity (all coronal curves <30°)

- Sagittal Modifiers
  - Pelvic harmony (PI minus LL)
    - 0: non pathologic (PI-LL<10°)
    - +: moderate deformity (10°<PI-LL<20°)
    - ++: marked deformity (PI-LL>20°)
Global alignment (SVA)
- 0: non pathologic (SVA<4 cm)
- +: moderate deformity (4 cm < SVA < 9.5 cm)
- ++: marked deformity (SVA > 9.5 cm)

Pelvic Tilt (PT)
- 0: non pathologic (PT<20°)
- +: moderate deformity (20° < PT < 30°)
- ++: marked deformity (PT > 30°)

73.7 Treatment/management

73.7.1 Options
1. observation
2. focal decompression
3. surgical correction of deformity
   a) MIS (minimally invasive (spine) surgery)
   b) Hybrid (MIS+open)
   c) Traditional open surgery (transforaminal lumbar interbody fusion (TLIF), posterior lumbar interbody fusion (PLIF)...

Treatment options are based on clinical symptoms (axial back pain ± radiculopathy vs. radiculopathy alone) and degree of abnormalities in sagittal (balance need for open osteotomies or anterior column release ACR). Neuropathic symptoms most often originate from foraminal compromised on the
concavity of the curve, but can be seen on the convexity in the setting of facet hypertrophy and may improve with indirect decompression and correction in the coronal plane. Significant central stenosis (neurogenic claudication) may require concomitant direct decompression in addition of deformity correction.

Goal of surgery: to improve quality of life measures, neuropathic and axial pain. A surgeon’s armamentarium includes traditional open, MIS and hybrid procedures, which is patient and deformity specific. More recently, the surgical decision making paradigms have included MIS techniques to limit approach related morbidity. MIS techniques include lateral interbody fusion, ALLR, MIS-TLIF and percutaneous pedicle screw fixation, which can be used with posterior osteotomies to enhance corrective power.

Fig. 73.2 Schematic lateral spine diagram showing method for measuring PT, PI and SS.

<td>Positive numbers are to the right, negative to left</td>
</tr>
</tbody>
</table>

*For measurements involving the femoral head (PT, PI & TPA) if the two femoral heads are not superimposed, measure to a point that is midway between the centers of the two femoral heads.

PI is unaffected by posture or degenerative changes (i.e. patients cannot compensate by changing this). A high PI correlates with a higher risk of progression of spondylolisthesis, a low PI correlates with a lower risk.
73.7.2 Correction of global spinal balance

Indications for surgery
● Axial back pain ± neuropathic symptoms (deleterious to ADLs)
○ Abnormal SVA
○ ± CSVL (central sacral vertical line) abnormality
○ or derangement of spino-pelvic parameters.
● Patient age and co-morbidities must be taken into consideration (osteopenia, anesthetic risk and medical co-morbidities can limit correction goal and amount of surgery that is safe)

Summary of spino-pelvic objectives
● LL = PI ± 9°
● PT < 20°
● SVA < 5 cm

In most instances, correction of sagittal imbalance is due to a shortfall of lumbar lordosis (LL) relative to the pelvic incidence (PI) – which can be considered flat back syndrome. That is, LL is usually more than 9° below PI.

Pelvic tilt > 20° suggests the patient is trying to compensate by retroverting the pelvis (some authors accept up to 25° as normal).

The minimum amount of correction that the surgeon tries to achieve is therefore that amount that LL needs to increase to bring it within 9° of PI, and typically also adds in the amount that the patient is compensating (i.e. the amount that PT is greater than 20°) which yields the following approximation (applies when LL is more than 9° lower than PI, and PT is greater than 20°); see Eq (73.1):

\[
\text{Increase in LL needed} \% = \frac{\text{PT} - 20}{\text{PI} - \text{LL} - 9} \text{ or } \frac{\text{PT} - 20}{\text{LL} - \text{PI} + 9}
\]

Coronal balance. Measured on AP standing scoliosis x-ray. A plumb line is dropped from the center of the C7 VB. If it falls >4 cm from the midline of the sacrum (where the CSVL is located), there is coronal imbalance (if the plumb line falls to the right of the CSVL it is positive, to the left it is negative).

73.7.3 Surgical options for increasing lumbar lordosis

Various surgical techniques may be used to increase the lumbar lordosis to bring it within the desired specifications. If necessary, these techniques can be combined with procedures to decompress the neural elements (e.g. laminectomy). A comparison of the approximate amount of lordosis that can be achieved with different techniques is shown in Table 73.2.

Transforaminal lumbar interbody fusion (TLIF) and posterior lumbar interbody fusion (PLIF). Traditional operation. May be done open or MIS.

Lateral lumbar interbody fusion (LLIF). E.g. XLIF™, DLIF™, OLIF™. Approach through psoas muscle (XLIF; DLIF) or anterior to psoas muscle (OLIF) through a lateral or anterolateral approach. Can distract the vertebral bodies by increasing the height of the disc space and thereby indirectly decompressing the neural elements. If bone quality is good, and there is no instability nor spondylolisthesis > Grade I, a standalone procedure (i.e. without screw instrumentation) may be an option if cage width of at least 22 mm (or preferably 26 mm) in the AP dimension is used.

Table 73.2 Comparison of the amount of lumbar lordosis that can be obtained from various surgical techniques.

Abbreviations: TLIF = transforaminal lumbar interbody fusion; PLIF = posterior lumbar interbody fusion; LLIF = lateral lumbar interbody fusion; ALIF = anterior lumbar interbody fusion; SPO = Smith-Petersen osteotomy; ACR = anterior column release; PSO = pedicle subtraction osteotomy
Anterior column release (ACR). Involves division of the anterior longitudinal ligament (ALL release (ALLR)) typically with placement of a “hyperlordotic” cage (20–30° lordosis) from an anterior approach (e.g. lateral interbody technique). This is followed by posterior fixation, often with a Smith-Petersen osteotomy (especially for 30° cages) and compression. It can increase LL up to 12° per ACR level and improvement of SVA up to 3 cm (depending on the level at which it is performed).22,24

Risk of injury to great vessels, either directly (when cutting the ALL) or indirectly by elongating the anterior column. It is critical to evaluate the great vessels on axial MRI or CT or on angiogram and to not do the procedure if the vessels appear tightly approximated to the bodies or to osteophytes, at that level.

Smith-Petersen osteotomy (SPO). AKA “chevron or extension osteotomy” can increase lordosis up to 10° per level. Approximately one degree for each millimeter of bone resected.25,26 Involves removal of bilateral superior and inferior facets along with the ligamentum flavum and portion of the lamina above and below. The created gap is then closed with compression of the posterior elements to give lordosis (resecting posterior elements and using the middle column as a fulcrum to elongate the anterior column, Fig. 73.3 A).26,27 LL is increased approximately 1° for every 1 mm of bone removed.

Fig. 73.3 Comparison of A: Pedicle subtraction osteotomy and B: Smith Petersen osteotomy plus ACR. Abbreviations: ALL=anterior longitudinal ligament, ACR=anterior column release.
The term “Ponte osteotomy” is often used interchangeably with SPO, but the Ponte was originally described for treating Scheuermann’s kyphoscoliosis.

Pedicle subtraction osteotomy (PSO). Involves removal of the posterior elements including the ligmanetum flavum, lamina and facets widely, followed by isolation and resection of pedicles bilaterally and wedge shaped removal of the vertebral body just barely up to the ventral cortex. The created gap is then closed by compression of the posterior elements and subsequent greenstick fracture of the isolated ventral cortex (Fig. 73.3.2). Can increase LL by 30°- 40° per level, improvement of SVA 5.5 – 13 cm per level.

This procedure is technically challenging and is associated with high blood loss (3 L in 1 series) and increased risk of complications (including proximal junctional kyphosis (PJK) in 23%) compared to SPO. Generally reserved for spines that have previously been fused where it is not possible to get the amount of lordosis needed from the unfused levels. The PSO is a spine “shortening” procedure.

Uses the anterior column as a fulcrum. Usually limited to levels below the conus medullaris (i.e. L1–2) due to inward buckling of the dura (L3 is the most common level). Intraoperative electrophysiologic monitoring is required. Relative contraindication: poor bone quality.

Anterior lumbar interbody fusion (ALIF). Best for L5-S1 (where the great vessels tend not to interfere with the access, and where every degree of correction produces a more significant amount of improvement in SVA than at other levels as a result of being at the lowest point in the spine).

73.7.4 Guidelines for MIS treatment for ASD

A simple algorithm for MIS management of sagittal imbalance based on spinopelvic parameters and the approximate SRS-Schwab class is shown in Table 73.3. See references for a more detailed protocol.

Currently under investigation by the SRS: when, and to what degree, does improvement in sagittal balance occur with simple decompression (possibly with a minimal fusion) as a result of pain relief permitting the patient to stand up straighter with less pain.

Recommendations for anterior procedure:
- MIS LLIF
- MIS-LLIF to neutral vertebrae + ACR
- MIS-LLIF to neutral vertebrae ± ACR

Recommendations for posterior procedure:
- If PT <20° consider standalone, otherwise percutaneous fixation
- Percutaneous fixation to S1 ± facetectomy(ies)
- Open fixation to S2 or iliac + osteotomy(ies)

To use this table, determine which category the patient fits into (Mild, Moderate or Severe) using either the Deukmedjian parameters (on which this reference is based) or the roughly equivalent SRS-Schwab parameters shown.

Abbreviations:
- CCA = Cobb coronal angle; LLIF = lateral lumbar interbody fusion (e.g. XLIF, DLIF, OLIF…); ACR = anterior column release
- a in the SRS-Schwab classification, PT <20° is considered normal
- b standalone meaning no posterior fixation, assumes that bone quality is not osteoporotic and that a cage width of at least 22 mm is used (to reduce the risk of subsidence)

Table 73.3 MIS management recommendations based on severity of ASD with approximate SRS-Schwab Class equivalence.

74 Special Conditions Affecting the Spine

74.1 Paget’s disease of the spine

74.1.1 Pathophysiology

Paget’s disease (PD) (AKA osteitis deformans) is a disorder of osteoclasts (possibly virally induced) causing increased rate of bone resorption with reactive osteoblastic overproduction of new, weaker, woven bone, producing characteristic “mosaic pattern.”

Initially there is a “hot” phase with elevated osteoclastic activity and increased intraosseous vascularity. Osteoblasts lay down a soft, nonlamellar bone. Later a “cool” phase occurs with disappearance of the vascular stroma and osteoblastic activity leaving sclerotic, radiodense, brittle bone ("ivory bone").

74.1.2 Malignant degeneration

A misnomer, since the malignant changes actually occur in the reactive osteoblastic cells. About 1% (reported range: 1–14%) degenerate into sarcoma (osteogenic sarcoma, fibrous sarcoma, or chondrosarcoma), with the possibility of systemic (e.g. pulmonary) metastases. Malignant degeneration is much less common in the spine than in the skull or femur.

74.1.3 Epidemiology

Prevalence: ≈ 3% of population >55 years old in the U.S. and Europe, much lower in Asia. Slight male predominance. Family history of Paget’s disease is found in 15–30% of cases (accuracy is poor since most are asymptomatic).

74.1.4 Common sites of involvement

Affinity for axial skeleton, long bones and skull. In approximate descending order of frequency: pelvis, thoracic and lumbar spine, skull, femur, tibia, fibula, and clavicles.

74.1.5 Neurosurgical involvement

PD may present to the neurosurgeon as a result of:
1. back pain: usually not as a direct result of vertebral bone involvement (see below)
2. spinal cord and/or nerve root symptoms
   a) compression of the spinal cord or cauda equina (relatively rare)
   b) spinal nerve-root compression
   c) vascular steal due to reactive vasodilatation adjacent to involved areas
3. with skull involvement:
   a) compression of cranial nerves as they exit through bony foramina: 8th nerve is most common, producing deafness or ataxia (p.1400)
   b) skull base involvement →basilar invagination
4. to ascertain diagnosis in unclear bone lesions of the spine or skull

74.1.6 Presentation

General information

Only ≈ 30% of pagetic sites are symptomatic, the rest are discovered incidentally. The overproduction of weak bone may produce bone pain (the most common symptom), predilection for fractures and compressive syndromes: cranial nerve (p.1400), spinal nerve root... Painless bowing of a long bone may be the first manifestation. A number of patients present due to pain from joint dysfunction related to PD.

The overwhelming majority of pagetic lesions are asymptomatic with lesions detected on radiographs or bone scan obtained for other reasons or as part of a work-up for an elevated alkaline phosphatase. Although the most common complaint in patients with Paget’s disease is of back pain, this is attributable to pagetic involvement alone in only ≈ 12%, in the remainder it is secondary to other factors, some of which are described below.
Symptoms that may be related to the Paget’s disease itself

Symptoms from the following are slowly progressive (usually present for >12 months; rarely <6 mos):

1. neural compression
   a) causes of compression
     • due to expansion of woven bone
     • due to osteoid tissue
     • pagetic extension into ligamentum flavum and epidural fat
   b) sites of compression
     • spinal cord (see below)
     • nerve root in neural foramen

2. osteoarthritis of facet joints (Paget’s disease may precipitate osteoarthritis)

Symptoms from the following tend to progress more rapidly:

1. malignant (sarcomatous) change of involved bone (rare, see above)
2. pathologic fracture (pain usually sudden in onset)
3. neurovascular (compromise of vascular supply to nerves or spinal cord) by
   a) compression of blood vessels (arterial or venous)
   b) pagetic vascular steal (see below)

Spinal cord symptoms

Myelopathy or cauda equina syndrome may be due to spinal cord compression or from vascular effects (occclusion, or “steal” due to reactive vasodilatation of nearby blood vessels). Only ≈ 100 cases had been described as of 1981. Characteristically, 3–5 adjacent vertebrae are involved, whereas monostotic involvement is usually asymptomatic. In case reports in the literature, progressive quadri- or paraparesis was the most common presentation. Sensory changes are usually the first manifestation, progressing to weakness and sphincter disturbance. Pain was the only symptom in a neurologically intact patient in only 5.5%.

A rapid course (averaging 6 wks) with a sudden increase in pain is more suggestive of malignant degeneration.

74.1.7 Evaluation

1. lab work (serum markers may be normal in monostotic involvement):
   a) serum alkaline phosphatase: usually elevated (this enzyme is involved in bone synthesis and so may not be elevated in purely lytic Paget’s disease); mean 380 ± 318 IU/L (normal range: 9–44).
   b) calcium: usually normal (if elevated, one should R/O hyperparathyroidism)
   c) urinary hydroxyproline: hydroxyproline is found almost exclusively in cartilage. Due to the high turnover of bone, urinary hydroxyproline is often increased in PD with a mean of 280 ± 262 mg/24 hrs (normal range 18–38)

2. bone scan: lights up in areas of involvement in most, but not all cases

3. plain x-rays:
   a) localized enlargement of bone: a finding unique to PD (not seen in other osteoclastic diseases, such as prostatic bone mets)
   b) cortical thickening
   c) sclerotic changes
   d) osteolytic areas (in skull → osteoporosis circumscripta; in long bones → “V” shaped lesions)
   e) spinal Paget’s disease often involves several contiguous levels. Pedicles and lamina are thickened, vertebral bodies are usually dense and compressed with increased width. Intervening discs are replaced by bone

4. CT: hypertrophic changes at the facet joints with coarse trabeculations

74.1.8 Treatment

Medical treatment for Paget’s disease

General information

There is no cure for Paget’s disease. Medical treatment is indicated for cases that are not rapidly progressive where the diagnosis is certain, for patients who are poor surgical candidates, and pre-op if
excessive bleeding cannot be tolerated. Medical therapy reverses some neurologic deficit in 50% of cases, but generally requires prolonged treatment (≈ 6–8 months) before improvement occurs, and may need to be continued indefinitely due to propensity for relapses. Medications used include the following.

Calcitonin derivatives
Parenteral salmon calcitonin (Calcimar®): reduces osteoclastic activity directly, osteoblastic hyperactivity subsides secondarily. Relapse may occur even while on calcitonin. Side effects include nausea, facial flushing, and the development of antibodies to salmon calcitonin (these patients may benefit from a more expensive synthetic human preparation (Cibacalcin®) starting at 0.5 mg SQ q d).

50–100 IU (medical research council units) SQ q d × 1 month, then 3 injections per week for several months. If used pre-op to help decrease bony vascularity, ≈ 6 months of treatment is ideal. Doses as low as ≈ 50 IU units 3 × per week may be used indefinitely post-op or as a sole treatment (alkaline phosphatase and urinary hydroxyproline decline by 30–50% in > half of patients in 3–6 months, but they rarely normalize).

Bisphosphonates
These drugs are pyrophosphate analogues that bind to hydroxyapatite crystals and inhibit reabsorption. They also alter osteoclastic metabolism, inhibit their activity, and reduce their numbers. They are retained in bone until it is resorbed. Oral absorption of all is poor (especially in the presence of food). Bone formed during treatment is lamellar rather than woven.

Etidronate (Didronel®) (AKA EHDP): reduces normal bone mineralization (especially at doses ≥ 20 mg/kg/d) producing mineralization defects (osteomalacia) which may increase the risk of fracture but which tend to heal between courses. Contraindicated in patients with renal failure, osteomalacia, or severe lytic lesions of a LE. 5–10 mg/kg PO daily (average dose: 400 mg/d, or 200–300 mg/d in frail elderly patients) for 6 months, may be repeated after a 3–6 month hiatus if biochemical markers indicate relapse.

Tiludronate (Skelid®): unlike etidronate, does not appear to interfere with bone mineralization at recommended doses. Side effects: abdominal pain, diarrhea, N/V. 400 mg PO qd with 6–8 ounces of plain water ≥ 2 hrs before or after eating × 3 months. Available: 200 mg tablets.

Pamidronate (Aredia®): much more potent than etidronate. May cause a transient acute flu-like syndrome. Oral dosing is hindered by GI intolerance, and IV forms may be required. Mineralization defects do not occur in doses < 180 mg/course. 90 mg/d IV × 3 days, or as weekly or monthly infusions.

Alendronate (Fosamax®): does not produce mineralization defects (p. 1010).

Clodronate (Ostac®, Bonefos®): 400–1600 mg/d PO × 3–6 months. 300 mg/d IV × 5 days (may be available outside the U.S.).

Risedronate (Actonel®): does not interfere with bone mineralization in recommended doses: 30 mg PO q d with 6–8 oz. of water at least 30 minutes before the first meal of the day.

Surgical treatment
General information
In general, conservative treatment of fractures in PD are associated with a high rate of delayed union.

Surgical indications for spinal Paget’s disease
1. rapid progression: indicating possible malignant change or spinal instability
2. spinal instability: severe kyphosis or compromise of canal by bone fragments from pathologic fracture. Although the collapse is usually gradual, sudden compression may occur
3. uncertain diagnosis: especially to R/O metastatic disease (osteoblastic lesions)
4. failure to improve with medications

Surgical considerations
1. profuse bleeding is common: if significant bleeding would present an unusual problem, treat for as long as feasible pre-op with a bisphosphonate or calcitonin (see above)
a) use bone wax to help control bleeding
b) hemostasis may be difficult
2. To treat resultant spinal stenosis: decompressive laminectomy is the standard procedure in the thoracic region. However, if most of the pathology is anterior, consideration should be given to anterior approach.

3. Bone is often thickened, and may be fused with obliteration of interspace landmarks. A high-speed drill is usually helpful.

4. Post-op medical treatment may be necessary to prevent recurrences.

5. Osteogenic sarcoma
   a) Surgery and chemotherapy are used, cure is less likely than in primary osteosarcoma of non-Pagetic origin.
   b) Biopsy proven of the scalp requires en-bloc excision of scalp and tumor.

Surgical outcome
See reference.

In 65 patients treated with decompressive laminectomy, 55 (85%) had definite but variable degrees of improvement. Patients who had only minimal improvement were often ones with malignant changes. One patient was worse after surgery, and the operative mortality was 7 patients (10%). Survival with malignant degeneration is <5.5 mos after admission.

74.2 Ankylosing spondylitis

74.2.1 General information

**Key concepts**

- Prototypal spondyloarthritid, now referred to as radiographic axial spondyloarthritis
- Seronegative (absence of rheumatoid factor), associated with HLA-B27
- Begins in SI joints (sine qua non of involvement) progressing rostrally
- Clinical: morning back stiffness, kyphotic deformity limits chest expansion
- X-ray findings: “bamboo spine”, Andersson lesions, progressive thoracic kyphosis
- Fragile rigid spine highly susceptible to fracture and SCI even after low energy trauma
- Severe deformity, neurologic involvement or unstable fracture warrants surgical intervention

Historically known as Marie-Strümpell disease, Ankylosing spondylitis (AS) is an HLA-B27 associated inflammatory disease and the prototype of a group of diseases known as the spondyloarthritides (SpA). Common features are inflammatory back pain, negative serology for rheumatoid factor and absence of rheumatoid nodules, and asymmetric oligoarthritis predominantly of lower extremities. Currently referred to in the literature as Radiographic axial Spondyloarthritis (RxSpA), AS is believed to be the late stage of a single disease entity, axial Spondyloarthritis (axSpA) distinguished by definitive evidence of sacroiliitis on plain radiographs. Other conditions under this rubric include: psoriatic arthropathy, Reiter’s disease, juvenile spondyloarthropathy... AS has in the past also been known as rheumatoid spondylitis, or rheumatoid arthritis of the spine, but use of these terms is discouraged because of the lack of rheumatoid factor. The spine is the primary skeletal site involved, usually starting in the sacroiliac joints and lumbar spine and progressing rostrally.

Enthesopathy: nongranulomatous inflammatory changes at the entheses (attachment points of ligaments, tendons or capsules on bones; the locus of involvement in AS) stimulates re-placement of ligaments by bone ultimately resulting in osteoporotic VBs, calcified intervertebral discs (sparing the nucleus pulposus), and ossified ligaments, producing square appearing VBs with bridging syndesmophytes, the so-called “bamboo spine” or “poker spine”. Extra-articular manifestations (EAMs) include: anterior uveitis, inflammatory bowel disease (IBD) and psoriasis.

Neurosurgical involvement usually results from the following:

1. Cauda equina syndrome (CES-AS): the etiology of CES in AS is frequently unclear, but is usually not due to stenosis or compressive lesion. Onset is slow and insidious and there is a high incidence of dural ectasia. Any patient with AS and neurologic deficit should be assumed to have CES until proven otherwise. Without treatment most patients’ neurological status continues to deteriorate.

2. Rotatory subluxation: at occipitoatlantal and atlantoaxial joints. May occur as these are typically the last mobile segments of the spine. Incidence is much less than with rheumatoid arthritis. Lesions that might be stable in otherwise normal spines are often not stable in AS.

3. Myelopathy secondary to bow-stringing of the cord: laminectomy may aggravate...
4. acute spinal cord injury (SCI): risk of SCI or CES due to fracture is increased in AS, and may occur following minimal trauma. Injuries are more common in the lower cervical spine. The kyphosed spine of AS when fractured creates long lever arms, limiting the ability to absorb impact and rendering even minor fractures very unstable. Delayed deterioration may be due to spinal epidural hematoma. 

5. Andersson lesion: discovertebral lesion that results from inflammation or fracture, mechanical stresses prevent lesion from fusion resulting in pseudarthrosis.

6. spinal deformity

7. spinal stenosis: rare

8. basilar impression

74.2.2 Epidemiology

Incidence in the general population is ≈ 0.44-7.3 cases per 100,000. Traditionally reported male: female ratio 3:1, however, likely stems from underdiagnosis in women, and more rapid progression of spinal ankylosis in men. Peak incidence: 17-35 yrs age. >90% of patients with AS are HLA-B27 positive (only 8% of people without AS have this antigen), but only 2% of people with HLA-B27 develop clinical AS. Although AS is not hereditary, first degree relatives are at increased risk.

74.2.3 Clinical

Symptoms. Typical initial presentation is with nonradiating low back pain, morning back stiffness, hip pain and swelling (due to large joint arthritis), exacerbated by inactivity and improved with exercise.

Signs. Patrick’s test (p.1048) usually positive. Compressing the pelvis with the patient in the lateral decubitus position produces pain.

Schober test (measure distraction between skin marks on the back before and after forward flexion to detect reduced mobility of the spine due to fusion). Is not specific for inflammatory spondylopathies but may be helpful for monitoring ongoing physical therapy.

74.2.4 Diagnosis

Diagnosis by experienced rheumatologist is closest thing to a gold standard. The Assessment of SpondyloArthritis international Society (ASAS) recently presented its recommendations for a modified Berlin Algorithm as a potentially useful tool for rheumatologists in diagnosing AS. SI joint involvement is the sine qua non for definite diagnosis. Diagnosis is very involved, and includes: chronic low back pain, buttock pain, sacroilitis, family history, psoriasis, an inflammatory bowel disease or an arthritis followed in ≤ 1 month with urethritis, cervicitis or acute diarrhea, an enthesopathy, and a family history, and positive x-rays. The (obsolete) New York Criteria (Table 74.1) are shown here to provide a small insight into early attempts to establish diagnostic criteria, but should no longer be used for definitive diagnosis.

74.2.5 Radiographic evaluation

Plain x-rays. Vital for diagnosis and follow-up. Sacroiliac (SI) joint involvement (on AP pelvic x-rays or on oblique views through the plane of the SI joints) is one of the earliest findings, and the often symmetric osteoporosis followed by sclerosis is characteristic. “Bamboo spine” (see above) is also classic. X-ray of the entire spine is recommended since multiple, non-contiguous (and often unsuspected) fractures are not unusual. See Fig. 74.1.

CT. Useful for diagnosis of cervical fracture not apparent on plain radiographs, and in preoperative assessment of bony anatomy.

MRI. Can rule out spinal epidural hematoma and the occasional herniated disc. May demonstrate dural ectasia in cases of CES-AS syndrome. Andersson lesions: pathologic changes at ligament insertion sites (MRI signal abnormalities at front and back of the endplates) are characteristic. Erosive changes due to pseudarthrosis at the disc space can mimic discitis (high signal on T1WI & T2WI with enhancement).

Bone scan. Ratio of uptake of SI joint to sacrum >1.3:1 is suggestive of AS.
Differential diagnosis

1. early on, AS may resemble rheumatoid arthritis. However, in AS nodules do not form in joints, and rheumatoid factor is absent in the serum
2. metastatic prostate Ca in elderly male patients with sacroiliac pain and blastic changes compatible with sacroiliitis
3. Forestier’s disease (p. 1130) and DISH (p. 1129): these overlapping conditions produce exuberant bony overgrowth anterior and lateral to the disc without degeneration and ossification of the disc as in AS. Both spare the facets and SI joints, do not produce flexion deformity, and tend to occur in men > 50 yrs old (older than typical AS)
4. Psoriasis, Reactive Arthritis (Reiter’s syndrome), Enteropathic (IBD-related) Arthritis: the spondylitis with these tends to be milder and less uniform, and SI joint involvement is asymmetrical. Cutaneous findings (erythema nodosum, and pyoderma gangrenosum) are absent in AS.

Clinical criteria

- low back pain > 3 months, improved by exercise, not relieved by rest
- limitation of lumbar spine motion in both sagittal and frontal planes
- limitation of chest expansion relative to normal values for age and sex

Radiological criteria

- sacroiliitis

Fig. 74.1 AP lumbar/pelvic x-ray demonstrating “Bamboo spine” and sclerosis of sacroiliac joints

74.2.6 Differential diagnosis

1. early on, AS may resemble rheumatoid arthritis. However, in AS nodules do not form in joints, and rheumatoid factor is absent in the serum
2. metastatic prostate Ca in elderly male patients with sacroiliac pain and blastic changes compatible with sacroiliitis
3. Forestier’s disease (p. 1130) and DISH (p. 1129): these overlapping conditions produce exuberant bony overgrowth anterior and lateral to the disc without degeneration and ossification of the disc as in AS. Both spare the facets and SI joints, do not produce flexion deformity, and tend to occur in men > 50 yrs old (older than typical AS)
4. Psoriasis, Reactive Arthritis (Reiter’s syndrome), Enteropathic (IBD-related) Arthritis: the spondylitis with these tends to be milder and less uniform, and SI joint involvement is asymmetrical. Cutaneous findings (erythema nodosum, and pyoderma gangrenosum) are absent in AS.
74.2.7 Natural history

Progression is slow, and patients usually remain functionally active. Thoracic kyphosis with compensatory increase in cervical and lumbar lordosis is common. The shift in center of gravity together with spine stiffness and fragility predisposes to frequent falls and further spine injuries. Eventually can progress to involvement of costovertebral joints resulting in restrictive lung disease pattern. AS patients are also predisposed to development of fibrotic lung disease in late stages.

74.2.8 Treatment

General information

Combined ASAS/EULAR recommendations for management of AS are the most comprehensive currently available (copy available at ASAS website). Multidisciplinary, coordinated by a rheumatologist. Goal of treatment is long term quality of life through symptomatic control and prevention of progressive structural damage. NSAIDs are first line pharmacological management. Management of the disease itself may involve TNF inhibitors in patients with persistently high disease activity.

Surgical treatment

General information

The most common surgical intervention is orthopedic total hip arthroplasty.

Cervical fracture

The cervical spine is the most frequent fracture site in AS patients. Patients often cannot distinguish acute fracture pain from chronic inflammatory pain; therefore there should be a low threshold to obtain imaging. It is imperative to determine pre-injury alignment as application of C-collar may cause hyperextension injury. Gentle, low-weight traction with the force vector directed anteriorly and superiorly may be used for initial stabilization. Halo vest or surgery for unstable fracture pattern.

Surgical indications:

- irreducible deformity
- deteriorating neurological status in the presence of epidural hematoma or other source of compression
- unstable fracture (e.g. most 3-column fractures which are very unstable as a result of long lever arms of fused segments above and below): halo-vest immobilization is becoming a less frequently employed option for this

Procedures: Decompressive laminectomy if evidence of spinal cord compression. Given poor bone quality and extended lever arms, good fusion bed and a construct extending multiple levels above and below the fracture are critical. Proximally, lateral mass screws up to C3, possible pedicle screw in C2, and pedicle screws in thoracic spine for distal fixation. 360° fusion may provide optimal stabilization in some cases (where feasible).

Thoracolumbar fracture

The majority occur at thoracolumbar junction. Can be divided into 3 types: 1. shearing injury: typically acute. Resembles chance fracture, highly unstable 3 column injury 2. wedge compression: typically chronic 3. pseudarthrosis: typically subacute previously missed fracture

Wedge compression or pseudarthrosis; rule out posterior element involvement to determine if fracture is unstable. Stable fracture can be treated with external orthosis. Unstable fractures, consider thicker rods or more rigid rod material to account for increased forces across fracture, and PMMA augmentation to prevent screw pullout.

Kyphotic deformity

ASAS/EULAR recommendations include corrective osteotomy for severe disabling deformity. Can be accomplished via open wedge osteotomy, polysegmental wedge osteotomy, or closed wedge osteotomy (lowest complication rate). Cervical deformity is most commonly addressed with wedge
osteotomy at C7 and T1 given absence of vertebral artery in foramen transversarium at these levels. Current trend in literature is to address deformity simultaneously with acute fracture fixation.31,32

Cauda equina syndrome
Although evidence is limited, in the absence of demonstrable neural compression, a lumbo-peritoneal (LP) shunt may provide the best chance of improving neurologic dysfunction or halting progression of neurologic deficit.36

Surgical considerations
• Anesthesia team should be aware of Kyphotic deformity and fracture location: nasotracheal or fiberoptic intubation to prevent hyperextension of the neck and exacerbation of neurologic injury.33
• Extensive pre-op evaluation: fracture pattern, posterior ligamentous restraint, neurologic compression and function, preexisting bone quality.33
• Surgical positioning modified to account for preexisting deformity; support in all regions to prevent hyperextension and exacerbation of neurologic injury.33
• ICBG is gold standard; however, often a significant pain source potentially limiting mobilization and increasing likelihood of stasis sequelae (e.g. DVT), consider allograft.32
• Extensive knowledge of lateral mass and pedicle anatomy to ensure adequate hardware placement despite distorted bony anatomy and obscuring of typical landmarks.33
• Post-op immobilization via halo-vest or TLSO.33
• Expedited mobilization out-of-bed as AS patients are predisposed to pulmonary complications.33
• Plastic surgery to help manage skin necrosis and wound closure.33

74.3 Ossification of the posterior longitudinal ligament (OPLL)

74.3.1 General information

Key concepts

- fibrosis followed by calcification and then ossification of the posterior longitudinal ligament. The process may involve the dura
- more common in Asian population
- most patients have only mild subjective complaints
- 50% of patients have impaired glucose tolerance, respiratory compromise may result from ossification of the costotransverse and costovertebral ligaments
- surgery is best for moderate neuro involvement (Nurick grade 3 & 4)

The age of patients with OPLL ranges from 32–81 years (mean = 53), with a slight male predominance. The prevalence increases with age. Duration of symptoms averages ≈ 13 months. It is more prevalent in the Japanese population (2–3.5%).37,38

74.3.2 Pathophysiology
The pathologic basis of OPLL is unknown, but there is an increased incidence of ankylosing hyperostosis which suggests a hereditary basis.

OPLL begins with hypervascular fibrosis in the PLL which is followed by focal areas of calcification, proliferation of periosteal cartilaginous cells and finally ossification.39 The process frequently extends into the dura. Eventually active bone marrow production may occur. The process progresses at varying rates among patients, with an average annual growth rate of 0.67 mm in the AP direction and 4.1 mm longitudinally.40

When hypertrophied or ossified, the posterior longitudinal ligament may cause myelopathy (due to direct spinal cord compression, or ischemia) and/or radiculopathy (by nerve root compression or stretching). Changes within the spinal cord involve the postero-lateral gray matter more than white matter, suggesting an ischemic basis for the neurologic involvement.
74.3.3 Distribution
Average involvement: 2.7–4 levels. Frequency of involvement:
1. cervical: 70–75% of cases of OPLL. Typically begins at C3–4 and proceeds distally, often involving C4–5 and C5–6 but usually sparing C6–7
2. thoracic: 15–20% (usually upper, ≈ T4–6)
3. lumbar: 10–15% (also usually upper, ≈ L1–3)

74.3.4 Pathologic classification
See reference.31
1. segmental: confined to space behind vertebral bodies, does not cross disc spaces
2. continuous: extends from VB to VB, spanning disc space(s)
3. mixed: combines elements of both of the above with skip areas
4. other variants: includes a rare type of OPLL that is contiguous with the endplates and is confined to the disc space (involves focal hypertrophy of the PLL with punctate calcification)

74.3.5 Clinical
Most patients are asymptomatic, or have only mild subjective complaints. This is probably explained by the protective effect of the fusion resulting from OPLL and the very gradual compression.

Natural history: 17% of patients without myelopathy developed myelopathy in one study42 over 1.6 years mean follow-up. Statistically, the myelopathy-free rate in patients without initially presenting with myelopathy was 71% after 30 years.42

74.3.6 Evaluation
Plain x-rays
Often fail to demonstrate OPLL. Flexion/extension views may be helpful in assessing stability.

MRI
OPLL appears as a hypointense area and is difficult to appreciate until it reaches ≈ 5 mm thickness. On T1WI it blends in with the hypointensity of the ventral subarachnoid space; on T2WI it remains hypointense while the CSF becomes bright. Sagittal images may be very helpful in providing an overview of the extent of involvement, and T2WI may demonstrate intrinsic spinal cord abnormalities which may be associated with a worse outcome.

Myelography/CT
Myelography with post-myelographic CT (especially with 3D reconstructions) is probably best at demonstrating and accurately diagnosing OPLL.

74.3.7 Treatment
Treatment decisions
Based on clinical grade41 as follows:
1. Class I: radiographic evidence without clinical signs or symptoms. Most patients with OPLL are asymptomatic.38 Conservative management unless severe
2. Class II: patients with myelopathy or radiculopathy. Minimal or stable deficit may be followed expectantly. Significant deficit or evidence of progression warrants surgical intervention
3. Class IIIA: moderate to severe myelopathy. Usually requires surgical intervention
4. Class IIIB: severe to complete quadriplegia. Surgery is considered for incomplete quadriplegics showing progressive slow worsening. Rapid deterioration or complete quadriplegia, advanced age or poor medical condition are all associated with worse outcome

In moderate grade patients (Nurick grades 3 & 4,43 see Table 74.2), surgery provided a statistically significant reduction in deterioration. There was no difference between surgery and conservative treatment in mild grade (Nurick 1 or 2), and surgery was ineffective in severe grade (Nurick 5).42
Pre-op assessment

Appropriate cardiorespiratory assessment should be made knowing that:
1. respiratory compromise may result from ossification of the costotransverse and costovertebral ligaments
2. 50% of patients have impaired glucose tolerance with the attendant risks associated with diabetes

Technical considerations for surgery

Severe OPLL increases the risk of spinal cord injury during neck positioning for intubation, and strong consideration should be given to awake nasotracheal intubation.

An anterior approach is generally favored, although laminectomy may be acceptable. SSEP monitoring has been recommended by some. Distraction should be avoided until the spinal cord has been decompressed from the OPLL.

Some authors advocate complete removal of bone from the dura, while others feel it is permissible to leave a thin rim of bone adherent to the dura. Care must be taken in removing bone because it tends to blend imperceptibly with dura and the next thing one may see is bare spinal cord.

Depending on the distance of vertical involvement, vertebral corpectomy with strut grafting may be required. Internal plate fixation is often used as an adjunct. Post-operative immobilization for at least 3 months is employed with rigid collars for single level ACDF or 1–2 level corpectomies, or halo-vest traction for corpectomies >2 levels.

74.3.8 Results with surgery

The incidence of pseudarthrosis after vertebral corpectomy and strut graft ranges from 5–10% and increases with the number of levels fused.

In one series there was a 10% incidence of transient worsening of neurologic function following anterior surgery which may have been related to distraction.

The risk of dural tear with CSF leak following an anterior approach depends on the aggressiveness with which bone is removed from the dura, and ranges ≈ 16–25%.

Other risks of anterior approaches, e.g. esophageal injury (p. 1074), also pertain.

74.4 Ossification of the anterior longitudinal ligament (OALL)

OALL of the cervical spine and/or hypertrophic anterior cervical osteophytes may produce dramatic radiographic findings and minimal clinical symptoms. Distinct from Forestier’s disease (see below). Cervical involvement may produce dysphagia.

74.5 Diffuse idiopathic skeletal hyperostosis (DISH)

Key concepts

- usually asymptomatic, but may present with globus
- W/U: speech therapy consult for dysphagia evaluation (usually includes modified barium swallow), CT of cervical spine, ± digital video esophagoscopy
AKA “DISH,” AKA spondylitis ossificans ligamentosa, AKA ankylosing hyperostosis, among others. A condition characterized by flowing osteophytic formation of the spine in the absence of degenerative, traumatic, or post-infectious changes. Affects Caucasians and males more commonly, and usually seen in patients in their mid-60s.

97% of cases occur in the thoracic spine, also in the lumbar spine in 90% cervical spine in 78% and all three segments in 70% Sacroiliac joints are spared, unlike ankylosing spondylitis (AS) (p.1123).

As with AS, unfused levels may be very unstable.

Risk factors for DISH include: elevated body mass index, elevated serum uric acid, diabetes mellitus, elevated growth hormone or insulin levels. Usually does not produce clinical symptoms. Patients may have early morning stiffness and mild limitations of activities. Cervical involvement may present with dysphagia or globus pharyngis (the subjective sensation of a lump in the throat, not to be confused with globus hystericus which refers to the sensation of a lump in the throat where there is no identifiable pathology) due to compression of the esophagus between the osteophytes and the rigid laryngeal structures (part of Forestier’s disease).

Plain x-rays and CT scan demonstrate the pathology. In cases of dysphagia, evaluation should include speech therapy consult for dysphagia evaluation, barium swallow to help localize the site of obstruction, and DVE (digital video esophagoscopy) to rule-out intrinsic esophageal disease.

In cases of dysphagia, evaluation should include speech therapy consult for dysphagia evaluation, barium swallow to help localize the site of obstruction, and DVE (digital video esophagoscopy) to rule-out intrinsic esophageal disease. Plain x-rays and CT scan helps demonstrate the pathology. Cases that do not respond satisfactorily to dietary modifications in patients who are losing weight or are having recurrent episodes of choking or pneumonia should be considered for surgery. An anterior or cervical approach, and utilization of a high-speed drill with careful protection of soft-tissue structures (esophagus, carotid sheath) without need for discectomy nor spine stabilization has been recommended. Patients need to be made aware that post-op they are likely to be worse initially (from manipulation of esophagus and possibly disruption of some of the autonomic innervation of the esophagus) and will probably need a gastrostomy feeding tube. By 1 year post-op there may be some improvement.

74.6 Scheuermann’s kyphosis

74.6.1 General information
AKA Scheuermann juvenile kyphosis AKA Scheuermann disease AKA juvenile osteochondrosis of the spine.

Definition: anterior wedging of at least 5° of ≥ 3 adjacent thoracic vertebral bodies.

Other findings include: Schmorl nodes (p.1060) and endplate narrowing.

74.6.2 Presentation
Adolescents: often present as a result of the cosmetic deformity associated with progressive kyphosis which may be mistaken for “slouching.”

Adults: often present with pain.

74.6.3 Evaluation
Patients require standing scoliosis x-rays and a careful neurologic exam.

The role of MRI is controversial, and not all practitioners obtain this.

74.6.4 Radiographic findings
Anterior wedge deformities at multiple levels. End plate irregularities and Schmorl’s nodes.

74.6.5 Treatment
Bracing may be used in adolescents, unless the patient meets surgical criteria listed below.

Adults presenting with pain often respond to nonsurgical treatment including: physical therapy and NSAIDs.
Surgery is generally indicated for:
1. Curves exceeding 70–75°
2. Unacceptable cosmetic appearance
3. Refractory pain
4. Progressive kyphosis
5. Neurologic deficit

74.7 Spinal epidural hematoma

74.7.1 General information
Rare. Over 200 cases of varying etiology have been reported, although one-third of recent cases have been associated with anticoagulation therapy. NSAIDs may also be a risk factor. Etiologies include:
1. Traumatic: including following LP or epidural anesthesia, fracture (see below), spinal surgery or chiropractic manipulation. Occurs predominantly in patient who is: anticoagulated, thrombocytopenic, or has bleeding diathesis or a vascular lesion
2. Spontaneous: rare. Etiologies: hemorrhage from spinal cord AVM (p. 1140), from vertebral hemangioma (p. 794) or tumor

May occur at any level of the spine, however, thoracic is most common. Most often located posterior to spinal cord (except for hematomas following anterior cervical procedures), facilitating removal via laminectomy.

74.7.2 Traumatic spinal epidural hematoma (TSEH) associated with spine fracture
In one series, among 74 trauma patients who underwent emergent spinal MRI, half of the patients with spine fractures also had TSEH. Treatment was based solely on the fracture, and the outcome in patients with neurologic deficits was no worse in the group with TSEH than in the group without.

74.7.3 Presentation
The clinical picture of spontaneous spinal epidural hematoma is fairly consistent but nonspecific. Usually starts with severe back pain with radicular component. It may occasionally follow minor straining, and is less commonly preceded by major straining or back trauma. Spinal neurologic deficits follow, usually progressing over hours, occasionally over days. Motor weakness may go unnoticed when patients are bedridden with pain.

74.7.4 Treatment
Recovery of neurologic deficit without surgery is rare (only a handful of case reports in the literature), therefore optimal treatment is immediate decompressive laminectomy in those patients who can tolerate surgery. In one series, most patients who recovered underwent decompression within 72 hrs of onset of symptoms. In another, decompression within 6 hours was associated with better outcome.

High-risk patients: for medically high-risk patients (e.g. acute MI) on anticoagulation, surgical mortality and morbidity is extremely high, and this must be considered when making the decision of whether or not to operate. In patients not operated, anticoagulants should be stopped, and reversed if possible; see Correction of coagulopathies or reversal of anticoagulants (p. 166). Consider use of high dose methylprednisolone to minimize cord injury; see Methylprednisolone under spinal cord injury (p. 951). Percutaneous needle aspiration may be a consideration in high-risk patients.

74.8 Spinal subdural hematoma
Rare. May be posttraumatic (including iatrogenic causes) or may occur spontaneously. Spinal subdural hematomas (SSH) that occur spontaneously or following lumbar puncture usually occur in patients with coagulopathies (primary or iatrogenic). Conservative treatment is possible in nontraumatic SSHs with minimal neurologic impairment.
References

75 Other Non-Spine Conditions with Spine Implications

75.1 Rheumatoid arthritis

75.1.1 General information

More than 85% of patients with moderate or severe rheumatoid arthritis (RA) have radiographic evidence of C-spine involvement. The grading system of Ranawat et al. for myelopathy is shown in Table 75.1 is used in RA as well as some other etiologies of myelopathy.

75.1.2 Cervical spine involvement in RA

Common involvement
1. upper cervical spine: involved in 44–88% of RA cases (often found together):
   a) anterior atlantoaxial subluxation: the most common manifestation of RA in the cervical spine, found in up to 25% of patients with RA (see below)
   b) basilar impression (BI): upward translocation of the odontoid process, found in ≥ 8% of patients with RA (p. 1138)
   c) pannus of granulation tissue: forms around the odontoid
2. subaxial C-spine (i.e. below C2) subluxation (p. 1138)

Less common involvement of the cervical spine in RA
1. posterior subluxation of the atlantoaxial joint: must have either associated fracture of or near total arthritic erosion of odontoid
2. vertebral artery insufficiency secondary to changes at the cranio-cervical junction

75.1.3 Atlantoaxial subluxation (AAS) in RA

General information

Inflammatory involvement of the atlantoaxial synovial joints causes erosive changes in the odontoid process (anteriorly at the synovial joint with the C1 arch, and posteriorly at the synovial joint with the transverse ligament) and decalcification and loosening of the insertion of the transverse ligament on the atlas. These changes lead to instability allowing a scissors effect with anterior subluxation of C1 on C2. AAS occurs in ≥ 25% of patients with RA. Mean time between onset of RA symptoms to the diagnosis of AAS in 15 patients: 14 years.

Clinical

Signs and symptoms of AAS are shown in Table 75.2. AAS is usually slowly progressive. Mean age at onset of AAS symptoms: 57 years. Pain is experienced locally (upper cervical and suboccipital regions, often from compression of C2 nerve root) or is referred (to mastoid, occipital, temporal, or frontal regions). VBI may occur from VA involvement (p. 1305).

Table 75.1 Ranawat classification of myelopathy
Radio graphic evaluation

General information

The magnitude of AAS is usually increased with neck flexion.

Lateral C-spine x-ray

Both the ADI and PADI below are surrogate markers for instability and for spinal cord compression. With the availability of MRI, the ability to directly assess spinal cord compression has diminished the usefulness of these measures, especially for that aspect.

Anterior atlantodental interval (ADI)

The ADI (p. 213) only gives information about the stability of the C1–2 joint. The normal ADI in adults is <3–4 mm.6,7 Widening of the ADI suggests possible incompetence of the transverse ligament. However, the ADI does not correlate with the risk of neurologic injury7,8 and is not predictive of progression from asymptomatic AAS to symptomatic AAS.

Posterior atlantodental interval (PADI)

The amount of room available for the spinal cord can vary for any given ADI depending on the AP diameter of the spinal canal and the thickness of any pannus. The PADI (p. 213) and the AP diameter of the subaxial canal measured on a lateral C-spine x-ray correlates with the presence and severity of paralysis.7

The PADI also predicts neurologic recovery following surgery. Patients with paralysis from AAS showed no recovery if the pre-op PADI was <10 mm.7

PADI ≤14 mm has been proposed as an indication for surgical stabilization.

MRI

The optimal test to evaluate the source and magnitude of upper cord or medulla compression. Demonstrates location of odontoid process, extent of pannus, and effects of subluxation (may need to be performed with head flexed to evaluate this).

Treatment

General information

Requires knowledge of the following information:

1. natural history: AAS in most patients progresses, with a small percentage either stabilizing or fusing spontaneously. In one series9 with 4.5 years mean follow-up, 45% of patients with 3.5–5 mm subluxation progressed to 5–8 mm, and 10% of these progressed to >8 mm
2. once myelopathy occurs, it may be irreversible
3. the worse the myelopathy, the higher the risk for sudden death
4. the chances of finding myelopathy are significantly increased once the subluxation reaches ≥9 mm10

Note: other possible findings not reported in this series: clumsiness, neurogenic bladder, Babinski sign.
5. associated cranial settling further decreases the tolerance for AAS
6. the life expectancy of patients with RA is 10 years less than the general population
7. the morbidity and mortality of surgical treatment (see below)
8. pannus may regress some after medical treatment

When to treat?
1. symptomatic patients with AAS: almost all require surgical treatment (C1–2 fusion in most cases). For management, see below. Some surgeons do not operate if the maximal dens-C1 distance is <6 mm
2. asymptomatic patients: controversial
   a) some authors feel surgical fusion is not necessary in asymptomatic patient if the dens-C1 distance is below a certain cutoff. Recommendations for this cutoff have ranged from 6 to 10 mm, with 8 mm commonly cited (an unvalidated delineation)
   b) these patients are often placed in a rigid cervical collar, e.g. while outside the home, even though it is generally acknowledged that a collar probably does not provide significant support or protection
   c) NB: some cases of sudden death in previously asymptomatic RA patients may be due to AAS and may then be erroneously attributed to cardiac arrhythmias, etc.

Surgical management
It is necessary to either reduce the subluxation or to decompress the upper cord before doing a C1-C2 or occipital-C1-C2 fusion.
Menezes assesses all subluxed patients for reducibility using MRI compatible Halo cervical traction as follows: start with 5 lbs, and gradually increase over a period of a week. Most cases reduce within 2–3 days. If not reduced after 7 days then it is probably not reducible. Only ≈20% of cases are not reducible (most of these have odontoid >15 mm above foramen magnum).
Most require stabilization via posterior wiring and fusion, either of C1 to C2, or of occiput to C2. The latter is used when fusion is combined with decompression (posterior laminectomy of C1 with posterior enlargement of the foramen magnum). See Atlantoaxial fusion (C1–2 arthrodesis) (p.1479).
Posterior fusion alone does not provide adequate relief if the subluxation is irreducible, or if pannus causes significant compression (however, there may be some reduction of pannus after fusion). In these cases, transoral odontoidectomy may be indicated. Performing the posterior stabilization and decompression first allows some patients to avoid a second operation, and permits the remainder to undergo the anterior approach without becoming destabilized. Still, some surgeons do the odontoidectomy first (requires the patient to remain in traction until the fusion).
Reminder: the patient must be able to open the mouth greater than ≈25 mm in order to perform transoral odontoidectomy without splitting the mandible.

Posterior fusion
See Atlantoaxial fusion (C1–2 arthrodesis) (p.1479) for technique. In RA, erosion and osteoporosis weakens the C1 arch, and extra care is needed to avoid fracturing it.

75.1.4 Surgical morbidity and mortality
Because of the frequency of simultaneous involvement of other systems in RA including pulmonary, cardiac, and endocrine, operative mortality ranges from 5–15%.
The non-fusion rate for C1–2 wiring and fusion has been reported as high as 50% typical rates are lower (with 18% of patients in one series developing a fibrous union). The most common site of failure of osseous fusion is the interface between the bone graft and the posterior arch of C1.

75.1.5 Post-operative care
The patient is usually mobilized almost immediately post-op in halo vest traction (some use an optional period of maintained traction before mobilization). Impaired healing in RA dictates that the Halo be worn until fusion is well established, as seen on x-ray (usually 8–12 weeks). Sonntag evaluates the patient with flexion-extension lateral C-spine x-rays by disconnecting the halo ring from the vest.
75.1.6 Basilar impression in rheumatoid arthritis

General information

AKA atlantoaxial impaction. Erosive changes in the lateral masses of C1 → telescoping of the atlas onto the body of C2 causing ventral migration of C1 with resultant ↓ in AP diameter of the spinal canal. There is concomitant upward displacement of the dens. The posterior arch of C1 often protrudes superiorly through the foramen magnum. All of these factors lead to compression of the pons and medulla. Rheumatoid granulation tissue behind the odontoid also contributes to the brainstem compression. Vertebral artery and/or anterior spinal artery compression may also cause neurologic dysfunction.

The degree of erosion of C1 correlates with the extent of odontoid invagination.

Clinical

See Table 75.3 for signs & symptoms.

Pain may occur as a result of compression of the C1 and/or C2 nerve roots. Compression of the medulla can cause cranial nerve dysfunction.

Motor exam usually difficult because of severe polyarticular degeneration and associated pain. Sensory findings (all non-localizing): diminished vibratory, position, and light touch.

Radiographic evaluation

See Basilar invagination & basilar impression (BI) (p.217) for radiographic criteria of BI. Erosion of the tip of the odontoid, commonly seen in RA, obviates use of any measurement that is based on the location of the tip of the odontoid. For this reason, other measures have been developed, including the Clark station, Redlund-Johnell criteria, and Ranawat criteria. Since even these methods will miss up to 6% of cases of BI in RA, it is recommended that suspicious cases be investigated further (e.g. with CT and/or MRI).

MRI: optimal for demonstrating brain stem impingement, poor for showing bone. Cervicomedullary angle: the angle between a line drawn through the long axis of the medulla on a sagittal MRI

and a line drawn through the cervical spinal cord. The normal CMA is 135–170°. A CMA <135° correlates with signs of cervicomедullary compression, myelopathy or C2 radiculopathy. CT: primarily done to assess bony anatomy (erosion, fractures…). CTA should be performed when surgery is contemplated, to show detail of VA anatomy. Myelography (water soluble) with CT: also good for delineating bony pathology.

**Treatment**

See also Cranioce r vical jun ct ion and upper cervical spine abnormalities (p.1151).

Cervical traction

May attempt with Gardner-Wells tongs. Begin with ~7 lbs, and slowly increase up to 15 lbs. Some may require several weeks of traction to reduce.

Surgery

Reducible cases: posterior occipitocervical fusion ± C1 decompressive laminectomy.

Irreducible cases: requires transoral resection of odontoid. May perform before posterior fusion (but then must be kept in traction while waiting for posterior fusion).

75.1.7 Subaxial subluxation in rheumatoid arthritis

The direct effects of RA on the subaxial spine involves the facet joints posteriorly. Degenerative disc disease, which is generally a late manifestation in RA, is not the result of synovitis. Involvement is most common at C2–3 and C3–4.

75.2 Down syndrome

75.2.1 General information

Down syndrome is associated with ligamentous laxity of the spine. This has implications whenever a fusion is contemplated, as adjacent segment failure with kyphosis is very common. Ligamentous laxity may also result in atlantoaxial subluxation (AAS).

75.2.2 Atlantoaxial subluxation (AAS) in Down syndrome

General information

Not all cases of AAS are unstable (an unstable spine, by definition, needs treatment). Incidence of AAS in Down syndrome (DS) is 20% but only 1–2% of DS patients have symptomatic AAS. AAS in DS appears to be due to laxity of the transverse atlantal ligament (TAL). This laxity may decrease with age as the TAL stiffens.

Management

Controversial. There have been position statements and rebuttals. Recommendations (modified): ADI=atlantodental interval (p.213), PADI=posterior atlantodental interval (p.213):

1. children who have been screened and do not have AAS: no further screening after age 10 years (since AAS does not develop later; the cutoff age is controversial)
2. os odontoideum: surgical fusion
3. asymptomatic AAS
   a) symptoms may include: gait difficulties, neck pain, limited neck motion, torticollis, clumsiness, sensory deficits, and other symptoms of myelopathy
   b) for ADI >4.5 mm or PADI <14 mm or spinal cord damage on cervical MRI: surgical fusion
4. asymptomatic AAS seen on lateral C-spine x-ray:
   a) for ADI ≤4.5 mm and PADI ≥14 mm: no need for further testing
   b) for ADI >4.5 mm or PADI <14 mm: cervical MRI
      • if the MRI shows spinal cord damage: surgical fusion
      • if MRI shows no spinal cord damage: surgical fusion is optional. If fusion is not done, prohibit high-risk activities and restudy in 1 year
75.3 Morbid obesity

Morbid obesity, defined as a body mass index (BMI) >40. Approximately doubles risks (13.6% vs. 6.9%) of complications of all types (cardiac, renal, pulmonary, wound complications...) with spine surgery. Mortality is tripled (but is still low, 0.41 in morbid obese vs. 0.13). Hospital costs and length of stay is also longer.

76 Special Conditions Affecting the Spinal Cord

76.1 Spinal vascular malformations

76.1.1 General information

Often also referred to by the term spinal AVMs which technically refers to a subset of spinal vascular malformations (SVMs). Incidence of SVM is about 4% of primary intraspinal masses. 80% occur between age 20 and 60 years.\(^1\)(p 1850–3)

76.1.2 Classification

For a review of the history of classification systems, see the excellent review by Black\(^2\).

There are three current era classification systems.

The “American/English/French Connection” classification

References for classification: include\(^2,3,4,5,6,7,8,9,10\)

1. Type I: dural AVM AKA AV-fistula (AVF). The most common type (80% of SVM in the adult).\(^11\) Fed by radicular artery which forms an AV shunt (fistula) at the dural root sleeve (located in the intervertebral foramen),\(^3\) drains into an engorged spinal vein on posterior cord. Usually in lumbar or lower thoracic spine. Slow flow. High pressure in draining vein may cause venous congestion of the cord. Cord involvement may be distant to the fistula. Symptoms: LBP and progressive myeloradiculopathy or cauda equina syndrome (due to venous congestion) with urinary retention usually in middle-aged patients, 90% males. Up to 35% have pain. 15–20% are associated with other AVMs (cutaneous or other). Rarely bleed
   a) Type IA: single arterial feeder
   b) Type IB: two or more arterial feeders

2. intradural AVMs (high flow): 75% present with acute onset of symptoms, usually from hemorrhage (SAH or intramedullary)
   a) Type II: AKA spinal glomus AVM. Intramedullary. True AVM of the spinal cord. 15–20% of all SVMs. Compact nidus fed by medullary arteries with the AV shunt contained at least partially within the spinal cord or pia. May be associated with feeding artery aneurysms. Worse prognosis than dural AVM.\(^8\) Fed by 1, or at most 2–3 feeders 80% of the time
   b) Type III: AKA juvenile spinal AVM. Essentially an enlarged glomus AVM which occupies the entire cross-section of the cord and invades the vertebral body which may cause scoliosis
   c) Type IV: intradural perimedullary AVM (also called arteriovenous fistulae (AVF)). Direct fistula between artery supplying spinal cord (usually anterior spinal artery, often artery of Adamkiewicz) and draining veins. Typically occur in younger patients than Type I, and may present catastrophically with hemorrhage into the subarachnoid space.\(^12\) Table 76.1 shows the 3 subtypes.\(^5\)

3. miscellaneous spinal vascular lesions:
   a) spinal cord cavernomas
   b) spinal cord venous angiomas: extremely rare. Difficult to visualize angiographically
   c) vertebral body hemangiomas (p.794)

76.1.3 Presentation
85% present as progressive neuro deficit (back pain associated with progressive sensory loss and LE weakness over months to years). Yet, SVMs account for <5% of lesions presenting as spinal cord “tumors.” 10–20% of SVMs present as sudden onset of myelopathy usually in patients <30 yrs age,\(^\text{15,16}\) secondary to hemorrhage (causing SAH, hematomyelia, epidural hematoma, or watershed infarction). Coup de poignard = sudden excruciating back pain with SAH (clinical evidence of SVM).

Foix-Alajouanine syndrome (subacute necrotic myelopathy): acute or subacute neurologic deterioration in a patient with a SVM without evidence of hemorrhage. Presents as spastic → flaccid paraplegia, with ascending sensory level and loss of sphincter control. Initially thought to be due to spontaneous thrombosis of the AVM causing subacute necrotizing back pain with SAH (clinical evidence of SVM).

Clinical. Auscultation over spine reveals a bruit in 2–3% of cases. Cutaneous angioma over back is present in 3–25% valsalva maneuver may enhance the redness of the angioma.\(^\text{16}\)

76.1.4 Evaluation
Spinal angiography: necessary for treatment planning. Best performed at centers that do this study regularly. For Type I dural AVMs, angiography must encompass all dural feeders of the neuraxis, which includes:
1. ICA: because of the artery of Bernasconi & Cassinari (p. 79)
2. every radicular artery including the artery of Adamkiewicz (p. 87)
3. internal iliac arteries: for sacral feeders

MRI: detects some SVMs with greater sensitivity and safety than angiography,\(^\text{19}\) but is inadequate for treatment planning. 82% show extramedullary flow voids. Variable degree of cord enhancement (from venous congestion or venous infarction). Negative MRI does not rule out diagnosis.

Myelography: classically shows serpiginous intradural filling defects. Generally superseded by MRI. If done, patient should be imaged prone and supine (to avoid missing a dorsal AVM) Risk of bleeding from puncture of a dilated artery/vein with myelography needle.
76.1.5 Treatment

Type I (dural AVMs): usually require treatment. Usually amenable to endovascular techniques using glue, in which case the proximal vein must be taken as well. If you don’t completely eliminate a dural fistula (spinal or intracranial) it will come back!

Type II (spinal glomus AVMs): may be amenable to interventional neuroradiologic procedures including embolization, especially type IIA (single feeder). However recurrence may be higher with endovascular treatment than surgery, and surgery is often preferred for Type IIB (≥2 feeders). Surgical strategy: similar to intracranial AVMs except that the parenchyma cannot be retracted, bleeding is rarely life threatening, and arteries of passage must be preserved to avoid devastating deficits. Intraoperative ICG angio is often helpful. The nidus is compact, and the hemosiderin ring around the nidus on MRI often represents a plane that can be exploited.

Type III (juvenile spinal AVMS): the natural history is probably better than the prognosis with any type of treatment.

Type IV (perimedullary fistulae): suggested management is shown in Table 76.2.

76.2 Spinal meningeal cysts

76.2.1 General information

Spinal meningeal cysts (SMC): diverticula of the meningeal sac, nerve root sheath or arachnoid. May have familial tendency.

Terminology in literature is confusing. One classification system is shown in Table 76.3. Previously AKA Tarlov’s perineural cysts, spinal arachnoid cysts, and extradural diverticula, pouches or cysts. Only congenital lesions are considered here.

1. Type I SMCs above the sacrum usually have a pedicle adjacent to entrance of dorsal nerve root
2. Type II SMCs: formerly called Tarlov’s cysts and were differentiated from nerve root diverticula because the former were defined as communicating with subarachnoid space, and the latter not. However, intrathecal contrast CT (ICTC) shows both communicate. Often multiple, occur on dorsal roots anywhere, but are most prominent and symptomatic in sacrum
3. Type III SMCs: may also be multiple and asymptomatic. More common along posterior subarachnoid space. Attributed to proliferation of arachnoid trabeculae

76.2.2 Presentation

May be asymptomatic (i.e. incidental finding). May cause radiculopathy by pressure on adjacent nerve root (may or may not cause symptoms of nerve root from which it actually arises). Symptom complex depends on size of SMC, and proximity to spinal cord and nerve roots.

1. Type I SMCs: in thoracic and cervical region, may present with acute myelopathy (spasticity and sensory level); lumbar region → LBP and radiculopathy; sacral region → sphincter disturbance
2. Type II SMCs: often asymptomatic, but sacral lesions may → sciatica and/or sphincter disturbance
3. Type III SMCs: may also be multiple and asymptomatic; more common along posterior subarachnoid space

76.2.3 Evaluation

MRI to identify the mass, then water-soluble ICCT scan to evaluate communication of cyst with subarachnoid space.

1. Type II SMCs: all 18 cases had bony erosion (demonstrated by canal widening, pedicle erosion, foraminal enlargement, or vertebral body scalloping)
2. Type III SMCs: may also cause bony erosion; appear on myelogram as intradural defect, may not appear on ICCT if they communicate with subarachnoid space which causes them to blend with adjacent subarachnoid space

76.2.4 Treatment

1. Type I SMCs: close ostium between cyst and subarachnoid space. Above sacrum, can usually be dissected from dura; occasionally fibrous adhesions prevent this
2. Type II SMCs: no pedicle, thus either partially resect and oversew cyst wall, or excise cyst and involved nerve root. Simple aspiration is not recommended
3. Type III SMCs: excise completely unless dense fibrous adhesions prevent this, in which case marsupialize cyst. Tend to recur if incompletely excised

76.3 Juxtafacet cysts of the lumbar spine

76.3.1 General information

The term juxtafacet cyst (JFC) was originated by Kao et al.\textsuperscript{22} in 1974 and includes both synovial cysts (those having a synovial lining membrane) and ganglion cysts (those lacking synovial lining) adjacent to a spinal facet joint or arising from the ligamentum flavum. Distinction between these two types of cysts may be difficult without histology (see below) and is clinically unimportant.\textsuperscript{23} JFC occur primarily in the lumbar spine (although cysts in the cervical\textsuperscript{24,25,26} and thoracic\textsuperscript{27} spine have been described). They were first reported in 1880 by von Gruker during an autopsy,\textsuperscript{28} and were first diagnosed clinically in 1968.\textsuperscript{29} The etiology is unknown (possibilities include: synovial fluid extrusion from the joint capsule, latent growth of a developmental rest, myxoid degeneration and cyst formation in collagenous connective tissue...), increased motion seems to have a role in many cysts, and the role of trauma in the pathogenesis is debated\textsuperscript{25,30} but probably plays a role in a small number (\(\approx 14\%\)).\textsuperscript{31} JFC are relatively rare, only 3 cases were identified in a series of 1,500 spinal CT exams,\textsuperscript{32} but the frequency of diagnosis may be on the rise due to the widespread use of MRI and an increasing awareness of the condition.

76.3.2 Pathology

Cyst walls are composed of fibrous connective tissue of varying thickness and cellularity. There is usually no signs of infection or inflammation. There may be a synovial lining\textsuperscript{33} (synovial cyst) or it may be absent\textsuperscript{34} (ganglion cyst). The distinction between the two may be difficult,\textsuperscript{23} possibly owing in part to the fact that fibroblasts in ganglion cysts may form an incomplete synovial-like lining.\textsuperscript{35} Proliferation of small venules is seen in the connective tissue. Hemosiderin staining may be present, and may or may not be associated with a history of trauma.\textsuperscript{31}

76.3.3 Clinical

The average age was 63 years in one series\textsuperscript{31} and 58 years in a review of 54 cases in the literature\textsuperscript{33} (range: 33–87) with a slight female preponderance in both series. Most occur in patients with severe spondylosis and facet joint degeneration\textsuperscript{34} 25% had degenerative spondylolisthesis.\textsuperscript{31} L4–5 is the
most common level. They may be bilateral. Pain is the most common symptom, and is usually radicular. Some JFC may contribute to canal stenosis and can produce neurogenic claudication (p. 1100) or on occasion a cauda equina syndrome. Symptoms may be more intermittent in nature than with firm compressive lesions, such as HL D. A sudden exacerbation in pain may be due to hemorrhage within the cyst. Some JFC may be asymptomatic.

76.3.4 Differential diagnosis

Also see Differential diagnosis, Sciatica (p. 1410). Differentiating JFC from other masses relies largely on the appearance and location. Other distinguishing features include:

1. neurofibroma: unlikely to be calcified
2. free fragment of HL D: not cystic in appearance
3. epidural or nerve root metastases: not cystic
4. dural subarachnoid root sleeve dilatation (p. 1142)
5. arachnoid cyst (from arachnoid herniation through a dural defect): not associated with facet joint, margins thinner than JFC
6. perineurial cysts (Tarlov’s cyst): arise in space between perineurium and endoneurium, usually on sacral roots, occasionally show delayed filling on myelography. Usually associated with remodelling of adjacent bone

76.3.5 Evaluation

Identifying a JFC pre-op helps the surgeon, as the approach differs slightly from that for HL D, and the cyst might otherwise be missed or unknowingly deflated and unnecessary time wasted afterwards trying to find a compressive lesion. Or, the unwitting surgeon may misinterpret the cyst as a “transdural disc extrusion” and needlessly open the dura. Pre-op diagnoses were incorrect in 30% of operated cases of JFC.

Myelography: posterolateral filling defect (whereas most discs are situated anteriorly, an occasional fragment may migrate posterolaterally, whereas a JFC will always be posterolateral), often with a round extradural appearance.

CT scan: shows a low density epidural cystic lesion typically with a posterolateral juxtaarticular location. Some have calcified rim, and some may have gas within. Erosion of bony lamina is occasionally seen.

MRI: variable findings (may be due to differing composition of cyst fluid: serous vs. proteinaeous). Unenhanced signal characteristics of non-hemorrhagic JFC are very similar to CSF. Hemorrhagic JFC are hyperintense. MRI usually misses bony erosion.

76.3.6 Treatment

Optimal treatment is not known. There is one case report of a cyst that resolved spontaneously. If symptoms persist with conservative treatment, some promote cyst aspiration or facet injection with steroids, while most advocate surgical excision of the cyst.

Surgical treatment considerations: The cyst may be adherent to the dura. The cyst may also collapse during the surgical approach and may be missed. A JFC may serve as a marker for possible instability and should prompt an evaluation for the same. Some argue for performing a fusion since JFC may arise from instability, however, it appears that fusion is not required for a good result in many cases. Therefore it is suggested that consideration for fusion be made on the basis of any instability and not merely on the basis of the presence of a JFC.

Minimally invasive spine surgery (MISS) has also been used for removal, long-term follow-up is lacking. A 15 mm entry incision is made 1.5 cm lateral to midline.

Following surgical treatment, symptomatic JFCs may recur or may develop on the contralateral side.

76.4 Syringomyelia

76.4.1 General information

Key concepts

- AK A syrinx. Cystic cavitation of the spinal cord
- 70% are associated with Chiari I malformation, 10% with basilar invagination. May also be posttraumatic or associated with tumor, infection...
Symptoms: progressive neurologic deterioration over months to years, usually affecting UE first. Diameter >5 mm + associated edema predict a more rapid deterioration. Preferred treatment is directed at correcting the causative pathophysiology.

AKA syrinx. Cystic cavitation of the spinal cord. Other terms not precisely defined include: hydrosyringomyelia, communicating or noncommunicating syringomyelia.

Syringobulbia: Rostral extension into brainstem (usually medulla). May present with (bilateral) peri-oral tingling and numbness, due to compression of the spinal trigeminal tracts as the fibers decussate.

76.4.2 Etiologies

Primary syringomyelia

This term is used differently by different authors. Herein, refers to syrinx in the absence of identifiable cause.

Secondary syringomyelia

Most cases are thought to be secondary to partial obstruction of the spinal subarachnoid space. Unanswered question: Why then do patients with varying degrees of degenerative cervical spinal stenosis generally not get syringomyelia? Etiologies include:

1. Chiari I malformation: the most common cause of syrinx (p.277)
2. postinflammatory
   a) postinfectious
   • granulomatous meningitides (TB and fungal)
   • postoperative meningitis, especially after intradural procedure
   b) chemical or other sterile inflammations
   • rarely after SAH
   • after myelography: especially with older oil-based agents no longer in use
3. posttraumatic: also see below
   a) with severe posttraumatic kyphotic deformity: e.g. with retropulsed bone, scarring...
   b) arachnoid scarring without recognized trauma
   c) severe injury to spinal cord and/or its coverings. Blood may be a contributing factor

the older concept of syrinx developing as a coalescence of foci of traumatic hematomyelia has not been borne out
1. postsurgical: has been identified many years after uncomplicated intradural neoplasm removal (e.g. neurofibromas)
2. basilar arachnoiditis:
   a) idiopathic
   b) postinfectious: see above
3. basilar impression, with constriction of the foramen magnum (p.217)
4. associated with spinal tumors: this is distinct from a tumor cyst
5. associated with disc protrusion:
6. cerebellar ectopia
7. Dandy Walker syndrome

76.4.3 Epidemiology

See reference. Prevalence of non-posttraumatic syringomyelia: 8.4 cases/100,000 population. Usually presents between ages 20–50. Associated clinical syndromes are shown in Table 76.4.

76.4.4 Pathophysiology

Major theories of formation of the cyst:

1. hydrodynamic (“water-hammer”) theory of Gardner: systolic pulsations are transmitted with each heartbeat from the intracranial cavity to the central canal. Has been essentially disproven using MRI

[...]

Special Conditions Affecting the Spinal Cord 1145
2. Williams’ (“craniospinal dissociation”) theory: maneuvers that raise CSF pressure (valsalva, coughing...) cause “hydrodissection” through the spinal cord tissue. May be more common in noncommunicating syringomyelia

3. Heiss-Oldfield theory: occlusion at the foramen magnum causes CSF pulsations during cardiac systole to be transmitted through the Virchow-Robin spaces which increases the extracellular fluid which coalesce to form a syrinx (i.e. through the cord parenchyma)

76.4.5 Clinical

Presentation: highly variable. Usually progresses over months to years, with a more rapid deterioration early that gradually slows. Initially, pain, weakness, atrophy and loss of pain & temperature sensation in the upper extremities (with cervical syrinx) is common. Myelopathy that progresses slowly over years ensues.

76.4.6 Characteristic syndrome

(nonspecific for intramedullary spinal cord pathology):
1. sensory loss (similar to central cord syndrome) with a suspended (“cape”) dissociated sensory loss (loss of pain and temperature sensation with preserved touch and joint position sense → painless ulcerations from unperceived injuries and/or burns)
2. pain: commonly cervical and occipital. Dysesthetic pain often occurs in the distribution of the sensory loss
3. weakness: lower motor neuron weakness of the hand and arm
4. painless (neurogenic) arthropathies (Charcot’s joints) especially in the shoulder & neck due to loss of pain & temperature sensation: seen in <5%

76.4.7 Evaluation

Prior to the CT/MRI era, diagnosis relied on myelography or on autopsy.

MRI: defines anatomy in sagittal as well as axial plane. Test of choice. Cervical & thoracic spine and brain MRI (without & with contrast, to include craniocervical junction) should be obtained. Syringomyelic cavities may be complex, with noncommunicating channels (more common with posttraumatic syrinx).

CT: low attenuation area within cord seen on either plain CT or myelogram/CT (with water soluble contrast).

Myelogram: rarely used alone (usually performed in conjunction with CT). When used alone: often normal (false negative), some →complete block at level of syrinx; iodine contrast studies may show fusiform widening of spinal cord, whereas air contrast studies may show collapse of the cord. Dye may slowly leach into the cyst.

EMG: no characteristic findings, but may be useful to R/O other conditions that may be responsible for symptoms (e.g. peripheral neuropathy causing paresthesias).

76.4.8 Distinguishing from similar entities

1. tumor cyst:
   a) especially with intramedullary spinal cord gliomas. Tumors may secrete fluid, or may cause microcysts that eventually coalesce. Most (but not all) intramedullary tumors will enhance with IV contrast on MRI
   b) tumor cyst fluid is usually highly proteinaceous, syrinx fluid usually has the same MRI characteristics as CSF (NB: true syrinx can occur with tumor)
2. central spinal canal:
   a) residual central spinal canal: the central canal is present within the spinal cord at birth and normally gradually involutes with age.\textsuperscript{50} Persistence of the canal is a normal variant. Characteristic imaging features:
   - linear or fusiform on sagittal MRI
   - ≤2–4 mm in maximal width
   - may be singular, or there may be several discontinuous regions in the rostral-caudal direction
   - perfectly round in cross-section and centrally located on axial MRI
   - if IV contrast is given, there should be no enhancement
   b) simple dilatation of the central canal with ependymal cell lining has sometimes been called hydromyelia, but this usage is ambiguous

76.4.9 Management

General information

For an incidentally discovered syrinx (i.e. asymptomatic and no neurologic deficit) with no identified etiology, if the size remains stable over 2–3 years of observation, F/U studies at 2–3 year intervals can be done if there are no changes in symptoms.

Surgical treatment

Intervention is considered for symptomatic lesions (not all are symptomatic). If an underlying cause cannot be determined, it may be very difficult to treat a very small syrinx directly (however, these are unlikely to be causing reversible symptoms).

Options include:
1. current philosophy is to treat the underlying pathophysiology (and to use syrinx draining procedures as second choice when this is not feasible)
   a) posterior decompression: procedure of choice when posterior anomalies (e.g. Chiari malformation) are present
   b) decompression if a different site of compression is identified
2. shunts:
   a) disadvantages:
      - complication rate: 16%
      - clinical stabilization rate: 54% at 10 yrs
      - may produce traction on spinal cord with potential for further injury
      - prone to obstruction: 50% at 4 years
      - does not correct underlying pathophysiology and so syrinx may recur
   b) indications: cases of diffuse arachnoiditis (e.g. following tuberculous or chemical meningitis) where the obstruction extends over many levels, and syrinx diameter >3–4 mm
   c) Kor T tube drainage. Choice of distal sites includes:
      - peritoneum\textsuperscript{51} (difficult in cervical region): e.g. Edwards-Barbaro syringoperitoneal shunt (distributed by Integra)
      - pleural cavity
      - subarachnoid space (e.g. Heyer-Schulte-Pudenz system): requires normal CSF flow in subarachnoid space, therefore cannot use in arachnoiditis
3. percutaneous aspiration of the cyst\textsuperscript{52} (may be used repeatedly)
4. no longer recommended:
   a) plugging the obex with muscle, teflon or other material
   b) opening the subarachnoid space & removing inferior tonsils
   c) syringostomy: usually fails to remain patent, therefore using a stent or a shunt (syringosubarachnoid or syringoperitoneal) is recommended

Technical considerations:
1. intraoperative ultrasound is often helpful for:
   a) localizing the cyst
   b) assessing for septations (to avoid shunting only part of cyst)
2. if Chiari malformation is not present, consider syringosubarachnoid shunt as the initial procedure. If this fails, then syringoperitoneal shunt may be inserted
3. Rhoton suggests performing the myelotomy in the dorsal root entry zone (DREZ), between the lateral and posterior columns (instead of the midline as with a tumor) because this is consistently
the thinnest part and there is usually already an upper extremity proprioceptive deficit from the syrinx. There is ≈10% incidence of posterior column dysfunction with shunting.

4. with syringosubarachnoid shunts, be sure the distal shunt tip is subarachnoid (and not just subdural) or else it will not function.

5. with syringopleural shunt, the pleural opening can be made posteriorly, adjacent to one of the ribs as described for ventriculopleural shunt (p. 1515).

6. for peritoneal terminus of shunt: the proximal shunt may be placed in the syrinx with the patient in the prone position, and the peritoneal end of the catheter may be tunneled to an intermediate position in the flank in the midaxillary line where it can be coiled into a small subcutaneous pouch which can be temporarily closed with staples and dressed with Tegaderm. After the spinal incision is closed, the patient can be undraped and rotated to the supine position, the Tegaderm is removed, and the staples are removed and the catheter is retrieved from the sub-Q pocket and tunneled to the peritoneal opening that is made at this time. A small bump (rolled sheet) to elevate the flank may be employed in both parts of the operation to facilitate access to the pouch.

76.4.10 Outcome

Assessing treatment results is difficult due to rarity of the condition, variability of natural history (which may arrest spontaneously), and too short follow-up. Enthusiasm for direct treatment (shunts, fenestration) is low among neurosurgeons because of the perceived poor response and risk of iatrogenic neurologic worsening. However, this may remain as the only option for a deteriorating patient and positive outcomes do occur.

76.5 Posttraumatic syringomyelia

76.5.1 General information

Posttraumatic syringomyelia (PTSx) may follow significant spinal trauma (with or without clinical spinal cord injury). Includes penetrating injury or non-penetrating “violent” trauma to the spinal cord (injuries such as post-spinal anesthesia or following thoracic disc herniation are not included).

76.5.2 Epidemiology

Often a late presentation following spinal cord injury, therefore incidence is higher in series with longer follow-up. Incidence increasing with increasing survival following spinal cord injury and with increasing use of MRI. Range: ≈0.3–3% of cord injured patients (see Table 76.5).

In a large number of patients followed via multicenter cooperative data bank, there were fewer cases of syrinx following cervical injuries than following thoracic injuries (may be artifactual since patients with lower lesions may be more aware of ascending levels).

Latency following spinal cord injury:

1. latency to symptoms: 3 mos to 34 yrs (mean 9 yrs) (earlier in complete cord lesions than incomplete: mean 7.5 vs. 9.9 yrs)

2. latency to diagnosis: up to 12 yrs (mean 2.8 yrs) after onset of new symptoms

### 76.5.3 Clinical

The presentation of patients with PTSx is shown in Table 76.6. The late appearance of upper extremity symptoms in a paraplegic patient should raise a high index of suspicion of posttraumatic syringomyelia.\(^{58}\) Hyperhidrosis may be the only feature of descending syringomyelia in patients with complete cord lesions.\(^{60}\) For the differential diagnosis, see Delayed deterioration following spinal cord injuries (p.1019).

### 76.5.4 Evaluation

One end of the cavity is often found at a site of spinal column fracture or abnormal angulation.

### 76.5.5 Management

#### General information

Many authors advocate early surgical drainage of cyst as a means of reducing increased delayed deficit.\(^{61}\) Some authors feel that aside from disturbing sensory symptoms, that motor loss was infrequent and therefore conservative management is indicated in most cases.\(^{62}\)

#### Medical

Managed non-surgically: 31% remained stable, 68% progressed over yrs (longer F/U in latter).

#### Surgical

There is probably no benefit in operating on a patient with a small syrinx.\(^{56}\)

**Surgical options**

- Same as in Communicating syringomyelia, with the following differences:
  1. cord transection (cordectomy)\(^{63}\): an option in complete injuries only
  2. plugging the obex is probably not indicated (controversial in congenital syrinx)

#### Outcome

In 9 PTSx patients treated with syringosubarachnoid shunt\(^{56}\): pain relieved in all 9 (1 only slightly), motor recovery in 5/8, improved tendon reflex in 1/10. Some post-op complications in 9 patients included: 1 incomplete lesion became complete, 1 sensorimotor deterioration, transient pain in 3.
Most results are good for radicular symptoms, with dubious efficacy for autonomic symptoms or spasticity.

### 76.6 Spinal cord herniation (idiopathic)

#### 76.6.1 General information

Rare. Spinal cord herniates though a defect in the dura usually located anteriorly or anterolaterally between T2–8. Bone erosion anterior to the dural defect may occasionally be seen. Frequently associated with a calcified disc fragment which theoretically may have gradually eroded through the dura.

#### 76.6.2 Differential diagnosis

Main DDx is with dorsal arachnoid cyst (p.1407). Both result in increased subarachnoid space posterior to the cord, and a ventral kinking of the spinal cord. Contiguous CSF pulsation artifact on MRI can be seen with cord herniation, whereas an arachnoid cyst tends to interrupt this.

#### 76.6.3 Presentation

Commonly presents as an incomplete Brown-Séquard syndrome (with relative sparing of posterior columns). Symptoms may be due to distortion of the spinal cord, but vascular injury may also play a role.

#### 76.6.4 Surgery

Requires a lateral or anterolateral approach to minimize spinal cord manipulation (p.1061). The dural defect is widened which usually results in reduction of the spinal cord herniation. A sling of dural substitute can then be slid anterior to the cord to prevent reherniation.

### 76.7 Spinal epidural lipomatosis (SEL)

#### 76.7.1 General information

Hypertrophy of epidural fat. Most commonly seen with prolonged exogenous steroid therapy (in 75% of cases) usually moderate to high dosage for years, but may also be associated with: Cushing’s disease, Cushing’s syndrome, obesity, hypothyroidism or may be idiopathic. Male: female = 3:1. Back pain usually precedes all other symptoms. Progressive LE weakness and sensory changes are common. Sphincter disturbance occurs but is rare. SEL is most common in the thoracic spine (≈ 60% of cases), the rest are in the lumbar spine (no cases reported in cervical spine).

It is often very difficult to differentiate the patient with increased epidural fat (even to the point that CSF may be obliterated at the levels of involvement) that is not causing symptoms, from those cases where the exuberant fat is responsible for the findings.

#### 76.7.2 Evaluation

CT: density of adipose tissue is extremely low (-80 to -120 Hounsfield units) which distinguishes SEL from most other lesions (except lipoma).

MRI: signal follows fat (high signal on T1WI, intermediate on T2WI). Suggested diagnostic criteria: epidural adipose should be >7 mm thick to be considered SEL.

#### 76.7.3 Treatment

In those patients who can be weaned off steroids and lose weight, surgery may be avoided in some cases. If SEL is related to obesity, weight loss alone can be successful.

Surgery is indicated for symptomatic patients in whom the above interventions are unsuccessful or not feasible. An effort to normalize cortisol levels in those with endogenous hypercortisolism (Cushing’s disease…) should be made before laminectomy is performed. Due to potential complications and slow growth of the tissue, the decision to operate should be made with caution.
Surgery usually consists of laminectomy with removal of adipose tissue. Occasionally repeat surgery is needed for reaccumulation of adipose tissue.

76.7.4 Outcome
Surgery usually results in significant improvement.\textsuperscript{70} Idiopathic cases may fare better than those due to steroid excess. Cauda equina compression responds better than thoracic myelopathy.

Complications rates may be higher than expected in part due to medical comorbidities. Fessler et al.\textsuperscript{72} reported 22\%1-year mortality.

76.8 CranIOCervical junction and upper cervical spine abnormalities

76.8.1 Associated conditions
Also see Axis (C2) vertebra lesions (p. 1391).
Abnormalities in this region are seen in a number of conditions including:
1. rheumatoid arthritis (p.1134)
2. traumatic & post-traumatic: including fractures of odontoid, occipital condyles...
3. ankylosing spondylitis (p.1123): may result in fusion of the entire spine which spares the occipitoatlantal and/or atlantoaxial joints which can lead to instability there
4. congenital conditions:
   a) Chiari malformations (p.277)
   b) Klippel-Feil syndrome (p.271)
   c) Down syndrome
   d) atlantoaxial dislocation (AAD)
   e) occipitalization of the atlas: seen in 40\%of congenital AAD\textsuperscript{73}
   f) Morquio syndrome (a mucopolysaccharidosis): atlantoaxial subluxation occurs due to hypoplasia of the odontoid process and joint laxity
5. neoplasms: metastatic (p.815) or primary
6. infection
7. following surgical procedures of the skull base or cervical spine: e.g. transoral resection of the odontoid

76.8.2 Types of abnormalities
Abnormalities include:
1. basilar impression/invagination: as with Paget’s disease
2. atlanto-occipital dislocation
3. atlantoaxial dislocation
4. occipitalization of the atlas, or thin or deficient posterior arch of atlas\textsuperscript{74}

76.8.3 Treatment
Fractures of the occipital condyles, atlas or axis are usually adequately treated with external immobilization; also see Occipital condyle fractures (p.966). Because traumatic occipitocervical dislocations are usually fatal, optimal treatment is not well defined. Occipitalization of the atlas may be treated by creating an “artificial atlas” from the base of the occiput and wiring to that.

Indications and techniques are outlined in Atlantoaxial fusion (Cl–2 arthrodesis) (p.1479).

SAH and Aneurysms

77 Introduction and General Information, Grading, Medical Management, Special Conditions 1156

78 Critical Care of Aneurysm Patients 1177

79 SAH from Cerebral Aneurysm Rupture 1191

80 Aneurysm Type by Location 1210

81 Special Aneurysms and Non-Aneurysmal SAH 1222
77 Introduction and General Information, Grading, Medical Management, Special Conditions

77.1 Introduction and overview

77.1.1 Definition
Blood in the subarachnoid space, i.e. between the arachnoid membrane and the pia mater.

77.1.2 Miscellaneous facts about SAH
1. May be post-traumatic or spontaneous. Trauma is the most common cause
2. Most cases of spontaneous SAH are due to aneurysmal rupture
3. Peak age for aneurysmal SAH is 55–60 years, ≈ 20% of cases occur between ages 15–45 yrs
4. 30% of aneurysmal SAHs occurs during sleep
5. Sentinel headaches that precede the SAH-associated ictus have been reported by 10–50% of patients and most commonly occur within 2–8 weeks before overt SAH
6. Headache is lateralized in 30% most to the side of the aneurysm
7. SAH is complicated by intracerebral hemorrhage in 20–40% by intraventricular hemorrhage in 13–28% (p. 1192) and by subdural blood in 2–5% usually due to p-comm aneurysm when over convexity, or distal anterior intracerebral artery (DACA) aneurysm with interhemispheric subdural (p. 1211)
8. Soft evidence suggests that rupture incidence is higher in spring and autumn
9. Patients ≥ 70 yrs age have a higher proportion with a severe neurologic grade
10. Seizures may occur in up to 20% of patients after SAH, most commonly in the first 24 hours and are associated with ICH, HTN and aneurysm location (MCA & acomm)

77.1.3 Outcome of aneurysmal SAH
1. 10–15% of patients die before reaching medical care
2. Mortality is 10% within first few days
3. 30-day mortality rate was 46% in one series, and in others over half the patients died within 2 weeks of their SAH
4. Median mortality rate in epidemiologic studies from U.S. has been 32% vs. 44% in Europe and 27% in Japan (may be an underestimate based on underreported prehospital death)
5. Causes of mortality
   a) 25% die as a result of medical complications of SAH
      • Neurogenic pulmonary edema (p. 1178)
      • Neurogenic stunned myocardium (p. 1177)
   b) About 8% die from progressive deterioration from the initial hemorrhage (p. 27)
6. Among patients surviving the initial hemorrhage treated without surgery, rebleeding is the major cause of morbidity and mortality (p. 1167), the risk is ≈ 15–20% within 2 weeks. The goal of early surgery is to reduce this risk (p. 1200)
7. Of those reaching neurosurgical care, vasospasm (p. 1178) kills 7% and causes severe deficit in another 7%
8. About 30% of survivors have moderate to severe disability, with rates of persistent dependence estimated between 8–20% in population based studies
9. ≈ 66% of those who have successful aneurysm clipping never return to the same quality of life as before the SAH
10. Patients ≥ 70 yrs age fare worse for each neurologic grade. A multivariate analysis revealed age and WFNS grade to be most predictive of long-term outcome, regardless of treatment modality
11. The severity of clinical presentation is the strongest prognostic indicator

77.2 Etiologies of SAH
Etiologies of subarachnoid hemorrhage (SAH) include:
1. Trauma: The most common cause of SAH. In all of the following discussion, only non-traumatic (i.e. “spontaneous”) SAH will be considered
2. “spontaneous SAH”
   a) ruptured intracranial aneurysms: 75–80% of spontaneous SAHs (p.1191)
   b) cerebral arteriovenous malformation (AVM): 4–5% of cases; AVMs more commonly cause ICH & IVH than SAH (p.1239)
   c) certain vasculitides that involve the CNS, see Vasculitis and vasculopathy (p.195)
   d) rarely due to tumor (many case reports20,21,22,23,24,25,26,27,28,29,30,31)
   e) cerebral artery dissection (may also be post-traumatic)
      - carotid artery (p.1324)
      - vertebral artery: may cause intraventricular blood (especially 4th and third ventricle) (p.1325)
   f) rupture of a small superficial artery
   g) rupture of an infundibulum (p.1161)
   h) coagulation disorders:
      - iatrogenic or bleeding dyscrasias
      - thrombocytopenia
   i) dural sinus thrombosis
   j) spinal AVM: usually cervical or upper thoracic (p.1140)
   k) cortical subarachnoid hemorrhage
   l) pretruncal nonaneurysmal SAH (p.1231)
   m) rarely reported with some drugs: e.g. cocaine (p.207)
   n) sickle cell anemia
   o) pituitary apoplexy (p.720)
   p) no cause can be determined in 14–22% (p.1230)

77.3 Incidence

Estimated annual rate of aneurysmal SAH in the United States: 9.7-14.5 per 100,000 population.32,33
Reported rates are lower in South and Central America,34 and higher in Japan and Finland.35 Incident of SAH increases with age (avg. age of onset >5033,36,37,38; tends to be higher in women (1.24 times higher than men),34 and appears to be higher in African Americans and Hispanics (compared to Caucasians).32,39,40

77.4 Risk factors for SAH

See references.17,41
1. behavioral
   - hypertension
   - cigarette smoking
   - alcohol abuse
   - sympathomimetic drugs (p.207)
2. gender and race (see above)
3. history of cerebral aneurysm
   - ruptured aneurysm
   - unruptured aneurysm (esp. those that are symptomatic, larger in size and located in posterior circulation)
   - morphology: bottleneck shape43 and increased ratio of size of aneurysm to parent vessel have been associated with increased risk of rupture44,45
4. family history of aneurysms (at least 1 first-degree family member and especially if ≥2 are affected)
5. genetic syndromes
   - autosomal dominant polycystic kidney disease
   - type IV Ehlers-Danlos syndrome
6. pregnancy – there does not appear to be an increased risk of aneurysmal SAH in pregnancy, delivery, and puerperium46,47

77.5 Clinical features

77.5.1 Symptoms of SAH

Sudden onset of severe H/A (see below), usually with vomiting, syncope (apoplexy), neck pain (meningismus), and photophobia. If there is LOC, patient may subsequently recover consciousness.48 Focal
cranial nerve deficits may occur (e.g. third nerve palsy from aneurysmal compression of the third cranial nerve, causing diplopia and/or ptosis). Low back pain may develop due to irritation of lumbar nerve roots by dependent blood.

77.5.2 Headache

The most common symptom, present in up to 97% of cases. Usually severe (classic description: “the worst headache of my life”) and sudden in onset (paroxysmal). The H/A may clear and the patient may not seek medical attention (referred to as a sentinel hemorrhage or headache, or warning headache; they occur in 30–60% of patients presenting with SAH). If severe or accompanied by reduced level of consciousness, most patients present for medical evaluation. Patients with H/A due to minor hemorrhages will have blood on CT or LP. However, warning headaches may also occur without SAH and may be due to aneurysmal enlargement or to hemorrhage confined within the aneurysmal wall. Warning H/A are usually sudden in onset, milder than that associated with a major rupture, and may last a few days.

Differential diagnosis of severe, acute, paroxysmal headache (25% will have SAH):

1. subarachnoid hemorrhage, AKA “warning headache” or sentinel H/A (see above)
2. benign “thunderclap headaches” (BTH) or crash migraine. Severe global headaches of abrupt onset that reach maximal intensity in <1 minute, accompanied by vomiting in ≈ 50% They may recur, and are presumably a form of vascular headache. Some may have transient focal symptoms. There are no clinical criteria that can reliably differentiate these from SAH (although seizures and diplopia, when they occurred, were always associated with SAH). There is no subarachnoid blood on CT and LP, which should probably be performed on at least the first presentation to R/O SAH. Earlier recommendations to angiogram these individuals have since been tempered by experience. Warning H/A are usually sudden in onset, milder than that associated with a major rupture, and may last a few days.

3. reversible cerebral vasoconstrictive syndrome (RCVS) (AKA benign cerebral angiopathy or vasculitis): severe H/A with paroxysmal onset, ± neurologic deficit, and string of beads appearance on angiography of cerebral vessels that usually clears in 1–3 months. >50% report prior use of vasoconstrictive substances (cocaine, marijuana, nasal decongestants, ergot derivatives, SSRIs, interferon, nicotine patches) sometimes combined with binge drinking. May also occur post-partum. Complications occurred in 24% including:
   a) usually during the 1st week: SAH, ICH, seizures, RPLS
   b) usually during the 2nd week: ischemic events (TIA, stroke)
4. benign orgasmic cephalgia: a severe, throbbing, sometimes “explosive” H/A with onset just before or at the time of orgasm (distinct from pre-orgasmic headaches which intensify with sexual arousal). In a series of 21 patients neurologic exam was normal in all, and angiography done in 9 was normal. 9 had a history of migraine in the patient or a family member. No other symptoms developed in 18 patients followed for 2–7 yrs. Recommendations for evaluation are similar to that for thunderclap headaches above.

77.5.3 Signs

Meningismus (see below), hypertension, focal neurologic deficit (e.g. oculomotor palsy, hemiparesis), obtundation or coma (see below), ocular hemorrhage (see below).

Meningismus

Nuchal rigidity (especially to flexion) often ensues in 6 to 24 hrs. Patients may have a positive Kernig sign (flex thigh to 90° with knee bent, then straighten knee, positive sign if this causes pain in hamstrings) or Brudzinski sign (flex the supine patient’s neck, involuntary hip flexion is a positive sign).

Coma following SAH

Coma may follow SAH because of any one or a combination of the following:

1. increased ICP
2. damage to brain tissue from intraparenchymal hemorrhage (may also contribute to increased ICP)
3. hydrocephalus
4. diffuse ischemia (may be secondary to increased ICP)
5. seizure
6. low blood flow (reduced CBF) due to reduced cardiac output (p.1177)
Ocular hemorrhage

Three types of ocular hemorrhage (OH) may be associated with SAH. They occur alone or in various combinations in 20–40% of patients with SAH.61

1. subhyaloid (preretinal) hemorrhage: seen funduscopically in 11–33% of cases as bright red blood near the optic disc that obscures the underlying retinal vessels. May be associated with a higher mortality rate.62

2. (intra)retinal hemorrhage: may surround the fovea

3. hemorrhage within the vitreous humor (Terson syndrome). First described by the French ophthalmologist Albert Terson. Occurs in 4–27% of cases of aneurysmal SAH,63,64,65 usually bilateral. May occur with other causes of increased ICP including ruptured AVMs. Funduscopy reveals vitreous opacity. The location of the origin of the vitreous hemorrhage differs in various reports (subhyaloid, epiretinal, subinternal limiting membrane).66 May be more common with anterior circulation aneurysms (especially ACoA), although 1 study found no correlation with location.64 Also rarely reported with SDH and traumatic SAH. Often missed on initial examination. When sought, usually present on initial exam, however it may develop as late as 12 days post SAH, and may be associated with rebleeding.64 The mortality rate may be higher in SAH patients with vitreous hemorrhage than in those without. Patients should be followed for complications of OH (elevated intraocular pressure, retinal membrane formation →retinal detachment, retinal folds). Most cases clear spontaneously in 6–12 mos. Vitrectomy should be considered in patients whose vision fails to improve or if more rapid improvement is desired.68 The long-term prognosis for vision is good in ≈ 80% of cases with or without vitrectomy.68

The pathomechanics of OH are controversial. OH was originally attributed to extension of the blood from the subarachnoid space into the vitreous, but no communication exists between these two spaces. In actuality may be due to compression of the central retinal vein and the retinochoroidal anastomoses by elevated CSF pressure65 causing venous hypertension and disruption of retinal veins.

77.6 Work-up of suspected SAH

77.6.1 Overview

1. tests to diagnose SAH
   a) non-contrast high-resolution CT scan: see below
   b) if CT is negative: LP in suspicious cases (for findings, see below)

2. test to identify source of SAH. Options: CTA, MRA, or catheter angiography. The choice needs to take into account the patient’s age, renal function, and even best guess of where an aneurysm might be located
   a) MRA: no radiation, and 2D-TOF MRA does not use contrast (p.232). Poor sensitivity for aneurysm detection early after SAH (see below)
   b) CTA vs. angiogram: one needs to balance the risk of the procedure and ease of obtaining it against the information expected to be obtained
      • total iodine load in a healthy adult should be <90 gm in 24 hours. In older patients and/or possible compromised renal function, this volume should be less. CTA typically uses 65–75 cc of contrast with ≈ 300 mg iodine/ml, or ≈ 21 gm iodine. The amount of contrast with a cerebral arteriogram varies. However if an angiogram is needed after a CTA, in most cases you do not have to wait 24 hours
      • if there is concern about renal function (e.g. serum creatinine >100 mmol/L) hydrate the patient and optionally give Mucomyst® (p.221)
      • catheter angiography may be necessary after a positive CTA to better delineate the anatomy, or to determine dominant filling and cross flow, or in highly suspicious cases with a negative CTA (see below). While CTA permits reliable assessment of feasibility of endovascular treatment in most cases,69 DSA is still necessary in some

3. if CTA/angiogram is negative: see SAH of unknown etiology (p.1230)

77.6.2 Laboratory/radiographic findings

CT scan

A good quality (e.g. no motion artifact) non-contrast high-resolution CT will detect SAH in ≥95% of cases if scanned within 48 hrs of SAH. Blood appears as high density (white) within subarachnoid
spaces. For subtle SAH, look in the occipital horns of the lateral ventricles and the dependent portions of the sylvian fissures. CT also assesses:

1. ventricular size: hydrocephalus occurs acutely in 21% of aneurysmal ruptures (p.1170)
2. hematoma: intracerebral hemorrhage or large amount of subdural blood with mass effect may need emergent evacuation
3. infarct: not sensitive in first 24 hours after infarct (p.1280)
4. amount of blood in cisterns and fissures: important prognosticator for vasospasm (p.1180) and can identify pretruncal nonaneurysmal hemorrhage (p.1231)
5. CT can predict aneurysm location based on the pattern of blood in ≈78% of cases (but mostly for MCA and A-comm aneurysms)
   a) blood predominantly in anterior interhemispheric fissure (± blood in lateral ventricles) or within the gyrus rectus suggests a-comm aneurysm
   b) blood predominantly in 1 sylvian fissure is compatible with p-comm or MCA aneurysm on that side
   c) blood predominantly in the preoptic or peduncular cistern suggests a basilar apex or SCA aneurysm
   d) blood predominantly within ventricles (p.1192)
      • blood primarily in 4th and third ventricle: suggests lower posterior fossa source, such as PICA aneurysm or VA dissection
      • blood primarily in the 3rd ventricle suggests a basilar apex aneurysm
6. with multiple aneurysms, CT may help identify which one bled by the location of blood (see above). See also other “clues” (p.1226)

**Differential diagnosis of SAH on CT**

Things that can mimic the appearance of SAH on CT include:

1. pus
2. following contrast administration: sometimes IV, and especially intrathecal
3. occasionally the pachymeningeal thickening seen in spontaneous intracranial hypotension (p.389)

**Lumbar puncture**

The most sensitive test for SAH. However, false positives – e.g. with traumatic taps; see Differentiating SAH from traumatic tap (p.1506) – occur with enough frequency that this test is falling out of favor for diagnosis of SAH.

Caution: lowering the CSF pressure may possibly precipitate rebleeding by increasing the transmural pressure (p.1170). Therefore remove only a small amount of CSF (several ml) and use a small (≤20 Ga) spinal needle.

Findings (also, see Table 23.4):

1. opening pressure: elevated
2. appearance:
   a) non-clotting bloody fluid that does not clear with sequential tubes
   b) xanthochromia: yellow coloration of CSF supernatant (specimen must be centrifuged in the lab) due to heme pigments released by the breakdown of RBCs. The most reliable means of differentiating traumatic tap from SAH. In patients with a negative head CT, the minimal amount of time required for bilirubin to become detectable in the CSF, as well as the minimal amount of blood the needs to enter the CSF to give a positive xanthochromia remains unknown. However, xanthochromia is usually not apparent until 2–4 hours after the SAH. Is present in almost 100% by 12 hours after the bleed, and remains in 70% at 3 weeks, and is still detectable in 40% at 4 weeks. Spectrophotometry is more sensitive than visual inspection, but may lack sufficient specificity to warrant widespread use.\(^{72,73}\) False positives: xanthochromia may occur with jaundice or high protein levels in the CSF
3. cell count: RBC count usually >100,000 RBCs/mm\(^3\). Compare RBC count in first to last tube (should not drop significantly)
4. protein: elevated due to blood breakdown products
5. glucose: normal, or reduced (RBCs may metabolize some glucose with time)

**MRI**

Not sensitive for SAH acutely within the first 24–48 hrs\(^74\) (too little met-Hb) especially with thin layers of blood. Better after ≈4–7 days (excellent for subacute to remote SAH, >10–20 days). FLAIR
MRI is the most sensitive imaging study for detecting blood in the subarachnoid space. May be helpful in determining which of multiple aneurysms bled (p.1226).75

Magnetic resonance angiography (MRA)

Based on a systematic review, sensitivity is 87% and specificity is 92% for detecting intracranial aneurysms (IAs) (compared to catheter DSA) with significantly poorer sensitivity for aneurysms <3 mm diameter.76,77,78

MRA’s ability to detect IAs depends on aneurysm size, rate and direction of blood flow in the aneurysm relative to the magnetic field, and aneurysmal thrombosis and calcification. MRA may be most useful as a screening test in high-risk patients including patient’s with two first degree relatives with IAs, especially those who are also smokers or hypertensive themselves.79

CT angiography (CTA)

Many centers have shown good results with CTA (p.227), with a prospective study detecting 97% of aneurysms and demonstrating CTA as safe and effective when used as the initial and sole imaging study for ruptured and unruptured cerebral aneurysms.80 CTA shows a 3-dimensional image (as can modern catheter angiography) which can help differentiate adherent vessels from those arising from the aneurysm. CTA also demonstrates the relation to nearby bony structures which can be important in surgical planning. CTA use is increasing for evaluation of vasospasm.81

Catheter angiogram

General information

Injection of radio-opaque (iodinated) contrast (“dye”) into selective vessels using a catheter typically inserted into the femoral artery at the upper thigh, while taking serial x-rays to obtain a “video-like” representation of the vasculature.

The gold standard for evaluation of cerebral aneurysms. Current state of the art uses digital subtraction angiography (DSA). Demonstrates source (usually aneurysm) in ≈80–85% remainder are so-called “SAH of unknown etiology” (p.1230). Shows if radiographic vasospasm is present – clinical vasospasm almost never occurs <3 days following SAH (p.1178) – and assesses primary feeding arteries, collateral flow in case of a need for arterial sacrifice.

General principles:

1. study the vessel of highest suspicion first (in case patient’s condition should change, necessitating discontinuation of procedure)
2. continue to do complete 4 vessel angiogram (even if aneurysm(s) have been demonstrated) to rule out additional aneurysms and assess collateral circulation
3. if there is an aneurysm or suspicion of one, obtain additional views to help delineate the neck and orientation of the aneurysm (see index for specific aneurysm)
4. if no aneurysm is seen, before an arteriogram can be considered negative, must:
   a) visualize both PICA origins: 1–2% of aneurysms occur at PICA origin. Both PICAs can usually be visualized with one VA injection if there is enough flow to reflux down the contralateral VA. Occasionally it is necessary to see more of the contralateral VA than what reflexes to PICA and selective catheterization may be required
   b) flow contrast through the ACoA: if both ACAs fill from one side, this is usually satisfactory. It may be necessary to perform a cross compression AP study with carotid injection (first, rule-out plaque in the carotid to be compressed), or use a higher injection rate to facilitate flow through the ACoA
   c) if an infundibulum (see below) colocalizes to the SAH, it may be unwise to label the case as angiogram-negative and exploration is recommended by some82

Infundibulum

A funnel shaped initial segment of an artery, to be distinguished from an aneurysm. Found in 7–13% of otherwise normal arteriograms.83,84 with a higher incidence in cases of multiple or familial aneurysms. Bilateral in 25%.84 Most commonly found at the origin of the p-comms, but they rarely occur at other sites. Criteria for differentiating infundibula from aneurysms are shown in Table 77.1. Infundibula may represent incomplete remnants of previous fetal vessels.85 (p 272)

Although they may bleed,83,84,87,88,89 there is less risk of rupture than with a saccular aneurysm (no infundibulum <3 mm in size bled90 in the cooperative study). However, infundibula have been documented to progress to an aneurysm (i.e. they are preaneurysmal) which may bleed (13 case reports in the literature as of 2009). Recommended treatment: at the time of surgery for another reason,
consider treating an infundibulum with wrapping, or placing in an encircling clip, or sacrificing the artery if it can be done safely (infundibula lack a true neck).

**Angiographic findings**

1. general features to take note of when analyzing an aneurysm on angiogram (special considerations for specific aneurysms are covered in designated sections)
   a) size of aneurysm dome:
      - MRI or CT helps with this since the aneurysm may be partially thrombosed and the portion that is patent and fills with contrast and is therefore visualized on angiogram may be much smaller than the actual size
      - large aneurysms (≥15 mm dia.) are associated with lower rates of complete occlusion by endovascular coiling
         \(^91,92\)
   b) neck size
      - narrow necks <5 mm are ideal for coiling \(^93\)
      - broad necks ≥5 mm are associated with increased risk of incomplete occlusion and recanalization with coiling
         \(^92\)
      - stent or balloon-assisted coiling may be needed for wide necked aneurysms. Stents should be avoided if possible (p.1586).
   c) dome:neck ratio ≥2 is associated with higher rate of successful coil occlusion
         \(^93\)

2. for basilar bifurcation aneurysms (p.1218)

### 77.7 Grading SAH

#### 77.7.1 General information

Four grading scales are in common use. The 2 most widely quoted grading scales are presented here.

#### 77.7.2 Hunt and Hess grade

See Table 77.2 and Table 77.3 for grading system. Grades 1 and 2 were operated upon as soon as an aneurysm was diagnosed. Grade ≥3 managed until the condition improved to Grade 2 or 1. Exception: life threatening hematoma or multiple bleeds (which were operated on regardless of grade).

Analysis of data from the International Cooperative Aneurysm Study revealed that with normal consciousness, Hunt and Hess (H&H) grades 1 and 2 had identical outcome, and that hemiparesis and/or aphasia had no effect on mortality.

Add one grade for serious systemic disease (e.g. HTN, DM, severe atherosclerosis, COPD) or severe vasospasm on arteriography.

<sup>a</sup>original paper did not consider patient’s age, site of aneurysm, or time since bleed; patients were graded on admission and pre-op
Mortality:
Admission Hunt and Hess Grade 1 or 2: 20%.
Patients taken to O.R. (for any procedure) at H&H Grade 1 or 2: 14%.
Major cause of death in Grade 1 or 2 is rebleed.

Signs of meningeal irritation increases surgical risk.

77.7.3 World Federation of Neurosurgical Societies / World Federation of Neurological Surgeons (WFNS) grading of SAH

Due to lack of data on the significance of features such as headache, nuchal rigidity, and major focal neurologic deficit, the WFNS Committee on a Universal SAH Grading Scale developed a grading system which is shown in Table 77.4. It uses the Glasgow Coma Scale (GCS) to evaluate level of consciousness, and uses the presence or absence of major focal neurologic deficit to distinguish grade 2 from grade 3.

77.8 Initial management of SAH

77.8.1 General information

Practice guideline

**Practice guideline: Initial management of aneurysmal SAH**

**Level I**:  
- administer oral nimodipine to all patients with aneurysmal SAH. The value of other calcium channel blockers is uncertain  
- maintain euvolemia and normal circulating blood volume

**Level II**:  
- control of HTN: the ideal BP to reduce the risk of rebleeding has not been established. A reasonable target is to maintain SBP < 160 mm Hg
Initial management concerns

1. rebleeding: the major concern during the initial stabilization
2. hydrocephalus: precipitous development acute hydrocephalus may be obstructive (due to blockage of CSF flow by blood clot), but presence of ventriculomegaly early after SAH as well as at later stages is often due to communicating hydrocephalus (p.1170) (due to toxic effect of blood breakdown products on arachnoid granulations)
3. delayed ischemic neurologic deficit (DIND), usually attributed to vasospasm. Begins to be of concern several days following the SAH
4. hyponatremia with hypovolemia (p.1166)
5. DVT and pulmonary embolism (p.167)
6. seizures (p.1167)
7. determining source of bleeding: should be investigated early with CTA or catheter angiography.

The timing and choice of study takes into consideration the patient’s condition (unstable or pre-morbid patients are not candidates), the feasibility of early treatment (ideal), and the likelihood of endovascular therapy (based on patient’s age and predicted aneurysm location as well as availability)

Goals of medical management related to neurologic injury

In addition to prevention of hyponatremia, hypovolemia, seizures, etc. (see above), the goals of initial medical management include:

1. augmenting CBF: the main device for accomplishing this is hyperdynamic therapy (p.1186).
   Goals are:
   a) increasing cerebral perfusion pressure (CPP)
   b) improving blood rheology: RBC aggregability increases after SAH
   c) maintaining euvoolemia: the majority of patients become hypovolemic in the first 24 hrs after SAH. Also, avoid prophylactic hypervolemia
   d) maintaining normal ICP
2. neuroprotection: there are currently no medications shown to be effective or approved for use as neuroprotective agents for this or any other type of brain injury. Animal studies have shown time and again that the concept may someday be translated into clinical practice

77.8.2 Monitors/tubes

Also see below.

1. arterial-line: for patients who are hemodynamically unstable, stuporous or comatose, those with difficult to control hypertension, or those requiring frequent labs (e.g. ventilator patients)
2. intubate patients who are comatose or unable to protect airway (e.g. stridorous)
3. pulmonary-artery catheter (PA-catheter, AKA Swann-Ganz catheter): the safety and efficacy of this device has been debated in the critical care literature for over a decade now, with some calling for a moratorium on PA catheter use. It is possible that newer technologies may supplant the need for this invasive procedure while allowing close hemodynamic monitoring.

Nevertheless, a PA catheter can be considered for:
   a) Hunt and Hess (H&H) grade ≥3 (except good grade 3 patients)
   b) patients with possible CSW or SIADH
   c) hemodynamically unstable patients
4. cardiac rhythm monitor: arrhythmias may occur following SAH (p.1177)
5. intraventricular catheter (IVC) AKA ventriculostomy. Possible indications:
   a) patients developing acute hydrocephalus following SAH or in those with significant intraventricular blood (allows measurement of ICP as well as drainage of blood laden CSF). IVC causes symptomatic improvement in almost two-thirds. May increase the risk of rebleeding (p.1170), however, the risk of untreated hydrocephalus is probably higher
   b) H&H grade ≥3 (except good grade 3 patients). If a high grade patient improves with an IVC, the prognosis may be more favorable. If ICP is elevated, management includes the use of mannitol; see Treatment measures for elevated ICP (p.866).

77.8.3 Admitting orders

1. admit to ICU (monitored bed)
2. VS with neuro checks q 1 hr
3. activity: BR with HOB at 30°. SAH precautions (i.e. low level of external stimulation, restricted visitation, no loud noises)

4. nursing
   a) strict I's & O's
   b) daily weights
   c) knee high TED hose and pneumatic compression boots (PCB)
   d) indwelling Foley catheter if patient lethargic, incontinent, or unable to void in urinal or bedpan. Consider temperature sensing catheter for strict fever control

5. diet: NPO (in preparation for surgery or endovascular intervention)

6. IV fluids: early aggressive fluid therapy to head off cerebral salt wasting
   a) NS+20 mEq KCl/L at ≈ 2 ml/kg/hr (typically 140–150 ml/hr) (below)
   b) if Hct <40% give 500 ml of 5% albumin over 4 hrs upon admission

7. medications (avoid IM medications to reduce pain)
   a) prophylactic anticonvulsants: see post-SAH seizures below
   b) sedation (not oversedation): e.g. with propofol
   c) analgesics: fentanyl (unlike morphine, does not cause histamine release. Lowers ICP) 25–100 mcg (0.5–2 ml) IV, q 1–2 hrs PRN (avoid Demerol® because it may lower seizure threshold)
   d) dexamethasone (Decadron®): may help with H/A and neck pain. Effect on edema controversial. Usually given pre-op prior to craniotomy
   e) stool softener in patients able to take PO (docussate 100 mg PO BID)
   f) anti-emetics: avoid phenothiazines (especially in patients who seize) which may lower seizure threshold. Use e.g. Zofran® (ondansetron) 4 mg IV over 2–5 minutes, may repeat in 4 & 8 hours, and then q 8 hours for 1–2 days
   g) calcium channel blockers (p.1183): nimodipine (Nimotop®) 60 mg PO/NG q 4 hrs initiated within 96 hrs of SAH (some use 30 mg q 2 hrs to avoid periodic dips in BP). IV administration is equally as effective where available. Oral nimodipine should be administered to all patients with aSAH.
   h) H2 blockers (e.g. ranitidine) or proton pump inhibitors (e.g. Prevacid® (lansoprazole) 30 mg p.o. or IV q d): to reduce risk of stress ulceration
   i) these agents impair coagulation and are used with caution: ASA, dextran, heparin, and repeated administration of hetastarch (Hespan®) over a period of days
   j) statins: several clinical trials have investigated the utility of statins, with variable results. More recently, a meta-analysis reported no evidence for clinical benefit. In addition, a multicenter randomized phase 3 trial did not detect any short- or long-term benefit with the use of simvastatin.

8. oxygenation
   a) in non-intubated patient: O₂ 2 L per NC PRN (based on ABG) and if tolerated
   b) in ventilated patient: strive for normocarbia and pO₂ >100 mm Hg

9. temperature (normothermia): medications (Tylenol) and cooling measures (e.g. ice packs, Arctic Sun external cooling device) to reduce and prevent fever are encouraged, as fever has been shown to be independently associated with worse cognitive and functional outcome in survivors of aSAH.
   i) these agents impair coagulation and are used with caution: ASA, dextran, heparin, and repeated administration of hetastarch (Hespan®) over a period of days
   j) statins: several clinical trials have investigated the utility of statins, with variable results. More recently, a meta-analysis reported no evidence for clinical benefit. In addition, a multicenter randomized phase 3 trial did not detect any short- or long-term benefit with the use of simvastatin.

10. HTN: SBP 120–160 mm Hg by cuff is a guideline with unclipped aneurysm (below)

11. labs
   a) ABG, electrolytes, CBC, PT/PTT on admission
   b) ABG, electrolytes, CBC q day (ABG q 6 hrs if patient unstable, electrolytes q 12 hrs if hyponatremia develops, see Hyponatremia following SAH below)
   c) serum and urine osmolality if urine output high or low; see Syndrome of inappropriate antidiuretic hormone secretion (SIADH) (p.112)
   d) hemoglobin and hematocrit: some studies suggest that higher hemoglobin values are associated with improved outcomes after aSAH. However, liberal RBC transfusion has been associated with worse outcomes in aSAH. The optimal hemoglobin goal after aSAH in not yet known, and may depend on the presence or absence of vasospasm
   e) serum glucose: effective glucose control after aSAH can significantly reduce the risk of poor outcome
   f) CXR daily until stable: patients undergoing triple-H therapy can develop dangerous pulmonary edema as they “fall off” the Starling curve with volume expansion. Patients with SAH are also rarely at risk for neurogenic pulmonary edema (p.1178)
   g) if available, transcranial doppler to monitor MCA, ACA, ICA, VA and BA velocities and Lindegaard ratio (p.1182) q Mon, Weds & Fri
77.8.4 Blood pressure and volume management

General information

With an unsecured (unclipped or uncoiled) aneurysm, gentle volume expansion with slight hemodilution and mild elevation of blood pressure may help prevent or minimize the effects of vasospasm and cerebral salt wasting. However, extreme hypertension must be avoided (to reduce risk of re-bleeding). Hypervolemia is to be avoided since it does not mitigate vasospasm and increases complications.

Initial blood pressure

Ideal blood pressure is controversial, and must take patient’s baseline into consideration. The magnitude of blood pressure control to reduce the risk of rebleeding has not been established, but a decrease in systolic blood pressure to <160 mmHg is reasonable.

If blood pressure is labile, labetalol or nifedipine should be used in conjunction with an arterial line. Avoid hypotension as it may exacerbate ischemia.

Long acting drugs (e.g. ACE inhibitors should be started in patients requiring continued therapy. In patients who were normotensive prior to SAH with easily controlled hypertension, ACE inhibitors may be used PRN in conjunction with a beta blocker, e.g. labetalol (p.126).

77.8.5 Hyponatremia following SAH

Background

Hypovolemia and hyponatremia frequently follow SAH as a result of natriuresis and diuresis. The reported incidence of hyponatremia in aSAH ranges from 10-30%. Although hyponatremia had been attributed to a rise in ADH (thought to produce SIADH with hypervolemia), the ADH increment is usually transient, lasting only ≈4 days and hypervolemia did not occur. Another theory is based on the fact that there is often a delayed peak in atrial natriuretic factor (ANF) (a 28-amino acid polypeptide) after an initial smaller rise that was frequently followed by urinary loss of sodium (cerebral salt wasting (CSW) (p.118) that mimics SIADH, and volume depletion. Although CSW has clearly been shown to be the cause of hyponatremia in the majority of these patients, there are still doubts that ANF is the operative natriuretic factor in SAH. A rise in ANP and brain natriuretic peptide (BNP) after SAH is associated with the development of a negative fluid balance.

Routine labs are identical in SIADH and CSW, but the extracellular fluid volume (which is more difficult to measure) is low in CSW and is normal or elevated in SIADH (see Table 5.5 or a comparison of the two conditions). The neurologic effects of hyponatremia (p.112) may mimic delayed ischemic neurologic deficit from vasospasm, and hyponatremic patients have about 3 times the incidence of delayed cerebral infarction after SAH than normonatremic patients. Hyponatremia has been chronologically associated with the onset of sonographic and clinical vasospasm. Factors that may increase the risk of hyponatremia after SAH include: history of diabetes, CHF, cirrhosis, adrenal insufficiency, or the use of any of the following drugs: NSAIDs, acetaminophen, narcotics, thiazide diuretics.

Treatment

Caution! Restricting fluids which is the treatment for SIADH may be hazardous in the case of CSW (which is more likely to occur after SAH than is SIADH) since dehydration increases blood viscosity which exacerbates ischemia from vasospasm.

- Reat hypovolemia aggressively with infusions of crystalloid (e.g. NS), PRBCs, or colloids
- Hypertonic saline (3%) has been shown to be effective in correcting hyponatremia and appears to increase regional cerebral blood flow, brain tissue oxygen, and pH in patients with high-grade anSAH.
- Fludrocortisone has been shown to help correct hyponatremia, with a reduced need for fluids. Similarly hydrocortisone administration has been associated with reduced natriuresis and a lower rate of hyponatremia.

77.8.6 Post-SAH seizures

General information

No RCT has been performed to help guide decisions on prophylaxis or treatment of seizures. There is also conflicting evidence on whether onset seizures are predictive of late seizures or post-SAH
epilepsy. As such, there is no consensus amongst practitioners regarding the need for AEDs, the best AED to use, which patients should receive prophylactic AEDs, nor the optimal dose or duration of treatment.

Epidemiology

Incidence. The incidence of seizure-like episodes varies widely between observational studies. One literature review reported 4-26% of SAH patients had onset seizures, 1-28% had early seizures (within first 2 weeks), and 1-35% had late seizures (after 2 weeks). Additionally, non-convulsive status epilepticus has been reported in 3-18% of SAH patients, and should be suspected in patients with a poor neurological exam or in the setting of neurological deterioration.

Risk factors for post-SAHi seizures. Increasing age, MCA aneurysm, volume of subarachnoid blood/thickness of clot, associated intracerebral or subdural hematoma, poor neurological grade, rebleeding, cerebral infarction, vasospasm, hyponatremia, hydrocephalus, hypertension, treatment modality, see coiling vs. clipping (p.1195)

Outcome

The association between seizures and functional outcome remain unclear. One study showed that an in-hospital seizure was independently predictive of one year mortality (65% with seizures vs. 23% without seizures), but others have shown no association with a poorer prognosis. Two large, retrospective, single-institution studies of patients with aSAH found that nonconvulsive status epilepticus is a very strong predictor of poor outcome.

AEDs

Studies have assessed neurological outcome following short- and long-term phenytoin use, with higher doses and longer duration associated with poorer outcomes. When Keppra is compared to phenytoin, keppra is associated with a higher rate of short-term seizure recurrence, but improved long-term outcomes and fewer side effects. Although use of prophylactic AED for aSAH is controversial, a generalized seizure may be devastating in the presence of a tenuous aneurysm. As such, AEDs are given by many authorities in the acute setting, at least until the aneurysm is secured. One paradigm: Keppra® (levetiracetam) 1 g IV q 12 hours until the aneurysm is secured.

Practice guideline: Post-SAHi seizures

- Level II: prophylactic anticonvulsants may be considered in the immediate posthemorrhagic period
- Level III: the routine long-term use of anticonvulsants is not recommended
- Level III: long-term anticonvulsants may be considered with known risk factors for delayed seizure disorder (e.g. prior seizure, intracerebral hematoma, intractable hypertension, infarction, or MCA aneurysm)

77.9 Rebleeding

77.9.1 General information

Approximately 3000 North Americans die each year from rebleeding of ruptured cerebral aneurysms. For untreated ruptured aneurysms, the maximal frequency of rebleeding is in the 1st day
(between 4% and 13.6%), with more than 1/3 of rebleeds occurring within 3 hours and 1/2 within 6 hours of symptoms onset. After the first day, the subsequent risk is 1.5% daily for 13 d. Overall, 15–20% rebleed within 14 d, 50% will rebleed within 6 months, thereafter the risk is ≈ 3%/yr with a mortality rate of 2%/yr. (Note: to understand the calculation of long-term cumulative risk for aneurysmal rupture, see Annual and lifetime risk of hemorrhage and recurrent hemorrhage (p.1240); that discussion is related to AVMs but the same concepts pertain to aneurysms). 50% of deaths occur in the 1st month.

There is a risk of rebleeding during any period that the aneurysm is untreated. As such, early treatment of the ruptured aneurysm can reduce risk of rebleeding (see Timing of aneurysm intervention). In addition, higher Hunt and Hess grades, larger aneurysm size, and poorly controlled blood pressure (>160 mmHg) have also been associated with an increased risk of rebleeding.

Pre-operative ventriculostomy – e.g. for acute post-SAH hydrocephalus (p.1170) – and possibly lumbar spinal drainage (p.1202) increase the risk of rebleeding.

The risk of rebleeding in SAH of unknown etiology and with AVMs, as well as the risk of bleeding with incidental multiple unruptured aneurysms, are all similar at ≈ 1%/yr; may actually be less in SAH of unknown etiology (p.1230).

### 77.9.2 Prevention of rebleeding

The optimal method of preventing rebleeding is early coiling or surgical clipping. Bed rest and hypodynamic therapy do not prevent rebleeding.

### 77.9.3 Antifibrinolytic therapy

The role of clot lysis in early rebleeding is uncertain.

#### Practice guideline: Antifibrinolytic therapy

**Level II**41: for patients with aneurysmal SAH where there is an unavoidable delay in treatment of the aneurysm, in whom there is a significant risk of rebleeding and no compelling medical contraindications, up to 72 hours of therapy with tranexamic acid or amicaproic acid is reasonable

#### Drug info: Tranexamic Acid (Cyklokapron®)

Reduces the risk of early rebleeding.153

- 1 gm IV as soon as diagnosis of SAH is verified (if patient is to be transported to another facility for definitive care, the dose is given before the patient is transported), followed by 1 gm q 6 hours until the aneurysm is occluded; this treatment did not exceed 72 hours.

#### Drug info: Epsilon-aminocaproic acid (Amicar®)

Epsilon-aminocaproic acid (EACA) an antifibrinolytic agent, competitively inhibits activation of plasminogen to plasm. Existing plasmin is neutralized by endogenous antiplasmins. EACA does reduce the risk of rebleeding. However, the incidence of hydrocephalus and delayed ischemic deficits (vasospasm) have been shown to be higher with prolonged use163 with prolonged use. There may also be a lag of 24–48 hrs before effectiveness occurs.164 Because of the increased rate of cerebral infarction, EACA was found not to reduce early mortality, and its use was discouraged.

Reevaluation in a non-randomized study165 excluding grade IV and V patients, suggests that the problems with EACA may be minimized by use of an IV loading dose (to eliminate the lag-period to effectiveness) and by limiting the length of time of use to that time until the patient can undergo early surgery. A more recent investigation166 showed a significant decrease in rebleeding in EACA-treated patients versus non-EACA patients (2.7 vs. 11.4%). There was a 76% reduction in mortality attributable to rebleeding, a 13% increase in favorable outcome in good-grade (Hunt Hess I-II) EACA treated patients, and a 6.8% increase in poor grade patients (Hunt Hess IV/V), but these results did
not reach statistical significance. Although there was an 8-fold increase in DVT in the EACA group, there was no increase in pulmonary embolism. Additionally, there was no difference in ischemic complications between groups.

166. EACA 4 g IV loading dose, followed by 1 g/h with cessation of infusion 4 hours before angiography for a maximum duration of 72 hours after SAH.

77.10 Pregnancy and intracranial hemorrhage

77.10.1 General information

Intracranial hemorrhage (subarachnoid or intraparenchymal) is a rare occurrence during pregnancy (estimated range of incidence: 0.01–0.05% of all pregnancies167) and yet is responsible for 5–12% of maternal deaths during pregnancy.

Intracranial hemorrhage of pregnancy (ICHOP) commonly occurs in the setting of eclampsia, and is more commonly intraparenchymal168 and may be associated with loss of cerebrovascular autoregulation PRES (p.194).169 Symptoms of eclampsia with or without ICHOP include H/A, mental status changes, and seizures.

A literature review of 154 reported cases of ICHOP-related SAH revealed 77% were aneurysmal and 23% were from ruptured AVM (other series show the percentage of AVMs range from 21–48%). Mortality is ≈ 35% for aneurysmal and ≈ 28% for AVM hemorrhage (the latter being higher than in non-gravid patients). There is an increasing tendency for bleeding with advancing gestational age for both aneurysms and AVMs (earlier it had been asserted that this held true for aneurysms only170).

Patients with ICHOP having AVMs tend to be younger than those with aneurysm, paralleling the occurrence in the general population. One major oft-quoted study showed an increased risk of hemorrhage from AVMs during pregnancy171 (citing an 87% hemorrhage rate), however another investigation disputes this assertion,172 and found the risk of hemorrhage to be 3.5% during the pregnancy in patients with no history of hemorrhage, or 5.8% in those with previous hemorrhage. Another study evaluated risk of aneurysm rupture during pregnancy and delivery from the Nationwide Inpatient data and calculated the rupture risk during pregnancy and delivery to be 1.4% and 0.05%, respectively.173

77.10.2 Management modifications for pregnant patients

Modifications of evaluation and treatment techniques may be necessary for the pregnant patient.

1. neuroradiologic studies
   a) CAT scan: with shielding of the fetus, CAT scanning of the brain produces minimal radiation exposure to the child
   b) MRI:
      • generally felt to have low potential for complications, however, many centers will not do MRI during first trimester.
      • gadolinium based contrast agents (GBCAs) are teratogenic in animals in high repeated doses. It has not been studied in human pregnancy. A cohort of 26 women who received GBCAs during the first trimester showed no evidence of teratogenicity or mutagenicity.174 There have also been no reported issues related to nephrogenic systemic fibrosis. GBCAs are FDA Class C drugs – not recommended for use during pregnancy, but may be used if benefits outweigh potential risks.
   c) angiography: with shielding of the fetus, radiation exposure is minimal. Iodinated contrast agents pose little risk to the fetus. The mother should be well hydrated during and after the study167

2. antiepileptic drugs: see Pregnancy and antiepileptic drugs (p.458)
3. diuretics: the use of mannitol in pregnancy should be avoided to prevent fetal dehydration and maternal hypovolemia with uterine hypoperfusion
4. antihypertensives: nitroprusside should not be used in pregnancy
5. nimodipine is potentially teratogenic in animals, the effect on humans is unknown. It should be used only when the potential benefit justifies the risk
77.10.3 Neurosurgical management

The currently recommended treatment of a ruptured aneurysm in the pregnant patient is immediate surgical treatment to avoid rebleeding and ischemic complications due to vasospasm. A meta-analysis has demonstrated that mother and fetus both benefit from surgical treatment— with maternal mortality decreasing from 63% to 11% and fetal mortality decreasing from 27% to 5%. Successful endovascular treatment for aSAH has been reported, but fetal exposure to radiation is a concern. The absorbed fetal dose has been estimated to range from 0.17 to 2.8 mGy, corresponding to a fetal risk of a hereditary disease at birth and a cumulative risk for a fatal cancer by age 15 which are both substantially lower than that which naturally occur. Because endovascular treatment requires heparin for systemic anticoagulation, it carries the risk of hemorrhagic implications when labor spontaneously begins during or around the time of embolization.

77.10.4 Obstetric management following ICHOP

Several reports have indicated that the fetal and maternal outcome is no different for vaginal delivery vs. C-section, and is probably more dependent on whether the offending lesion has been treated. However, there are no formal studies to help guide the optimal treatment of pregnant women with aSAH. One strategy is to perform an emergent c-section, followed by aneurysm treatment, if the fetus is mature enough for survival outside the uterus. If the fetus is < 24 weeks, treat the aneurysm and maintain the pregnancy. If the fetus is between 24-28 weeks, a strategy should be tailored according to the maternal and fetal status. C-section may be used for fetal salvage for a moribund mother in the third trimester. During vaginal delivery, the risk of rebleeding may be reduced by the use of caudal or epidural anesthesia, shortening the 2nd stage of labor, and low forceps delivery if necessary.

77.11 Hydrocephalus after SAH

77.11.1 Hydrocephalus after traumatic SAH

See also posttraumatic hydrocephalus (p. 920).

77.11.2 Acute hydrocephalus

General information

The frequency of hydrocephalus (HCP) on the initial CT after SAH depends on the defining criteria used, with a reported range of 9–67%. A realistic range is 15–20% of SAH patients, with 30–60% of these showing no impairment of consciousness. Factors felt to contribute to acute HCP include: blood interfering with CSF flow through the Sylvian aqueduct, fourth ventricle outlet, or subarachnoid space, and/or with reabsorption at the arachnoid granulations.

Findings associated with acute HCP include:
1. increasing age
2. admission CT findings: intraventricular blood, diffuse subarachnoid blood, and thick focal accumulation of subarachnoid blood (intraparenchymal blood did not correlate with chronic HCP, and patients with a normal CT had a low incidence)
3. hypertension: on admission, prior to admission (by history), or post-op
4. by location:
   a) posterior circulation aneurysms have a higher incidence of HCP
   b) MCA aneurysms correlate with low incidence of HCP
5. miscellaneous: hyponatremia, patients who were not alert on admission, use of preoperative antifibrinolytic agents, and low Glasgow outcome score

Treatment

About half the patients with acute HCP and impaired consciousness improved spontaneously. Patients in poor grade (H&H IV-V) with large ventricles may be symptomatic from the HCP and consideration should be given to ventriculostomy which caused improvement in ~ 80% of patients in whom it was used. There may be an increased risk of aneurysmal rebleeding in patients undergoing ventriculostomy shortly after SAH especially if performed early and if ICP is lowered
precipitously. The risk of aneurysm rebleeding with EVD has been studied in retrospective case series with mixed results.\textsuperscript{181,182,183} The mechanism is controversial, but may be due to an increase in the transmural pressure (the pressure across the aneurysm wall which equals the difference between arterial pressure and ICP).

When a ventriculostomy is used, it is recommended to keep ICP in the range of 15–25 mm Hg\textsuperscript{184} and to avoid rapid pressure reduction (unless absolutely necessary) to decrease the risk of IVC induced aneurysmal rebleeding. One paradigm is to keep the EVD open with the drip chamber nozzle 15-20 cm above the tragus.

### Practice guideline: Acute hydrocephalus associated with aSAH

**Level B\textsuperscript{41}: CSF diversion (EVD or lumbar drain) for acute symptomatic hydrocephalus associated with aSAH.**

#### 77.11.3 Chronic HCP

### Practice guideline: Chronic hydrocephalus associated with aSAH

- **Level B\textsuperscript{41}:** permanent CSF diversion (shunt) for symptomatic chronic hydrocephalus following aSAH.
- **Level C\textsuperscript{41}:** Weaning an EVD over >24 hours does not appear to reduce the need for permanent CSF diversion.
- **Level C\textsuperscript{41}:** Routine fenestration of the lamina terminalis is not recommended as it does not reduce the need for permanent CSF diversion.

Chronic HCP is due to pia-arachnoid adhesions or permanent impairment of the arachnoid granulations. Acute HCP does not inevitably lead to chronic HCP. 8–45% (reported range in literature\textsuperscript{185}) of all ruptured aneurysm patients, and \(\approx\) 50% of those with acute HCP following SAH need permanent CSF diversion. A number of studies have attempted to identify factors predictive of aSAH-associated shunt dependent chronic hydrocephalus. Intraventricular blood increases this risk.\textsuperscript{185} There is controversy as to whether the use of ventriculostomy for acute HCP increases\textsuperscript{186} or possibly even decreases\textsuperscript{185} the incidence of shunt dependency. There may be a positive association between Fisher grade and likelihood of requiring CSF diversion for chronic hydrocephalus.\textsuperscript{187} In addition, Hoh et al.\textsuperscript{188} found age (2% increase/year), comorbidity score (presence of DM, HTN, or alcohol abuse), admission type, insurance type (increased with medicaid and private payer) and hospital aneurysm volume (high >low) to be predictive of shunt placement in ruptured aneurysm patients. Treatment type (clip versus coil) has also been studied with no clear advantage for one modality over the other (p.1195).

The method of determining which patients require shunt placement has also been studied in a single center RCT.\textsuperscript{189} There was no difference in the rate of shunt placement between those who underwent rapid weaning (<24 hrs) versus gradual weaning (96 hrs) of the EVD (63.4% rapid versus 62.5%gradual).

### References

78 Critical Care of Aneurysm Patients

78.1 Neurogenic stress cardiomyopathy (NSC)

78.1.1 General information

Key concepts

- impaired cardiac function (reduced ejection fraction) not attributable to underlying coronary artery disease or myocardial abnormalities. May be reversible
- cardiac enzymes (troponin) tend to be lower than expected for the degree of myocardial impairment, distinguishes NSC from acute MI
- putative mechanism: catecholamine surge (possibly in myocardial sympathetic nerves) as a result of hypothalamic stimulation or injury from the SAH
- possible sequelae: hypotension, CHF, arrhythmias... all of which may further exacerbate cerebral ischaemia
- peak incidence: 2 days to 2 weeks post SAH
- risk factors: higher Hunt and Hess grade
- treatment: may include dobutamine (for SBP<90 and low SVR) and/or milrinone (for SBP>90 and increased SVR)

Older terms: reversible postischemic myocardial dysfunction,1 neurogenic stunned myocardium. Classically seen in patients following cardiac surgery, and attributed to a defect in troponin-I (TnI).2
Some patients may develop myocardial hypokinesis following SAH.3 May appear compatible with an MI on echocardiography, yet, troponin levels are typically lower (often <2.8 ng/ml) than would be predicted given the level of myocardial impairment.4 Peak incidence: 2 days to 2 weeks post SAH. The condition reverses completely in most cases within about 5 days as normal myocardial cells replace those with defective TnI. However, ≈ 10% of patients may progress on to an actual MI.

Stroke volume and cardiac output are reduced. Risk factors include higher Hunt Hess grade (>3),5-6,7,8 female gender,8,9 smoking status and age.5 Hypotension does not always occur since the reduced cardiac output (CO) may be offset by an increase in SVR. However, the reduced CO may impair the ability to tolerate barbiturates administered for cerebral protection during early surgery due to their myocardi al suppressant effect. Intraoperative TEE monitoring may be a useful guide for titrating pressors. The reduced CO may also impede the use of hyperdynamic therapy for vasospasm.

78.1.2 Arrhythmias and EKG changes

EKG changes in over 50% of cases of SAH and include: broad or inverted T-waves, Q-T prolongation, S-T segment elevation or depression, U-waves, premature atrial or ventricular contraction, SVT, V-flutter or V-fib,10 bradycardia. In some cases EKG abnormalities may be indistinguishable from an acute MI.11,12

78.1.3 Possible mechanism

Elevation of intracranial pressure secondary to aSAH is thought to cause sympathetic activation resulting in hypercontraction of cardiac myocytes and subsequent myocardial injury.5 A related theory invokes hypothalamic ischemia resulting in increased sympathetic tone, whereby the hypothalamic ischemia results in increased sympathetic tone and the resultant catecholamine surge may produce subendocardial ischemia13 or coronary artery vasospasm.3 The catecholamine surge appears to be more focal (i.e. in the heart) than systemic.

78.1.4 Treatment

Interventions that have been studied for increasing cardiac output in NSC14,15:
1. milrinone: used when SBP>90 mmHg and normal SVR, or when the patient is on chronic beta blockers
2. dobutamine: more effective with hypotension (SBP<90 mmHg) and low SVR
3. other options: stellate ganglion block, magnesium
78.2 Neurogenic pulmonary edema

78.2.1 General information
A rare condition associated with a variety of intracranial pathologies, including:
- subarachnoid hemorrhage
- generalized seizures
- and head injury

78.2.2 Pathophysiology
Two possibly synergistic mechanisms. Sudden increased ICP or hypothalamic injury may produce a salvo of sympathetic discharge causing redistribution of blood to the pulmonary circulation, resulting in elevation of pulmonary capillary wedge pressures (PCWP) and increased permeability. Secondly, the associated surge of catecholamines directly disrupts the capillary endothelium which increases alveolar permeability.

78.2.3 Treatment
Supportive, using measures such as positive pressure ventilation with low levels of PEEP (p. 871) and treatment to normalize ICP.
A PA-catheter is usually helpful.
There may be some efficacy in using a dobutamine infusion supplemented with furosemide as needed. The theoretical advantage of dobutamine over previously attempted alpha- and beta-blockers is that dobutamine does not reduce cerebral perfusion.

78.3 Vasospasm

78.3.1 General information

Key concepts
- delayed cerebral ischemic symptoms and/or cerebral arterial narrowing on angiography that follows some cases of SAH (usually), trauma, or other insults
- time course: almost never before day 3 post SAH, peak incidence 6–8 days post SAH, rarely starts after day 17. Main time of risk: 3–14 days post SAH
- risk factors: higher SAH grade, more blood on CT
- results in pathologic changes within the vessel walls (not just vasoconstriction)
- diagnosis: may be clinical, angiographic, or with transcranial Doppler
- treatment: none are curative. Mainstays of treatment:
  - euvolemia and hemodynamic augmentation (formerly “triple H” therapy)
  - neuroendovascular intervention: angioplasty or intraarterial verapamil

Cerebral vasospasm is a condition that is most commonly seen following some cases of aneurysmal subarachnoid hemorrhage (SAH), but may also follow other intracranial hemorrhages (e.g. intraventricular hemorrhage from AVM, and SAH of unknown etiology), head trauma (with or without SAH), brain surgery, lumbar puncture, hypothalamic injury, infection, and may be associated with preeclampsia (p. 194). The concept of vasospasm was originated in 1951 by Ecker. Vasospasm has two not-necessarily reconcilable definitions (below):
1. clinical vasospasm: see below
2. radiographic vasospasm: see below

78.3.2 Definitions
Delayed cerebral ischemia (DCI) and early brain injury (EBI)
There has been a move away from thinking of the deleterious effects of SAH in terms of vasospasm, and the concepts of DCI and EBI are coming to the fore.
DCI: Delayed development of a neurological deficit, decline in Glasgow coma scale of at least 2 points, and/or cerebral infarction unrelated to aneurysm treatment or other causes. DCI is an umbrella term that encompasses a number of clinical entities including symptomatic vasospasm, delayed ischemic neurological deficit (DIND), and asymptomatic delayed cerebral infarction.  

EBI: In addition to direct mechanical damage from the SAH, EBI also refers to a number of other factors including the transient increase in ICP, reduction of CBF, apoptosis and edema formation.

Clinical vasospasm

Sometimes referred to as delayed ischemic neurologic deficit (DIND), or symptomatic vasospasm. A delayed ischemic neurologic deficit following SAH. Clinically characterized by confusion or decreased level of consciousness sometimes with focal neurologic deficit (speech or motor). The diagnosis is one of exclusion, and sometimes cannot be made with certainty.

See clinical findings (p. 1179).

Radiographic vasospasm (AKA angiographic vasospasm)

Arterial narrowing demonstrated on cerebral angiography, often with slowing of contrast filling. The diagnosis is solidified by previous or subsequent angiograms showing the same vessel(s) with normal caliber. In some cases a DIND corresponds to a region of vasospasm seen angiographically. The incidence of angiographic vasospasm following SAH is around 50% (range: 20-100%).

78.3.3 Characteristics of cerebral vasospasm

Clinical findings

Findings usually develop gradually, and may progress or fluctuate. May include:
1. non-localizing findings
   a) new or increasing H/A
   b) alterations in level of consciousness (lethargy...)
   c) disorientation
   d) meningeal pain
2. focal neurological signs may occur including cranial nerve palsies and focal motor deficits.
   Also, symptoms may cluster into one of the following "syndromes" (vasospasm incidence is higher in the distribution of the ACA than in that of the MCA)
   a) anterior cerebral artery (ACA) syndrome: frontal lobe findings predominate (abulia, grasp/suck reflex, urinary incontinence, drowsiness, slowness, delayed responses, confusion, whispering). Bilateral anterior cerebral artery distribution infarcts are usually due to vasospasm following an AComm aneurysm rupture
   b) middle cerebral artery (MCA) syndrome: hemiparesis, monoparesis, aphasia (or apractagnosia of non-dominant hemisphere – inability to use objects or perform skilled motor activities, due to lesions in the lower occipital or parietal lobes; subtypes: ideomotor apraxia and sensory apraxia)

Incidence

1. Radiographic cerebral vasospasm (CVS) is identified in 20–100% of arteriograms performed around the 7th day following SAH, whereas clinical vasospasm associated with radiographic CVS occurs in only ≈ 30% of patients with SAH.
2. radiographic CVS may occur in the absence of clinical deficit, and vice-versa

Severity

1. CVS is a significant cause of morbidity and mortality in patients surviving SAH long enough to reach medical care, exceeded only by the direct effects of aneurysmal rupture as well as re-bleeding.
2. CVS ranges in severity from mild reversible dysfunction, to severe permanent deficits secondary to ischemic infarction in up to 60% of SAH patients, extensive enough to be fatal in 7% of SAHs.
3. earlier onset of CVS is associated with greater deficit
Time course of vasospasm

1. onset: almost never before day 3 post-SAH
2. maximal frequency of onset during days 6–8 post-SAH (however, rarely can occur as late as day 17). Typical at-risk period is quoted as days 3–14.
3. clinical CVS is almost always resolved by day 12 post-SAH. Once radiographic CVS is demonstrated, it usually resolves slowly over 3–4 weeks.
4. onset is usually insidious, but \( \approx 10\% \) have an abrupt and severe deterioration.

Correlated findings

1. Risk is higher in conditions where arterial blood at high pressure contacts the vessels at the base of the brain. CVS rarely occurs in the setting of intraparenchymal or pure intraventricular hemorrhage (e.g. from AVM) or in SAH with distribution limited to the cerebral convexity.
2. blood clots are especially spasmogenic when in direct contact with the proximal 9 cm of the ACA and the MCA.
3. not all patients with SAH develop CVS, and CVS can follow other insults besides SAH, such as mass resection, meningitis, amygdalohippocampectomy. Can even be associated with sexual intercourse and over-consumption of black licorice.
4. the Hunt and Hess grade on admission correlates with the risk of CVS (Table 78.1)
5. the amount of blood on CT correlates with the severity of CVS (Table 78.2; also holds true for traumatic SAH).
6. higher incidence with increasing age of patient
7. a history of active cigarette smoking is an independent risk factor
8. history of preexisting hypertension
9. there is good but not perfect correlation between the site of major blood clots on CT, the focality of delayed ischemic neurological deficits, and the visualization of angiographic CVS in corresponding arteries.
10. pial enhancement on CT \( \approx 3 \) days after SAH (with IV contrast administration) may correlate with higher risk of CVS (indicates increased permeability of BBB), but this is controversial.

\(^*\)measurements made in the greatest longitudinal & transverse dimension on a printed EMI CT scan (no scaling to actual thickness) performed within 5 d of SAH in 47 patients; falx never contributed more than 1 mm thickness to interhemispheric blood.
11. For patients undergoing early surgery, if there is little SAH left on a CT done 24 hours post-op, there is little risk of vasospasm.
12. Antifibrinolytic therapy reduces rebleeding, but increases the risk of hydrocephalus and vasospasm (p. 1168).
13. Angiographic dye can exacerbate CVS.

### 78.3.4 Pathogenesis

Pathogenesis is still poorly understood. In humans, CVS is a chronic condition with definite long-term changes in the morphology of the involved vessels. Much of CVS is poorly understood because of lack of a good animal model (humans show a mild acute phase, and most animal studies fail to demonstrate a chronic phase).

Pathological changes observed within the vessel wall are outlined in Table 78.3.

**Direct mediators.** Vasospasm is caused by smooth muscle contraction, due to either impaired vasodilatory mediators, overactive vasoconstrictive mediators, or more likely, both.
- The formed components of blood have each been shown to contribute to vasospasm:
  - Oxyhemoglobin in pure form can cause contraction of cerebral arteries when contacting the abluminal surface of the vessel.
  - Hemoglobin scavenges Nitric Oxide, a powerful vasorelaxant.
  - Platelet-derived growth factor induces vascular proliferation → vascular stiffening and impaired ability to dilate.
- Endothelial dysfunction: theories include decreased production of Nitrous Oxide and prostacyclins, and overproduction of Endothelin-1.
- Vessel innervation by the sympathetic nervous system. Interruption of sympathetic innervation prevents vasospasm in rats.

Proposed mechanisms of vasospasm include:
- Contraction of the smooth muscle in the media of the vessel wall, as a result of:
  - Vasoconstrictors within the hemorrhagic arterial blood (see below).
  - Vasoactive substances released into the CSF.
  - Neuronal mechanisms via nervi vasorum (nerves in the vessel wall):
    - Increased vasoconstrictor tone (possibly due to denervation supersensitivity).
    - Loss of vasodilator tone.
    - Time dependent relative imbalance favoring vasoconstrictor over vasodilator innervation.
    - Sympathetic hyperactivity: e.g. due to hypothalamic injury from elevated ICP.
- Impairment of endothelial derived relaxant factor (EDRF): vascular endothelium plays an oblig-atory role in vasodilatation caused by several pharmacologic agents by releasing a relaxant substance called EDRF.
- Proliferative vasculopathy.
- Immunoreactive process.
- Inflammatory process.
- Mechanical phenomenon:
  - Stretching of arachnoid fibers.
  - Direct compression by blood clot.
  - Platelet aggregation.

78.3.5 Diagnosis of cerebral vasospasm

General information

Diagnosis requires appropriate clinical criteria, and ruling-out other conditions that can produce delayed neurologic deterioration, as shown in Table 78.4.

Ancillary tests for vasospasm

In addition to angiographically demonstrating vasospasm:
- transcranial doppler (TCD): see below
- alterations in intracranial pulse wave
- CTA: specific for vasospasm, but may overestimate the degree of stenosis
- MRA: may be useful for management of vasospasm (not a practical alternative to conventional angiography)
- continuous quantitatively analyzed EEG monitoring in the ICU:
  - a decline of the percent of alpha activity (defined here as 6–14 Hz) called “relative alpha” (RA) from a mean of 0.45 to 0.17 predicted the onset of vasospasm earlier than TCD or angiographic changes
  - a decline of total EEG power (amplitude) was 91% sensitive for predicting vasospasm
- alterations in cerebral blood flow (CBF):
  - MRI: DWI and PWI may detect early ischemia
  - CT perfusion study
  - Xenon CT: may detect large global changes in CBF, but too insensitive to detect focal blood flow changes and does not correlate with increase TCD velocities
  - positron emission tomography (PET) and SPECT scans (nonquantitative, and takes longer than xenon studies)

Transcranial doppler (TCD)

A noninvasive method of semiquantitatively measuring velocity of blood flow in a specific artery through the skull (in regions of thinner bone – insonation windows) utilizing ultrasound phase shift. Narrowing of the arterial lumen as occurs in vasospasm elevates the blood flow velocity which may be detected with TCD. Detectable changes may precede clinical symptoms by up to 24–48 hrs. Findings are often more helpful when baseline studies performed before vasospasm is likely to have begun are available.

Typical values are shown for the MCA in Table 78.5. Also, daily increases of >50 cm/sec may suggest vasospasm. There is less correlation between velocities and vasospasm in the anterior cerebral

*velocities in this range are specific for vasospasm but are only ≈ 60% sensitive
arteries (ACA). Distinguishing vasospasm from hyperemia (which increases blood flow velocities in both the MCA and the ICA) is facilitated by using the ratio of these velocities (the so-called Lindegaard ratio) also shown in Table 78.5.

Once values become elevated, it often takes several weeks to go back down.

Comparison of diagnostic modalities
Determining the sensitivities and specificities for the tests shown in Table 78.6 have allowed calculation of the positive predictive value (PPV) and negative predictive values (NPV) as listed.

78.3.6 Treatment for vasospasm

General information
See management protocol (p.1185).

Numerous treatments for cerebral arterial vasospasm (CVS) have been evaluated. Vasospasm in humans does not respond to the large variety of drugs that reverse experimental vasospasm in animal models.

Prevention of vasospasm
To date, there is no effective prophylactic intervention for CVS. Vasospasm can often be mitigated by preventing post-SAH hypovolemia and anemia by employing hydration and blood transfusion. Although early aneurysm treatment (clipping or coiling) does not prevent CVS (in fact, manipulation of vessels may increase the risk), it facilitates treatment of CVS by eliminating the risk of rebleeding (permitting safe use of hypertension as needed) and surgical removal of clot (see below) may reduce the incidence of CVS; see Timing of aneurysm surgery (p.1200) for discussion of early surgery. Prophylactic (i.e. before vasospasm has been diagnosed) hyperdynamic therapy – triple H therapy (p.1186) – is not indicated (it may cause complications and does not provide any benefit).

Vasospasm treatment options
Treatment options fall into the following categories:
1. direct pharmacological arterial dilatation
   a) smooth muscle relaxants:
      • calcium channel blockers (generally accepted for standard usage): nimodipine does not counteract vasospasm, but does improve neurologic outcomes (p.1186)
      • endothelin receptor antagonists (experimental or research technique with potential for future application): ET_A antagonists (clazosentan) and ET_A/B antagonists
      • Ryanodine receptor blocker: Dantrileone. Mediates intracellular calcium release from the sarcoplasmic reticulum. One of the few drugs shown to both prevent and reverse vasospasm
      • Magnesium: MASH-2 study showed no improvement in clinical outcome
   b) sympatholytics (technique that is accepted for use but not necessarily standard or available at all centers)

| Table 78.6 PPV & NPV of various tests for cerebral vasospasm |
|-----------------|-----------------|-----------------|
| Test            | PPV (%)         | NPV (%)         |
| TCD             |                 |                 |
| MCA             | 83-100          | 29-98           |
| ACA             | 41-100          | 37-80           |
| ICA             | 73              | 56              |
| PCA             | 37              | 78              |
| BA              | 63              | 88              |
| VA              | 54              | 82              |
| CTA             | 43-100          | 37-100          |
| CTP             | 71-100          | 27-99           |
c) intra-arterial papaverine\textsuperscript{76,77}; short-lived (see below)  
d) αICAM-1 inhibition (antibody to intracellular adhesion molecule; technique that is accepted for use but not necessarily standard or available at all centers)  

2. direct mechanical arterial dilatation: balloon angioplasty (see below)  
3. indirect arterial dilatation: utilizing hyperdynamic therapy (generally accepted for standard usage; see below)  
4. surgical treatment to dilate arteries: cervical sympathectomy (technique not generally used or no longer accepted)\textsuperscript{78}  
5. removal of potential vasospasmogenic agents  
   a) removal of blood clot: does not completely prevent vasospasm  
      • mechanical removal at the time of aneurysm surgery\textsuperscript{79,80}  
      • subarachnoid irrigation with thrombolytic agents at the time of surgery or post-op through cisternal catheters\textsuperscript{81,82,83,84} (must be initiated within \(\approx 48\) hrs of clipping) or intrathecally.\textsuperscript{55}  
      Hazardous with incompletely clipped aneurysm\textsuperscript{84}  
   b) CSF drainage: via serial lumbar punctures, continuous ventricular drainage, or postoperative cisternal drainage\textsuperscript{86}  
6. protection of the CNS from ischemic injury: calcium channel blockers (p.1183) – generally accepted for standard usage  
7. improvement of the rheologic properties of intravascular blood to enhance perfusion of ischemic zones; also an endpoint of hyperdynamic therapy (p.1185); generally accepted for standard usage  
   a) includes: plasma, albumin, low molecular weight dextran (technique not generally used or no longer accepted), perfluorocarbons (experimental or research technique with potential for future application), mannitol (p.1202)  
   b) the optimal hematocrit is controversial, but \(\approx 30–35\)% is a good compromise between lowered viscosity without overly reducing \(O_2\) carrying capacity (hemodilution is used to lower Hct; phlebotomy is not used)  
8. statins: no benefit was detected with simvastatin\textsuperscript{87}  
9. extracranial-intracranial bypass around zone of vasospasm (technique not generally used or no longer accepted)\textsuperscript{88,89}  

Vasodilatation by angioplasty  
Catheter directed balloon angioplasty of vessels demonstrated to be in vasospasm\textsuperscript{90,91}; available only in centers with interventional neuroradiologists. Risks of the procedure: arterial occlusion, arterial rupture, displacement of aneurysm clip,\textsuperscript{92,93} arterial dissection. Only feasible in large cerebral vessels (distal arteries not accessible). Clinical improvement occurs in \(\approx 60–80\)% . Improvements in vessel diameter and neuro deficits have been observed in most studies.\textsuperscript{94}  
Prophylactic TBA: phase II prospective trial failed to show primary end point benefit (Glasgow Outcome Score), but fewer patients developed vasospasm.\textsuperscript{95}  
Criteria for transluminal balloon angioplasty (TBA):  
1. failure of hyperdynamic therapy  
2. ruptured aneurysm is repaired  
3. optimal results when performed within 12 hours of onset of symptoms  
4. may be done immediately post-clipping for vasospasm that was observed pre-op  
5. controversial: asymptomatic vasospasm seen on the contralateral side during angioplasty for ipsilateral vasospasm. Some would balloon the asymptomatic side, but others cite the complication rate and would observe  
6. recent cerebral infarction (stroke): a contraindication to TBA. Prior to TBA, perform CT or MRI to rule-out  

Vasodilatation by intra-arterial drug injection  
Vasodilatation by intra-arterial drug (IAD) injection produces effects that are shorter-lived and less profound at their peak than with angioplasty. While IAD can be repeated, this requires multiple arterial catheterizations. IAD is also of value to help open up vessels to allow placement of the angioplasty balloon, and for vessels inaccessible to angioplasty balloons.  
Agents currently used for chemical spasmolysis (p.1587):  
1. verapamil: the primary drug employed  
2. nicardipine: a dihydropyridine calcium channel blocker which acts preferentially on vascular smooth muscle more than cardiac smooth muscle. Restores vessels to at least 60% of normal diameter. 70% of those treated had no stroke on CT. May cause a drop in SBP, but not >30%\textsuperscript{96} intra-arterial therapy: 10–40 mg per procedure. Three retrospective case series have reported vessel dilation and transient improvement in neuro deficits.\textsuperscript{94}
3. papaverine  
4. nitroglycerine

78.3.7 Vasospasm management

Pertinent guidelines

Practice guideline: Management of cerebral vasospasm/DCI after aneurysmal SAH

- Level I: maintain euvolemia and normal circulating blood volume
- Level I: Induce hypertension unless BP is elevated at baseline or if precluded by cardiac stents
- Level II: Endovascular angioplasty and/or selective intra-arterial vasodilator therapy is reasonable for patients not responding rapidly to or candidates for hypertensive therapy

Specific measures for Vasospasm/DCI after aSAH

Patients with clinical suspicion of vasospasm (DIND), or with transcranial doppler (TCD) increases of >50 cm/sec or with absolute velocities >200:

1. general care measures
   a) serial neuro exams: while important, sensitivity for CVS/DCI is limited in poor grade patients
   b) activity: bed rest, HOB elevated to ≈30°
   c) TED hose and/or sequential compression boots
   d) strict I & O measurements

2. diagnostic measures (primarily to rule-out other causes of deficit)
   a) STAT non-contrast CT to rule-out hydrocephalus, edema, infarct or rebleed
   b) option: perfusion CT or MRI (if available)
   c) STAT bloodwork
      - electrolytes to rule-out hyponatremia
      - CBC to assess rheology and rule-out sepsis or anemia
      - ABG to rule out hypoxemia
   d) repeat TCD if available to detect changes indicative of vasospasm

3. monitors
   a) A-line to monitor BP
   b) PA catheter to monitor PCWP and cardiac output when possible (central line to monitor CVP when PA catheter cannot be placed)
   c) insert ICP monitor if ICP felt to be problematic, treat elevated ICP with mannitol or CSF drainage before institution hemodynamic augmentation (caution: the diuresis from mannitol in treating ICP may produce hypovolemia; also, exercise caution in lowering ICP with unsecured aneurysm)

4. treatment measures
   a) continue nimodipine therapy. Give via NG tube if pt unable to swallow
   b) administer O₂ to keep pO₂ >70 mm Hg

5. ensure euvolemia: patients with SAH often develop hypovolemia early in their course

   a) primary IV fluid is crystalloid, usually isotonic (e.g. NS)
   b) blood (whole or PRBC) when Hct drops <40%
   c) colloid: plasma fraction or 5% albumin (at 100 ml/hr) to maintain 40% Hct (if Hct is >40% use crystalloids)
   d) mannitol 20% at 0.25 gm/kg/hr as a drip may improve rheologic properties of blood in the microcirculation (avoid hypovolemia from resultant diuresis)
   e) replace urinary output (U.O.) with crystalloid (if Hct <40% then use 5% albumin, usually @ ≈20-25 ml/hr)
   f) avoid hetastarch (Hespan®) (p.1165) and dextran which impair coagulation

6. monitoring labs
   a) ABG and H/H daily
   b) serum and urine electrolytes and osmolalities q 12 hr (creatinine elevations may indicate peripheral ischemia from vasospessors)
c) CXR daily  
d) frequent EKG  

7. initiate hyperdynamic (triple-H) therapy (see below) unless BP is elevated at baseline or cardiac stents preclude it for 6 hours  

8. if no response to 6 hrs of triple-H therapy, or if doppler or perfusion CT or MRI suggests vasospasm, patient is taken to angiography to confirm presence of vasospasm and for interventional neuroradiologic treatment (intraarterial verapamil, angioplasty...)

1. move patient to the ICU and placed on triple-H therapy for 6 hours if this is not already instituted  

2. option: perfusion CT or MRI (if available)  

3. if no response to 6 hrs of triple-H therapy, or if perfusion CT suggests vasospasm, patient is taken to angiography to confirm presence of vasospasm and for interventional neuroradiologic treatment (intraarterial verapamil, angioplasty...)

Hemodynamic augmentation (formerly “TRIPLE-H” therapy). Many older treatment schemes for CVS included so-called “triple-H” therapy (for: Hypervolemia, Hypertension and Hemodilution). This has given way to “hemodynamic augmentation” consisting of maintenance of euvolemia and induced arterial hypertension. While potentially confusing, this has now sometimes been referred to as triple-H therapy.

Inducing HTN may be risky with an uncliped ruptured aneurysm. Once the aneurysm is treated, initiating therapy before CVS is apparent may minimize morbidity from CVS.

Use fluids to maintain euvolemia. Administer pressors to increase SBP in 15% increments until neurologically improved or SBP of 220 mm Hg is reached. Agents include:

- dopamine (p.128)  
  - start at 2.5 mcg/kg/min (renal dose)  
  - titrate up to 15-20 mcg/kg/min  
- levophed  
  - start at 1-2 mcg/min  
  - titrate every 2-5 minutes: double the rate up to 64 mcg/min, then increase by 10 mcg/min  
- neosynephrine (phenylephrine): does not exacerbate tachycardia  
  - start at 5 mcg/min  
  - titrate every 2-5 minutes: double the rate up to 64 mcg/min, then increase by 10 mcg/min up to a max of 10 mcg/kg  
- dobutamine: positive inotrope  
  - start at 5 mcg/kg/min  
  - increase dose by 2.5 mcg/kg/min up to a maximum of 20 mcg/kg/min

Complications of hemodynamic augmentation:

- intracranial complications  
  - may exacerbate cerebral edema and increase ICP  
  - may produce hemorrhagic infarction in an area of previous ischemia  
- extracranial complications  
  - pulmonary edema in 17%  
  - 3 rebleeds (1 fatal)  
  - MI in 2%  
- complications of PA catheter  
  - catheter related sepsis: 13%  
  - subclavian vein thrombosis: 1.3%  
  - pneumothorax: 1%  
  - hemothorax: may be promoted by coagulopathy from dextran

78.4 Post-op orders for aneurysm clipping

- admit PACU, transfer to ICU (neuro unit if available) when stable  
- VS: q 15 min x 4 hrs, then q 1 hr. Temperature q 4 hrs x 3 d, then q 8 hrs. Neuro check q 1 hr  
- activity: bed rest (BR) with HOB elevated 20–30°  
- knee high TED hose and pneumatic compression boots  
- I & O q 1 hr (if no Foley: straight cath q 4 hrs PRN bladder distension)  
- incentive spirometry q 2 hrs while awake (do not use following transsphenoidal surgery)  
- IVF: NS+20 mEq KCl/L @90 ml/hr
For extubated patients:
- diet: NPO except minimal ice chips and meds as ordered
- O₂: 2 L per NC

For intubated patients:
- diet: NPO, NG tube to intermittent suction. May clamp for 1 hour after meds given
- ventilator orders

For all patients:
- meds:
  a) H2 antagonist, e.g. ranitidine 50 mg IV PB q 8 hrs
  b) Keppra® (levetiracetam): 500 mg PO or IV q 12 hours. Maintain therapeutic AED levels for 2–3 months post-op for most supratentorial craniotomies
  c) Cardene® drip: titrate to keep SBP<160 mm Hg and/or DBP <100 mm Hg (use cuff pressures, may use A-line pressures if they correlate with cuff pressures)
  d) analgesics: fentanyl (unlike morphine, does not cause histamine release. Lowers ICP) 25 mcg (0.5–2 ml) IV q 1–2 hrs PRN
  e) acetaminophen (Tylenol®) 650 mg PO/PR q 4 hrs PRN temperature T>100.5° F (38 C)
  f) mini-dose heparin or enoxaparin (for DVT prophylaxis; no diet changes if patient on ventilator)
  g) calcium channel blockers; see admitting orders (p.1165): nimodipine (Nimotop®) 60 mg PO/NG q 4 hrs or 30 mg q 2 hrs to avoid dips in BP. May be given IV where available
  h) continue prophylactic antibiotics if used: (e.g. cefazolin (Kefzol®) 500–1000 mg IVPB q 6 hrs x 24 hrs, then D/C)

- if available, transcranial doppler (p.1182) to monitor MCA, ACA, ICA, VA and LIN-perfusion and Lindegard ratio (typical protocol is 3 × per week)
- labs:
  a) CBC once stabilized in ICU and q d thereafter
  b) renal profile once stabilized in ICU and q 12 hrs thereafter
  c) ABG once stabilized in ICU and q 12 hrs × 2 days, then D/C (also check ABG after any ventilator change if patient on ventilator)
  d) call M.D. if any deterioration in crani checks, for T>101° F (38.5 C), sudden increase in SBP, SBP < 120, U.O.<60 ml/2-hrs

SAH from Cerebral Aneurysm Rupture

79.1 Epidemiology of cerebral aneurysms

The incidence of cerebral aneurysms is difficult to estimate. Range of autopsy prevalence of aneurysms: 0.2–7.9% (variability depends on use of dissecting microscope, hospital referral and autopsy pattern, overall interest). Estimated prevalence of incidental aneurysms range from 1-5% of the population,1,2,3,4,5 and they are becoming increasingly detected in clinical practice as use of CT and MRI is becoming more common.5 Ratio of ruptured:unruptured (incidental) aneurysm is 5:3 to 5:6 (rough estimate is 1:1, i.e. 50% of these aneurysms rupture).2 Unruptured intracranial aneurysms are more common in women (~3:1 ratio)8,9 and in the elderly,10 and only 2% of aneurysms present during childhood.11 When present in children, they tend to occur more frequently in males (2:1) and to a greater degree in the posterior circulation (40-45%).12,13

79.2 Etiology of cerebral aneurysms

The exact pathophysiology of the development of aneurysms is still controversial. In contrast to extracranial blood vessels, there is less elastic in the tunica media and adventitia of cerebral blood vessels, the media has less muscle, the adventitia is thinner, and the internal elastic lamina is more prominent.14,15 This, together with the fact that large cerebral blood vessels lie within the subarachnoid space with little supporting connective tissue,16(p 1644) may predispose these vessels to the development of saccular aneurysms. Aneurysms tend to arise in areas where there is a curve in the parent artery, in the angle between it and a significant branching artery, and point in the direction that the parent artery would have continued had the curve not been present.17

The etiology of aneurysms may be:
1. congenital predisposition (e.g. defect in the muscular layer of the arterial wall, referred to as a medial gap)
2. “atherosclerotic” or hypertensive: presumed etiology of most saccular aneurysms, probably interacts with congenital predisposition described above
3. embolic: as in atrial myxoma
4. infectious – so called “mycotic aneurysms” (p.1228)
5. traumatic; see Traumatic aneurysms (p.1227)
6. associated with other conditions (see below)

79.3 Location of cerebral aneurysms

Saccular aneurysms, AKA berry aneurysms are usually located on major named cerebral arteries at the apex of branch points which is the site of maximum hemodynamic stress in a vessel.18 More peripheral aneurysms do occur, but tend to be associated with infection (mycotic aneurysms) or trauma. Fusiform aneurysms are more common in the vertebrobasilar system. Dissecting aneurysms should be categorized with arterial dissection (p.1323).

Saccular aneurysms location:
1. 85–95%in carotid system, with the following 3 most common locations:
   a) ACoA (single most common): 30%(ACoA & ACA more common in males)
   b) p-comm: 25%
   c) middle cerebral artery (MCA): 20%
2. 5–15%in posterior circulation (vertebro-basilar)
   a) ~ 10%on basilar artery: basilar bifurcation, AKA basilar tip, is the most common, followed by BA-SCA, BA-VA junction, AICA
   b) ~ 5%on vertebral artery: VA-PICA junction is the most common
3. 20–30%of aneurysm patients have multiple aneurysms (p.1226)19

79.4 Presentation of cerebral aneurysms

79.4.1 Major rupture

The most frequent presentation
1. most commonly produces SAH (p.1167), which may be accompanied by:
2. intracerebral hemorrhage: occurs in 20–40% (more common with aneurysms distal to the Circle of Willis, e.g. MCA aneurysms)
3. intraventricular hemorrhage: occurs in 13–28%\(^0\) (see below)
4. subdural blood occurs in 2–5%

### 79.4.2 Intraventricular hemorrhage

See also other etiologies of intraventricular hemorrhage (IVH) (p. 1386).

IVH occurs in 13–28% of ruptured aneurysms in clinical series (higher in autopsy series)\(^{20}\) and appears to carry a worse prognosis (64% mortality).\(^{20}\) The size of the ventricles on admission was the most important prognosticator (large vents being worse). Patterns that may occur:
1. distal PICA aneurysms: may rupture directly into 4th ventricle through the foramen of Luschka\(^ {21}\)
2. a-comm aneurysm: it has been asserted that IVH occurs from rupture through the lamina terminalis into the anterior 3rd or lateral ventricles, however, this is not always borne out at the time of surgery
3. distal basilar artery or carotid terminus aneurysms: may rupture through the floor of the 3rd ventricle (rare)

### 79.4.3 Presentation other than major rupture

**General information**

May be thought of as possible “warning signs.”

1. **mass effect**
   - a) giant aneurysms: including brain stem compression producing hemiparesis and cranial neuropathies
   - b) cranial neuropathy (average latency from symptom to SAH was 110 days; note: the average latency quoted for some of these symptoms comes from a retrospective study of patients presenting with SAH who were identified as having a warning symptom\(^ {22}\)). See below:
   - c) intra- or suprasellar aneurysm producing endocrine disturbance\(^ {23}\) due to pituitary gland or stalk compression
2. minor hemorrhage: warning or sentinel hemorrhage; see Headache (p.1158). This group had the shortest latency (10 days) between symptom and SAH (note: the average latency quoted for some of these symptoms comes from a retrospective study of patients presenting with SAH who were identified as having a warning symptom\(^ {22}\))
3. small infarcts or transient ischemia due to distal embolization (including amaurosis fugax, homonymous hemianopsia...\(^ {24}\); average latency from symptom to SAH was 21 days A
4. seizures: at surgery, an adjacent area of encephalomalacia may be found.\(^ {24}\) The seizures may arise as a result of localized gliosis and do not necessarily represent aneurysmal expansion as there is no data to indicate an increased risk of hemorrhage in this group
5. headache\(^ {24}\) without hemorrhage: abates after treatment in most cases
   - a) acute: may be severe and “thunderclap” in nature,\(^ {25}\) some describe as “worst headache of my life.” Has been attributed to aneurysmal expansion, thrombosis, or intramural bleeding,\(^ {26}\) all without rupture
   - b) present for ≥2 weeks: unilateral in about half (often retro-orbital or periorbital), possibly due to irritation of overlying dura. Diffuse or bilateral in the other half, possibly due to mass effect → increased ICP
6. incidentally discovered (i.e. asymptomatic, e.g. those found on angiography, CT or MRI obtained for other reasons)

**Cranial neuropathies from aneurysmal compression**

1. oculomotor (3rd nerve) palsy (ONP): occurs in ≈ 9% of p-comm aneurysms\(^ {27}\) (ruptured and unruptured), less common with basilar apex aneurysm. Symptoms of ONP may include:
   - a) extraocular muscle palsy (eye deviates “down and out” → diplopia
   - b) Ptosis
   - c) dilated unreactive pupil (non-pupil-sparing third nerve palsy is the classic finding of 3rd nerve compression (p.562))
2. visual loss due to\(^ {24}\)
   - a) compressive optic neuropathy with ophthalmic artery aneurysms: characteristically produces nasal quadrantanopsia
   - b) chiasmal syndromes due to ophthalmic, a-comm, or basilar apex aneurysms
3. facial pain syndromes in the ophthalmic or maxillary nerve distribution that may mimic trigeminal neuralgia can occur with intracavernous or supraclinoid aneurysms\(^ {24,28}\)
Note. The development of a third nerve palsy in a patient with an unruptured aneurysm is a medical emergency as it probably results from aneurysmal expansion and may portend impending rupture.

79.5 Conditions associated with aneurysms

79.5.1 Overview
1. autosomal dominant polycystic kidney disease: (see below)
2. fibromuscular dysplasia (FMD): prevalence of aneurysms in renal FMD is 7% in aortocranial FMD 21%
3. arteriovenous malformations (AVM) including moyamoya disease; see AVMs and aneurysms (p.1241)
4. connective tissue disorders: 
   a) Ehlers-Danlos, especially type IV (deficient collagen type III) which also has a high rate of arterial dissection including with angiography or coiling
   b) Marfan syndrome (p.1322)
   c) pseudoxanthoma elasticum
5. multiple other family members with intracranial aneurysms. Familial intracranial aneurysm syndrome (FIA): 2 or more relatives, third degree or closer, harbor radiographically proven intracranial aneurysms. Also, see Familial aneurysms (p.1226)
6. coarctation of the aorta
7. Osler-Weber-Rendu syndrome
8. atherosclerosis
9. bacterial endocarditis
10. multiple Endocrine Neoplasia type I
11. hereditary hemorrhagic telangiectasia
12. neurofibromatosis type I

79.5.2 Autosomal dominant polycystic kidney disease

General information
Adult polycystic kidney disease is seen in 1 of every 500 autopsies, and approximately 500,000 people in the U.S. carry the mutant gene for autosomal dominant polycystic kidney disease (ADPKD; there is also an autosomal recessive polycystic kidney disease). Renal function is usually normal during the first few decades of life, with progressive chronic renal failure ensuing. HTN is a common sequelae. Transmission is autosomal dominant, with 100% penetrance by 80 yrs of age. Cystic disease of other organs may occur (viz.: liver in ≈ 33%, and occasionally lung, pancreas).

The first association between ADPKD and cerebral aneurysms is attributed to Duncer in 1904. Reported prevalence of intracranial aneurysms with ADPKD: 10–30% with 15%being a reasonable estimate. Most were located on the MCA, with multiple aneurysms present in 31%. In addition to the increased incidence of aneurysms, there appears to be an increased risk of rupture, with 64% occurring before age 50. As a result, patients with ADPKD carry a 10–20 fold increased risk of SAH compared to the general population. Aneurysms are rarely detectable before age 20 years. The average rate of rupture of incidental aneurysms is ≈ 2%/yr (p.1167).

Recommendations
Using the above statistics, together with the life expectancy of patients with ADPKD, and other estimations (of operative morbidity and mortality, etc.), results of decision analysis is that arteriography not be routinely employed in patients older than 25 yrs. However, patients with symptoms possibly due to unruptured aneurysms, and those with SAH, should undergo angiography and subsequent treatment of any aneurysms discovered (especially those >1 cm diameter). A decision analysis study determined that screening with MRA was beneficial compared to treating patients once they became symptomatic. Repeat MRA screening may be effectively repeated as follows:

1. every ≈ 2-3 years for a young patient with ADPKD with either:
   a) a history of aneurysms, or
   b) a kindred of ADPKD with aneurysms
2. every 5-20 years for a patient with ADPKD in a kindred of ADPKD with no history of aneurysms.
79.6 Treatment options for aneurysms

79.6.1 General information

The optimal treatment for an aneurysm depends on the age and condition of the patient, the anatomy of the aneurysm and associated vasculature, the ability of the surgeon and the availability of endovascular treatment options, and must be weighed against the natural history of the condition. Also, treatment of the aneurysm facilitates treatment of vasospasm, should it occur.

Natural history:
1. risk of bleeding into subarachnoid space
   a) for ruptured aneurysms: this is the risk of rebleeding (p.1170)
   b) for unruptured aneurysms (p.1222)
   c) for cavernous carotid artery aneurysms: this risk is low (p.1225)
2. spontaneous thrombosis of an aneurysm is a rare occurrence\(^42,43,44\) (estimates in autopsy series is 9–13\(^\%\)\(^44\)). However they may reappear,\(^45,46\) and delayed rupture may occur sometimes even years later.
3. enlargement of aneurysm to cause mass effect: some aneurysms go on to become giant aneurysms and can cause mass effect with or without rupture

Although still controversial, endovascular treatment should be initially considered in treating amenable ruptured aneurysms. See also unruptured aneurysms (p.1225).

79.6.2 Therapies that do not directly address the aneurysm

The hope here is that the aneurysm will not bleed and that it will thrombose (see above).
1. continue medical management initiated on admission: i.e. control of HTN, continue calcium-channel blockers, stool softeners, activity restrictions…
2. treatment options generally not used
   a) antifibrinolytic therapy (e.g. \(\varepsilon\)-aminocaproic acid (EACA)): NB: NOT USED. Reduces rebleeding, but increases the incidence of arterial vasospasm and hydrocephalus\(^47\)
   b) serial L Ps: an historical treatment,\(^48\) may increase the risk of aneurysmal re-rupture

79.6.3 Endovascular techniques to treat the aneurysm

1. thrombosing the aneurysm:
   a) “coiling” with Guglielmi electrolytically detachable coils (see below)
   b) Onyx HD 500 (p.1586) has been used for wide-necked or giant ICA aneurysms.\(^49\) Out of 22 patients, there was 1 parent ICA stenosis and 2 ICA occlusions caused by Onyx migration
   c) “flow diversion” with “covered stents” (tightly woven stents) which promotes thrombosis of the aneurysm (p.1586)
2. trapping: effective treatment requires distal AND proximal arterial interruption, usually by endovascular techniques,\(^50\) occasionally by direct surgical means (ligation or clip occlusion), or some combination. May also incorporate vascular bypass (e.g. EC-IC bypass) to maintain flow distal to trapped segment\(^51\)
3. proximal ligation (so-called hunterian ligation after Hunter ligated the popliteal artery proximal to a peripheral aneurysm in 1784\(^52\)): useful for giant aneurysms.\(^53,54\) For non-giant aneurysms provides little benefit and adds the risk of thromboembolism (which may be reduced by occluding the CCA rather than the ICA\(^54\)). May also elevate the risk of developing aneurysms in the contralateral circulation\(^55\)

79.6.4 Surgical treatment options for aneurysms

1. clipping: the surgical gold standard. Surgical placement of a clip across the neck of the aneurysm to exclude the aneurysm from the circulation (see below) without occluding normal vessels
2. wrapping or coating the aneurysm: although this should never be the goal of surgery, situations may arise in which there is little else that can be done (e.g. fusiform basilar trunk aneurysms, aneurysms with significant branches arising from the dome, or part of the neck within the cavernous sinus)
   a) with muscle: the first method used to surgically treat an aneurysm\(^56\) (the patient described died from rebleeding)
b) with cotton or muslin: popularized by Gillingham.\textsuperscript{37} An analysis of 60 patients showed that 8.5\% rebled in \textless 6 mos, and the annual rebleeding rate was 1.5\% thereafter\textsuperscript{58} (similar to the natural history).

c) with plastic resin or other polymer: may be slightly better than muscle or gauze.\textsuperscript{59} One study with long follow-up found no protection from rebleeding during the first month, but thereafter the risk was slightly lower than the natural history.\textsuperscript{59} Other studies show no difference from natural course\textsuperscript{60}

d) teflon and fibrin glue\textsuperscript{61}

79.6.5 Treatment decisions: coiling vs. clipping

General information

The use of endovascular treatment for aneurysms has increased, with coil embolization being the most common endovascular modality (see above for other options). From 2002-2008, the rate of aneurysm coiling in the U.S. and U.K. increased from 17 and 35\% to 58 and 68\% respectively.\textsuperscript{62,63} There is considerable controversy and debate as to the best therapeutic approach for aneurysms (ruptured and unruptured). Impediments to resolving the debate include methodological shortcomings of published studies, the fact that endovascular methods are still rapidly evolving which renders many studies obsolete before completion, and the critical need for long-term follow-up of endovascular results.

This section reviews some of the available information comparing surgical treatment to coil embolization.

Ruptured intracranial aneurysms

To date, four randomized controlled trials have been published comparing functional outcome after coil embolization versus surgical clip ligation for ruptured intracranial aneurysms: the “Finnish Study”,\textsuperscript{64} ISAT 2002,\textsuperscript{65} the “Chinese Study”,\textsuperscript{66} and BRAT 2012.\textsuperscript{67} Table 79.1 summarizes the treatment data from the 4 RCTs.

ISAT. The largest trial, the International Subarachnoid Hemorrhage Aneurysm Trial (ISAT), enrolled 2143 patients and ran from 1997 to 2002, and was stopped prematurely because of a significant outcome difference between the 2 groups favoring endovascular coil embolization. Despite the limitations of ISAT (see below), the findings have often been generalized to all patients with aneurysms, resulting in a dramatic change in management.

\(\textsuperscript{a}\) Rebleeding from target aneurysm after first procedure
\(\textsuperscript{b}\) Result achieved after treatment during first hospitalization
\(\textsuperscript{c}\) ISAT\(\textsuperscript{5}\) & ISAT\(\textsuperscript{10}\) refer to the 5 and 10 year follow-up studies. Rebleeding results for these studies refer to recurrent SAH after the 1\textsuperscript{st} year of follow-up
\(\textsuperscript{d}\) BRAT\(\textsuperscript{3}\) refers to the 3-year follow-up study. BRAT & BRAT\(\textsuperscript{3}\) are “as-treated” results
\(\textsuperscript{e}\) Both rebleeding events occurred during the initial hospitalization
Results: At 1 year, there was an absolute reduction of risk of having a poor outcome (i.e. Modified Rankin score > 2) by 7% with coiling (24%) compared to open surgery (31%; p = 0.0019). Although not statistically significant, rebleeding in the first year after treatment was higher for coiling (2.6%) than clipping (1.0%). As such, the durability of coil embolization and its ability to prevent subsequent rebleeding of the treated aneurysm was questioned. Additionally, ISAT had many important shortcomings, as detailed in Table 79.2.

Following the initial report, medium-term follow-up results have been published. In the endovascular cohort, there were 10 episodes of rebleeding from the treated aneurysm after 1 year, in 8447 person-years of follow-up. In the surgical cohort, 3 patients rebled from the treated aneurysm after 1 year, in 8177 person-years of follow-up. One of these patients had declined surgery after randomization and underwent coiling instead. There was a non-significant increased risk of rebleeding from the treated aneurysm in the endovascular cohort (p = 0.06), by an intention-to-treat analysis, but a significant difference when analysis was by actual treatment (p = 0.02). The probability of death at 5 years was significantly lower in the coiled group (11%) than in the clipping group (14%; p = 0.03). However, when patients who died before treatment are excluded from this analysis, the statistical difference is no longer present (p = 0.1). The probability of independent survival for those patients alive at 5 years was no different between groups (83% coil; 82% clip).

The 10-year results have been reported for the UK cohort from the initial trial. Similar to the 5-year results, the proportion of patients with a good outcome did not differ between the two groups, but the probability of being alive with a good outcome compared with death or dependence was significantly better for the endovascular group. Thirteen patients in the endovascular group rebled from the target aneurysm (1 per 641 patient-years) compared to 4 in the surgical group (1 per 2041 patient-years). Although the risk of rebleeding was higher in the endovascular group, the overall risk was small and the risk of death or dependency from a rebleed did not differ between the groups.

A follow up study, ISAT II (multicenter RCT), is currently being conducted to help elucidate differences in outcomes between treatment modalities.

Chinese study. 192 patients with aSAH randomized to coiling or clipping. Surgical clipping increased the risk of symptomatic vasospasm (OR 1.24), and there were significantly more new cerebral infarctions in the clipping group (21.7% vs. 12.8%). Incidence of complete aneurysm occlusion was significantly lower in the coiling group (64.9% vs. 83.7%). Rebleeding rates were similar in both groups (~5%). At 1 year, there was no significant difference in probability of mortality (coiling: 10.6%, clipping: 15.2%). Furthermore, there was no significant difference in probability of a good outcome (coiling: 75% clipping: 67.9%).

BRAT. Initiated at Barrow Neurologic Institute in 2002. Designed to reflect “real-world” practices of ruptured aneurysm treatment in North America. Randomly assigned in an alternate fashion every patient with SAH who agreed to participate. A large number of patients allocated to endovascular treatment crossed over to the surgical arm because patients could be enrolled regardless of whether the aneurysm was amenable to both treatment modalities (75 crossed over from coil to surgery; 4 crossed over from surgery to coil). Proportion of patients with a poor outcome (i.e. mRS > 2) was 33.7% in the surgical group versus 23.2% in the endovascular group (p = 0.02, intention-to-treat analysis). An “as-treated” analysis yielded similar results (33.9 vs 20.4%; p = 0.01). There were 2 episodes of rebleeding following treatment – one assigned to and treated with clipping and the other
assigned to coil, but treated with surgical clipping. Twelve patients (2.9%) required retreatment during the initial hospitalization (9 surgical and 3 coil patients). Overall, during the 1st year, there was a significant increased probability of retreatment in patients actually treated with coiling compared with those actually treated by clipping (10.6% of coil vs. 4.49% of surgical patients, \( p=0.03 \)).

At 3 years,\(^7\) there was no significant difference in poor-outcome between clipping (30%) and clipping (35.8%). Subgroup analysis: there were no differences in mRS scores between treatment groups at any time point among patients with anterior circulation aneurysms (83%). However, among posterior circulation aneurysms (17%), mRS scores were significantly better after endovascular management than after surgical treatment at every time point. Of note, with the exception of basilar tip aneurysms, the randomization of the posterior circulation aneurysms was unexpectedly skewed (large majority of SCA and PICA were clipped, whereas majority of PCA, vertebral and basilar where coiled). The lack of anatomical parity between the treatment groups makes it difficult to draw strong conclusions. In addition, the degree of aneurysm obliteration (87 vs. 52%), rate of aneurysm recurrence and rate of retreatment (5 vs. 13%) were significantly better in the group treated with clipping compared with coiling. However, no rebleeding occurrences were documented in the 2nd or 3rd year of BRAT.

Meta-analyses. Lanzino et al.\(^73\) conducted a meta-analysis on the 3 prospective controlled studies (Finnish, ISAT, BRAT). Pooled data showed poor outcome at 1 year to be lower in the embolization group; no difference in mortality between groups; and rebleeding rates within the first month were higher in coiled patients. However, the results were largely skewed by ISAT data. Li et al.\(^74\) conducted a meta-analysis on the 4 RCTs (see above) and 23 observational studies. The result of the RCT analysis with regard to poor outcome at 1 year paralleled that by Lanzino et al. However, there was no difference in poor outcome between groups in the nonrandomized controlled trial analysis. Additional subgroup analysis showed a higher incidence of rebleeding after coiling (\( \approx 2-3 \) vs. 1%), corresponding to a better complete occlusion rate of clipping (84 vs. 66.5%).

Procedural complications rates and 1-year mortality did not differ significantly between the groups.

Vasospasm. Whether coiling or clipping has an independent correlation with symptomatic vasospasm is debatable. One meta-analysis\(^75\) suggested a trend toward less symptomatic vasospasm after clipping compared with clipping. However, the analysis had multiple limitations – the two treatment groups were not comparable (age, clinical grade, aneurysm location); there were differences in study design and definitions of vasospasm; and there was a lack of angiographic diagnosis of vasospasm. In the Chinese RCT (above) symptomatic vasospasm and consequent cerebral infarction was more common in the clipping group. Li et al.\(^74\) found vasospasm was more common after clipping (48.8 vs. 43.1%), however, ischemic infarction did not differ significantly. Treatment choice may also alter the spasm pattern: on one study,\(^76\) patients who underwent clipping developed localized vasospasm around the rupture site, whereas those treated with coiling demonstrated progressive distal vasospasm over time (possibly related to treatment-specific effects on CSF circulation).

Shunt-dependent hydrocephalus. One study showed a lower incidence of shunt-dependent hydrocephalus in the surgical treatment group (19.9 vs. 47.1%),\(^77\) however many others have failed to show this relationship.\(^74,75,79,80,81,82,83,84,85,86\) A suggestion that fenestration of the lamina terminalis at the time of surgery may decrease shunt-dependent chronic hydrocephalus was refuted by a meta-analysis\(^87\) of 11 non-randomized studies (hydrocephalus rates of 10% with fenestration compared to 15% without).

Seizures. A literature review\(^88\) of seizures after aSAH reported a rate of \( \approx 2\% \) following either neurosurgical clipping or endovascular coiling. In contrast, ISAT showed endovascular intervention had lower seizure rates (13.3%) to 3.3% compared to surgical clipping (2.2%-5.2%) in the first year. As such, there is no consensus as to whether treatment modality independently impacts seizure and/or epilepsy occurrence.

Factors to consider (clipping vs. coiling)
- health care environment / equipment available
- skill set and experience of the neurosurgeon and interventionalist
  - greater annual numbers of aneurysms treated by individual practitioners were significantly related to decreased in morbidity\(^89\)
- anatomy and location of the aneurysm
  - favorable dome/neck ratio versus wide neck aneurysms
  - MCA aneurysms may be difficult to coil because of a branch near the neck
  - Basilar apex: favors coiling
- associated IPH/SDH: surgery allows both evacuation of hemorrhage and treatment of aneurysm
symptoms due to mass effect: clipping may be better than coiling. In 13 patients with p-comm aneurysms and oculomotor nerve (3rd nerve) palsy (ONP), 6 of 7 patients clipped vs. 2 of 6 with coiling recovered completely. Partial ONP improved with either treatment, but complete ONP recovered in 3 of 4 patients clipped vs. 0 of 3 coiled.

- patient age
- younger age: lower risk of surgery, and lower lifetime risk of recurrence than with coiling
- clinical state / comorbidities
- good outcome seen in 63% clip vs. 46% coil in poor grade (WFNS IV/V) pts (contrary to findings in practice guidelines) therefore microsurgery and endovascular treatment, when selected primarily according to angiographic features, were equally likely to achieve good outcome.
- patients on anticoagulation (e.g. Plavix) favor endovascular treatment

Practice guideline: Aneurysm treatment decisions

Level C: Treatment decisions should be multidisciplinary (made by experienced cerebrovascular and endovascular specialists) based on characteristics of the patient and aneurysm.

Level C: Microsurgical clipping may receive increased consideration in patients presenting with large (>50 ml) intraparenchymal hematomas and middle cerebral artery aneurysms.

Level C: Endovascular coiling may receive increased consideration in the elderly (>70 yo), in those presenting with poor-grade WFNS classification (IV/V) SAH, and in those with aneurysms of the basilar apex.

Level B: For patients with ruptured aneurysms judged to be technically amenable to both endovascular coiling and neurosurgical clipping, endovascular coiling should be considered.

Unruptured intracranial aneurysms

As with ruptured aneurysms, there is controversy over the best treatment method for unruptured intracranial aneurysms (UIA s), and additional uncertainty surrounds the question of which UIAs need to be treated (vs. observed). Darsaut et al. found that practitioners do not agree regarding management of UIAs, even when they share a background in the same specialty, similar capabilities in aneurysm management, or years of practice.

There are no prospective randomized studies of treatment interventions vs. conservative management, or comparing treatment options to each other. Most data are either from personal series or are retrospective.

Surgical clipping. One summary of 260 patients (including a retrospective multicenter analysis) show no surgical mortality, and morbidity of 0-10.3% (6.5% major and 8% minor morbidity in the multicenter study). Findings from one meta-analysis of 733 patients who underwent surgical clipping showed a mortality rate of 1% and major morbidity rate of 4%. A larger meta-analysis of 2460 patients revealed mortality and morbidity rates of 2.6% and 10.9% respectively.

The ISUIA investigators found surgical mortality to be 2.3% at 30 days, and 3.8% at 1 year. Additionally, they found a combined morbidity and mortality at 1 year of 12.6% for those without previous hemorrhage and 10.1% for those with previous subarachnoid hemorrhage from another aneurysm. For patients treated with surgical clipping, morbidity and mortality was greatest in those with aneurysms that were large or in the posterior circulation, and in patients older than age 50. In comparison, the combined morbidity and mortality for the 451 patients treated with an endovascular procedure was 9.1% at 30 days and 9.5% at 1 year. Predictors of adverse outcome included aneurysm size and posterior circulation aneurysms. Additionally, the presence of calcification (independent of aneurysm size) has been shown to increase the likelihood of poor outcome.

Comparison of clipping to coil embolization. Early retrospective studies have shown a lower incidence of in-hospital death and discharge to skilled nursing facilities with endovascular therapy compared to those treated surgically. A recent retrospective study conducted at a single center showed early outcome and lower complication rates favoring clipping, but the results did not remain significant long-term. A meta-analysis showed that clipping resulted in significantly higher disability compared to coiling (OR 2.38-2.83). However, subgroup analysis by outcome-measurement time, revealed clipping to be associated with greater risk of disability in the short-term (<6 months), but not in the long-term (>6 months). In addition, mortality (in-hospital and overall), hemorrhage, and infarction were no different between groups. Despite inclusion of a large number of studies and
patients, it is very challenging to draw any conclusion from the meta-analysis, as all the studies were observational (i.e. low levels of evidence), and the analysis did not stratify outcomes based on size and/or location of aneurysms.

Lawson et al.\textsuperscript{104} compared natural history rupture risk to national treatment risk for coiling and clipping (taken from the Nationwide Inpatient Sample from 2002-2008). Overall mortality rate for clipping and coiling was 2.66\% and 2.17\% respectively. Poor outcome was significantly greater for clipping (4.75\%) versus coiling (2.16\%). Data regarding the homogeneity of the two groups regarding aneurysm size or location was not available. Treatment risk curves were generated and compared against natural history actuarial risk curves calculated from four prominent studies.\textsuperscript{103,106,9,107} Overall, the analysis demonstrated rationale for clipping small, unruptured aneurysms in patients <61-70 years, and clipping small unruptured aneurysms in patients <70-80 years.

Additional studies have focused on the effect of age on outcomes. Mahaney et al.\textsuperscript{108} showed that procedural and in-hospital morbidity and mortality increased with age in patients treated with surgery, but remained relatively constant with endovascular treatment. Poor neurological outcome from aneurysm or procedure-related morbidity and mortality did not differ between management groups for patients 65 years old and younger, but was significantly higher in the surgical group for patients older than 65 years. Surgery appeared to show a surgical benefit in patients <50 years old at 1 year. Others have suggested an overall benefit of endovascular treatment over surgical clipping, which becomes more pronounced with age.\textsuperscript{109}

Cost. Several studies have compared total hospital costs for treatment of unruptured aneurysms with mixed results. Halke et al.\textsuperscript{110} and Hoh et al.\textsuperscript{111} found endovascular treatment to be associated with higher total hospital costs. A later study by Hoh et al.\textsuperscript{112} found that on a national level, surgical clipping was associated with higher costs. A long-term outcome study\textsuperscript{113} showed that clipping was associated with higher initial costs, but overall costs at 2 and 5 years were similar to coiling (due to higher number of follow-up angiograms and outpatient costs). More recently, total hospital cost was shown to be lower for clipping, despite higher fixed-direct and fixed-indirect costs.\textsuperscript{114} This is a function of much higher variable costs (i.e. the cost of coils and devices) overcoming any substantial cost reduction due to shorter length of stay in patients treated endovascularly.

Miscellaneous. Oculomotor nerve palsy: Complete recovery of oculomotor nerve palsy associated with p-comm aneurysms is more common with surgical clipping than with endovascular treatment (87\% vs. 44\%).\textsuperscript{115}

Pregnancy: No studies have directly compared clipping versus coiling. Clipping may be preferred by some\textsuperscript{116}; see pregnancy and SAH (p.1169).

79.7 Timing of aneurysm surgery

79.7.1 Background

Historically, there was controversy between so-called “early surgery” (generally, but not precisely defined as ≤48–96 hrs post SAH) and “late surgery” (usually ≥10–14 days post SAH). The current consensus is that there should be intervention for a ruptured aneurysm (clipping or coiling) as promptly as possible to secure the aneurysm and prevent rebleeding. In a review of all patients with SAH treated by clipping or coiling in the Nationwide Inpatient Sample between 2002-2010, treatment at non-teaching hospitals and older age (>80) were associated with delays in time to aneurysm clipping, but these associations were not seen when endovascular treatment was performed.\textsuperscript{117} Increased time to procedure (>3 days) was significantly associated with an increased likelihood of moderate to severe neurological deficit. Ultra-early (<24 h after SAH) coiling of ruptured aneurysms has also been associated with improved clinical outcomes (mRS 0-2) compared to coiling at >24 hours in poor grade SAH patients (Hunt-Hess IV/V).\textsuperscript{118} This does not rule out a selection bias, however. Additionally, the increased morbidity and mortality associated with surgical intervention on patients who present subacutely with evidence of vasospasm on imaging, may be better suited for endovascular intervention.

Early surgery advocated for the following reasons:
1. if successful, virtually eliminates the risk of rebleeding which occurs most frequently in the period immediately following SAH (p.1167)
2. facilitates treatment of vasospasm which peaks in incidence between days 6–8 post SAH (never seen before day 3) by allowing induction of arterial hypertension and volume expansion without danger of aneurysmal rupture
3. allows lavage to remove potentially vasospasmogenic agents from contact with vessels, including use of thrombolytic agents (p.1183)
4. although operative mortality is higher, overall patient mortality is lower.\textsuperscript{119}
Arguments against early surgery, in favor of late surgery include:
1. inflammation and brain edema are most severe immediately following SAH
   a) this necessitates more brain retraction
   b) at the same time this softens the brain making retraction more difficult (retractors have more tendency to lacerate the more friable brain)
2. the presence of solid clot that has not had time to lyse impedes surgery
3. the risk of intra-operative rupture is higher with early surgery
4. possible increased incidence of vasospasm following early surgery from mechanotrauma to vessels

Factors that favor choosing early surgery include:
1. good medical condition of patient
2. good neurologic condition of patient (Hunt and Hess (H&H) grade ≤3)
3. large amounts of subarachnoid blood, increasing the likelihood and severity of subsequent vasospasm (p.1186), Table 78.2. Having the aneurysm clipped permits use of hyperdynamic therapy for vasospasm
4. conditions that complicate management in face of unclipped aneurysm: e.g. unstable blood pressure; frequent and/or intractable seizures
5. large clot with mass effect associated with SAH
6. early rebleeding, especially multiple rebleeds
7. indications of imminent rebleeding: (see below)

Factors that favor choosing delayed surgery (10–14 days post SAH) include:
1. poor medical condition and/or advanced age of patient (age may not be a separate factor related to outcome, when patients are stratified by H&H grade^{120})
2. poor neurologic condition of patient (H&H grade ≥4): controversial. Some say the risk of rebleeding and its mortality argues for early surgery even in bad grade patients^{121} since denying surgery on clinical grounds may result in withholding treatment in some patients who would do well (54% of H&H grade IV and 24% of H&H grade V patients had favorable outcome in one series^{120}). Some data show no difference in surgical complications in good and bad grade patients with anterior circulation aneurysms^{122}
3. aneurysms difficult to clip because of large size, or difficult location necessitating a lax brain during surgery (e.g. difficult basilar bifurcation or mid-basilar artery aneurysms, giant aneurysms)
4. significant cerebral edema seen on CT
5. the presence of active vasospasm

### 79.7.2 Conclusions

**Practice guideline: Timing of intervention for ruptured aneurysm**

*Level B*:\ Surgical clipping or endovascular coiling of a ruptured aneurysm causing aSAH should be performed as early as feasible in the majority of patients to reduce the risk of rebleeding.

### 79.7.3 Imminent aneurysm rupture

Findings that may herald impending aneurysm rupture and may therefore increase the need for expedient intervention include:
1. progressing cranial nerve palsy e.g. development of 3rd nerve palsy with p-comm aneurysm; traditionally regarded as an indication for urgent treatment (p.1192)
2. increase in aneurysm size on repeat angiography
3. beating aneurysm sign^{123}: pulsatile changes in aneurysm size between cuts or slices on imaging (may be seen on angiography, MRA, or CTA)

### 79.8 General technical considerations of aneurysm surgery

#### 79.8.1 General information

The goal of aneurysm surgery is to prevent rupture or further enlargement of the aneurysm, while at the same time preserving all normal vessels and minimizing injury to brain tissue and cranial
nerves. This is usually accomplished by excluding the aneurysm from the circulation with a clip across its neck. Placing the clip too low on the aneurysm neck may occlude the parent vessel, while too distal placement may leave a so-called “aneurysmal rest” which is not benign since it may enlarge (see below).

See Intraoperative aneurysm rupture (p.1204) for general measures to reduce the risk of this complication during surgery.

79.8.2 Aneurysmal rest

When a portion of the aneurysm neck is not occluded by a surgical clip, it is referred to as an aneurysmal rest. A “dog-ear” occurs when a clip is angled to leave part of the neck at one end, and obliterates the neck at the other. Rests are not innocuous, even if only 1–2 mm, because they may later expand and possibly rupture years later, especially in younger patients. The incidence of rebleeding was 3.7% in one study, with an annual risk of 0.4–0.8% during the observation period of 4–13 yrs. Patients should be followed with serial angiography, and any increase in size should be treated by reoperation or endovascular techniques if possible.

**Booking the case: Craniotomy for aneurysm**

Also see defaults & disclaimers (p.27).
1. position: (depends on location of aneurysm), radiolucent head-holder
2. intraoperative angiography (optional)
3. equipment: microscope (with ICG capability if used)
4. blood: type and cross 2 U PRBC
5. post-op: ICU
6. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery through the skull to place a permanent clip on the base of the aneurysm to prevent future bleeding, intraoperative angiogram, possible placement of external (ventricular) drain, possible lumbar drain
   b) alternatives: nonsurgical management, endovascular treatment only for aneurysms that are candidates
   c) complications: usual craniotomy complications (p.28) plus (the following are not really complications of surgery but are possible developments) post-op vasospasm, hydrocephalus, formation of new aneurysms

79.8.3 Surgical exposure

**General information**

To avoid excessive brain retraction, surgical exposure requires sufficient bony removal and adequate brain relaxation (see below).

**Brain relaxation**

More critical for ACoA and basilar tip than for easier to reach aneurysms such as p-comm or MCA....

Techniques include:
1. hyperventilation
2. CSF drainage: provides brain relaxation and a field dry of CSF, and removes blood & blood breakdown products along with the CSF. CSF drainage before opening the dura is associated with an increased risk of aneurysmal rebleeding (p.1167)
   a) ventriculostomy: risks include seizures, bleeding from catheter insertion, infection (ventriculitis, meningitis), possible increased risk of vasospasm
      • placed pre-op in cases of acute post-SAH hydrocephalus (p.1170)
      • placed intra-op
   b) lumbar spinal drainage (see below)
   c) intra-operative drainage of CSF from cisterns
3. diuretics: mannitol and/or furosemide. Although proof is lacking, lowering ICP by this or any means may theoretically increase the risk of rebleeding.
Lumbar spinal drainage
May be inserted with Tuohy needle following induction of anesthesia (to minimize BP elevation), prior to final positioning. CSF is gradually withdrawn by the anesthesiologist only after the dura is opened (to minimize chances of intraoperative aneurysmal bleeding), usually a total of 30–50 cc are removed in ≈ 10 cc aliquots.
Risks include: aneurysmal rebleeding (≤ 0.3%), back pain (10% may be chronic in 0.6%), catheter malfunction preventing CSF drainage (< 5%), catheter fracture or laceration resulting in retained catheter tip in the spinal subarachnoid space, post-op CSF fistula, spinal H/A (may be difficult to distinguish from post-craniotomy H/A), infection, neuropathy (from nerve root impingement with needle), epidural hematoma (spinal and/or intracranial).

Cerebral protection during surgery
Pathophysiology of cerebral ischemia
The cerebral metabolic rate of oxygen consumption (CMRO₂) (p. 1265) arises from neurons utilizing energy for two functions: 1) maintenance of cell integrity (homeostasis) which normally accounts for ≈ 40% of energy consumption, and 2) conduction of electrical impulses. Occlusion of an artery produces a central core of ischemic tissue where the CMRO₂ is not met. The oxygen deficiency precludes aerobic glycolysis and oxidative phosphorylation. ATP production declines and cell homeostasis cannot be maintained, and within minutes irreversible cell death occurs; a so-called cerebral infarction. Surrounding this central core is the penumbra, where collateral flow (usually through leptomeningeal vessels) provides marginal oxygenation which may impair cellular function without immediate irreversible damage. Cells in the penumbra may remain viable for hours.

Cerebral protection by increasing the ischemic tolerance of the CNS
1. drugs that mitigate the toxic effects of ischemia without reducing CMRO₂
   a) calcium channel blockers: nimodipine, nicardipine, flunarizine
   b) free radical scavengers: superoxide dismutase, dimethylthiourea, lazaroïds, barbiturates, Vitamin C
   c) mannitol: although not a cerebral protectant per se, it may help re-establish blood flow to compromised parenchyma by improving the microvascular perfusion by transiently increasing CBV and decreasing blood viscosity
2. reduction of CMRO₂
   a) by reducing the electrical activity of neurons: titrating these agents to an isoelectric EEG reduces CMRO₂ by up to a maximum of ≈ 50%
   • barbiturates: in addition to reducing CMRO₂, they also redistribute blood flow to ischemic cortex, quench free radicals, and stabilize cell membranes. For dosing of thiopental, see below
   • isoflurane (p. 105): shorter acting and less myocardial depression than with barbiturates
   b) by reducing the maintenance energy of neurons: no drugs developed to date can accomplish this, only hypothermia has any effect on this. Below mild hypothermia, extracerebral effects must be monitored (p. 871)
   • mild hypothermia (core temperatures down to 33°C): in a multicenter RCT mild hypothermia was demonstrated to be safe, but did not improve the neurological outcome after craniotomy among good-grade (Hunt Hess I-III) patients with aSAH
   • moderate hypothermia: 32.5–33°C has been used for head injury
   • deep hypothermia to 18°C permits the brain to tolerate up to 1 hour of circulatory arrest
   • profound hypothermia to <10°C allows several hours of complete ischemia (the clinical usefulness of this has not been substantiated)

Adjunctive cerebral protection techniques used in aneurysm surgery
1. systemic hypotension
   a) usually used during final approach to aneurysm and during manipulation of aneurysm for clip application
   b) theoretical goals
   • to reduce turgor of aneurysm facilitating clip closure, especially with atherosclerotic neck
   • to decrease transmural pressure (p. 1170) to reduce the risk of intraoperative rupture
   c) One retrospective study suggests that a decrease in MAP >50% is associated with poor outcome. However, after adjustment for age, this association was no longer statistically significant. Because of the potential danger of hypoxic injury to brain and other organs (including areas of impaired autoregulation as well as normal areas), some surgeons avoid this method.
2. “focal” hypotension: using temporary aneurysm clips (specially designed with low closing force to avoid intimal injury) placed on parent vessel (small perforators will not tolerate temporary clips without injury)
   a) used in conjunction with methods of cerebral protection against ischemia
   b) may be combined with systemic hypertension to increase collateral flow
   c) the proximal ICA can tolerate an hour or more of occlusion in some cases, whereas the perforator bearing segments of the MCA and the basilar apex may tolerate clipping for only a few minutes
   d) in addition to the risk of ischemia, there is the risk of intravascular thrombosis and subsequent release of emboli upon removal of the clip
3. circulatory arrest, utilized in conjunction with deep hypothermia
   a) candidates include patients with large aneurysms that contain significant atherosclerosis and/or thrombosis that impedes clip closure and a dome that is adherent to vital neural structures
4. blood glucose: intraoperative hyperglycemia has been associated with long-term decline in cognition and gross neurologic function and should be avoided

Systematic approach to cerebral protection
See reference.

The following factors may mandate the use of temporary clips (and associated techniques of cerebral protection): giant aneurysm, calcified neck, thin/fragile dome, adherence of dome to critical structures, vital arterial branches near the aneurysm neck, intraoperative rupture. Aside from giant aneurysms, most of these factors may be difficult to identify pre-op. Therefore, Solomon provides some degree of cerebral protection to all patients undergoing aneurysm surgery.

1. spontaneous cooling is permitted during surgery, which usually results in a body temperature of 34°C by the time that dissection around the aneurysm begins
2. if temporary clipping is utilized
   a) if a long segment of the ICA is being trapped, administer 5000 U IV heparin to prevent thrombosis and subsequent emboli
   b) <5 mins temporary clip occlusion: no further intervention
   c) up to 10 or 15 mins occlusion: administer IV brain protection anesthesia (e.g. thiopental, propofol, and/or etomidate) and titrate to burst suppression on EEG
      • administration of IV brain protection anesthesia to burst suppression has been shown to significantly decrease infarction rate with temporary clipping within this time range
      • intermittent reperfusion has been shown to be advantageous in some studies, while in others findings have been contradictory
   d) >20 mins occlusion: not tolerated (except possibly ICA proximal to p-comm), terminate operation if possible and plan repeat operation utilizing
      • deep hypothermic circulatory arrest (see above)
      • endovascular techniques
      • bypass grafting around the segment to be occluded

79.8.4 Postoperative angiography
Due to the fact that unexpected findings (aneurysmal rest, unclipped aneurysm, or major vessel occlusion) were seen on 19% of post-op angiograms (the only predictive factor identified was a new post-op deficit, which signaled major vessel occlusion) the use of routine post-op angiography has been recommended.

79.8.5 Some drugs useful in aneurysm surgery

Drug info: Propofol (Diprivan®)

May be used to achieve burst suppression with shorter duration of action than other barbiturates. Results are preliminary, further investigation is needed to demonstrate the degree of neuroprotection. Has been reported at doses 170 mcg/kg/min for neuroprotection (if tolerated) but this may be risky. May also be used as a continuous drip for sedation (p. 133), and for ICP management (p. 869). Reverses rapidly upon discontinuation (usually within 5–10 minutes).

Side effects: possible anaphylactic reaction with angioneurotic edema (angioedema) of the airways, Propofol Infusion syndrome (p. 133).
79.8.6 Intraoperative aneurysm rupture

Epidemiology

Reported rates of intraoperative aneurysm rupture (IAR) range from ≈ 18% in the cooperative study (1963–1978)\(^1\) to ≈ 36% in a pre-microscope series\(^2\) (NB: this series had an unexplained high IAR rate of 61% with the microscope) and 40% in a more recent series.\(^3\) Although rupture rate may be higher in early surgery than with late surgery,\(^4\) other series found no difference.\(^5\)

Morbidity and mortality for patients experiencing significant IAR is ≈ 30–35% (vs. ≈ 10% in the absence of this complication), although IAR may primarily affects outcome when it occurs during induction of anesthesia or opening of dura.\(^6\)

Prevention of intraoperative rupture

Presented as a list here to be incorporated into general operative techniques.

1. prevent hypertension from catecholamine response to pain:
   a) insure deep anesthesia during headholder pin placement and skin incision
   b) consider local anesthetic (without epinephrine) in headholder pin-sites and along incision line
2. minimize increases in transmural pressure: reduce MAP to slightly below baseline just prior to dural opening
3. reduce shearing forces on aneurysm during dissection by minimizing brain retraction:
   a) radical removal of sphenoid wing for circle of Willis aneurysms
   b) reduce brain volume by a number of mechanisms: diuretics (mannitol, furosemide), CSF drainage through lumbar subarachnoid drain placed pre-operatively and opened by the anesthesiologist at the time of dural incision, hyperventilation
4. reduce risk of large tear in aneurysm fundus or neck:
   a) utilize sharp dissection in exposing aneurysm and in removing clot from around aneurysm
   b) whenever possible, completely mobilize and inspect aneurysm before attempting clip application

Details of intraoperative rupture

Rupture can occur during any of the three following stages of aneurysm surgery\(^7\):

1. initial exposure (predissection)
   a) rare. Brain can become surprisingly tight even when bleeding seems to be into open subarachnoid space. Usually carries poor prognosis
   b) possible causes:
      • vibration from bone work: dubious
      • increasing transmural pressure upon opening the dura
      • hypertension from catecholamine response to pain (see above)
   c) management tactics:
      • have anesthesiologist radically drop BP
      • control bleeding (with anterior circulation aneurysms) by placing temporary clip across ICA as it exits from cavernous sinus, or if not possible then compress ICA in patient’s neck through drapes
      • if necessary to gain control, resect portions of frontal or temporal lobe
2. dissection of the aneurysm: accounts for the majority of IARs, two basic types:
   a) tears caused by blunt dissection
      • tends to be profuse, proximal to the neck, and difficult to control
      • do not attempt definitive clipping unless adequate exposure has been achieved (which is usually not the case with these tears)
      • temporary clipping: this step is often necessary in this situation, after the temporary clip is in place return the MAP to normal and administer neuroprotective agent (e.g. propofol)
      • once the temporary clip is in place, it is better to take a few extra moments to improve the exposure and apply a well placed permanent clip instead of hastily clipping and trying to restore circulation
      • microsutures may need to be placed to close any portion of the tear that extends onto the parent vessel
   b) laceration by sharp dissection
      • tend to be small, often distally on fundus, and usually easily controlled by a single suction
      • may respond to gentle tamponade with a small cottonoid
may shrink down with repeated low current strokes with the bipolar (avoid the temptation to use continuous high current)

3. clip application: bleeding at this point is usually due to either
   a) inadequate exposure of aneurysm: clip blade may penetrate unseen lobe of aneurysm. Similar to tears caused by blunt dissection (see above). Bleeding worsens as clip blades become approximated
      • prompt opening and removal of clip at the first hint of bleeding may minimize the extent of the tear
      • utilize 2 suckers to determine if definitive clipping can be done, or what is more common, to allow temporary clipping (see above)
   b) poor technical clip application: tends to abate as clip blades become approximated. Inspect the blade tips for the following:
      • to be certain that they span the breadth of the neck. If not, a second longer clip is usually applied parallel to the first, which may then be advanced
      • to verify that they are closely approximated. If not, tandem clips may be necessary, and sometimes multiple clips are needed

79.8.7 Aneurysm recurrence after treatment
Incompletely treated aneurysms may increase in size and/or bleed. This includes aneurysms that are clipped or coiled where there is still aneurysm filling, as well as a persistent aneurysm rest or a neck (p.1201). While most aneurysm rests appear to be stable, there is a small subset that may enlarge or rupture.\(^\text{144}\)

Additionally, even an aneurysm that has been completely obliterated may recur, and therefore one has to consider the durability of treatment. The risk of recurrence of a completely clipped aneurysm is \(\approx 1.5\%\) at 4.4 years.\(^\text{144}\)

79.8.8 Follow-up after aneurysm treatment
Based on the above, together with the small risk of de novo aneurysm formation,\(^\text{144}\) there is a trend to indefinitely follow patients with known aneurysms. One suggested follow-up schedule is shown in Table 79.3.

SAH and Aneurysms

[7] Fox JL. Intracranial Aneurysms. New York: Springe-
Verlag; 1983.

80 Aneurysm Type by Location

80.1 Anterior communicating artery aneurysms

80.1.1 General information

The single most common site of aneurysms presenting with SAH.¹ May also present with diabetes insipidus (DI) or other hypothalamic dysfunction.

80.1.2 CT scan

SAH in these aneurysms results in blood in the anterior interhemispheric fissure in essentially all cases, and is associated with intracerebral hematoma in 63% of cases.² Intraventricular hematoma is seen in 79% of cases, with the blood entering the ventricles from the intracerebral hematoma in about one-third of these. Acute hydrocephalus was present in 25% of patients (late hydrocephalus, a common sequela of SAH, was not studied).

Frontal lobe infarcts occur in 20% usually several days following SAH.² One of the few causes of the rare finding of bilateral ACA distribution infarcts is vasospasm following hemorrhage from rupture of an ACoA aneurysm. This results in prefrontal lobotomy-like findings of apathy and abulia.

80.1.3 Angiographic considerations

Also see Table 102.2 in Endovascular section. Essential to evaluate contralateral carotid, to determine if both ACAs fill the aneurysm. If the aneurysm fills with one side only, it is desirable to inject the other side while cross compressing the side that fills the aneurysm to see if collateral flow is present. Also, determine if either carotid fills both ACAs, or if each ACA fills from the ipsilateral carotid injection (may permit trapping, see below).

If additional views are needed to better demonstrate aneurysm. Try oblique 25° away from injection side, center beam 3–4 cm above lateral aspect of ipsilateral orbital rim, orient x-ray tube in Towne’s view. A submental vertex view may also visualize the area but the image may be degraded by the large amount of interposed bone.

80.1.4 Surgical treatment

Approaches

General information
1. pterional approach: the usual approach (see below)
2. subfrontal approach: especially useful for aneurysms pointing superiorly when there is a large amount of frontal blood clot (allows clot removal during approach)
3. anterior interhemispheric approach³: contraindicated for anteriorly pointing aneurysms as the dome is approached first and proximal control cannot be obtained (see below)
4. transcallosal approach

Pterional approach

Side of craniotomy:
A right pterional craniotomy is used with the following exceptions (for which a left pterional crani is used):
1. large ACoA aneurysm pointing to right: left crani exposes neck before dome
2. dominant left A1 feeder to aneurysm (with no filling from right A1): left crani provides proximal control
3. additional left sided aneurysm

See Pterional craniotomy (p. 1453) for positioning, etc. (use shoulder roll, rotate head 60° from vertical; see Fig. 94.5). Craniotomy is as shown in Fig. 94.7 (slightly more frontal lobe needs to be exposed than, e.g. for a p-comm aneurysm).

Lumbar drain (if IVC not already inserted) assists with brain relaxation.
Microsurgical dissection

Dissect down sylvian fissure with gentle retraction of frontal lobe away from base of skull. Olfactory nerve visualized first, then optic nerve. Open arachnoid over carotid and optic cistern and drain CSF. Elevate temporal tip, coagulate any bridging temporal tip veins that are present, and expose ICA.

Follow the ICA distally, looking for A1 (exposure of this allows temporary clipping in event of rupture). If the A1 take-off is too high, it may be hidden and would require excessive retraction to expose. Options to increase exposure include

1. gyrus rectus resection: a 1 cm long gyrus rectus corticectomy is performed just medial to the olfactory tract. Helps find the ipsilateral A1 and often ACoA and A2. This is also helpful for down-pointing aneurysms because it permits visualization of the contralateral A1 before exposing the dome of the aneurysm (for proximal control). May lead to neuropsychiatric deficits. A subpial resection is performed with preservation of the small arterial branch that is consistently located here.
2. fronto-temporal-orbital-zygoma removal
3. splitting the sylvian fissure: about 50% of experts do this routinely
4. ventricular drainage

Once found, A1 is followed until the ipsilateral A2 is identified. Then the contralateral A2 is identified and is followed proximally until the contralateral A1 is exposed. The a-comm is usually encountered in the process.

Critical branches to preserve: recurrent artery of Heubner; small ACoA perforators (may be adherent to aneurysm dome). If the aneurysm cannot be clipped, it may be trapped by clipping both ends of the ACoA only if each ACA fills from the carotid on its own side.

Post clipping, some authors recommend fenestrating the lamina terminalis in an effort to reduce the need for post-op shunting.

Anterior interhemispheric approach

See reference.

Involves minimal brain retraction.

More suitable for an aneurysm that points straight up, but even with this proximal control is poor.

Position: supine with the neck extended ≈ 15°. A transverse skin incision is made in a skin crease in the lower forehead. The authors describe using a 1.5 inch trephine craniotomy in the midline just superior to the glabella. Alternatively, better advantage of the dural opening may be possible with a more rectangular opening. The dural flap is hinged on the superior sagittal sinus. The depth of the aneurysm is ≈ 6 cm from the dura. Proximal control of the A1 branch of the ACA is difficult with this approach.

80.2 Distal anterior cerebral artery aneurysms

80.2.1 General information

Aneurysms of the distal anterior cerebral artery (DACA) (i.e. the ACA distal to the ACoA) are usually located at the origin of the frontopolar artery, or at the bifurcation of the pericallosal and callosomarginal arteries at the genu of the corpus callosum. Aneurysms located more distally are usually posttraumatic, infectious (myotic), or due to tumor embolus. DACA aneurysms are often associated with intracerebral hematoma or interhemispheric subdural hematoma since the subarachnoid space is limited here. Conservative treatment of DACA aneurysms is often associated with poor results. Unruptured DACA aneurysms have a higher incidence of bleeding than unruptured aneurysms in other locations. These aneurysms are fragile and adherent to the brain, which predisposes to frequent premature intraoperative rupture.

On arteriography, if both ACAs fill from a single sided carotid injection, it may be difficult to make the important determination as to which ACA feeds the aneurysm. Multiple aneurysms are commonly associated with DACA aneurysms.

80.2.2 Treatment

Mycotic aneurysms should be treated as outlined (p. 1228).

Aneurysms up to 1 cm from the ACoA may be approached through a standard pterional craniotomy with partial gyrus rectus resection.
Aneurysms $>1$ cm distal to the ACoA up to the genu of the corpus callosum, including those of the pericallosal/callosomarginal bifurcation, may be approached surgically by a basal frontal interhemispheric approach via a frontal craniotomy using a bicoronal skin incision. The patient is positioned supine with the neck slightly extended, positioned vertically or just a few degrees to the left. A right sided craniotomy is preferred in most instances (exception: aneurysm dome buried in the right cerebral hemisphere making retraction hazardous), but should cross to the contralateral side by a couple centimeters. It must be taken all the way to the floor of the frontal fossa to permit exposure of the anterior cerebral artery for proximal control. The craniotomy extends $\approx 8$ cm above the supraorbital ridge in order to provide leeway in circumnavigating veins bridging to the superior sagittal sinus. The dural flap is based on the superior sagittal sinus. If the sinus needs to be mobilized, it may be divided low anteriorly.

ACA aneurysms distal to the genu of the corpus callosum may also be approached by an interhemispheric approach using a unilateral skin incision. For these, the patient’s neck is not extended, and a parasagittal craniotomy is used that doesn’t need to be as low on the frontal fossa. The cingulate gyri may be difficult to separate, and care must be taken because excessive retraction may pull the cingulate gyrus off the dome of the aneurysm and produce premature rupture.

Ideally, A2 proximal to the aneurysm should be identified initially for proximal control and then followed distally to the aneurysm. When this is not possible, dissection should follow distal ACA branches proximally, towards the aneurysm, taking care not to disturb the aneurysm. Often, a portion of the cingulate gyrus may need to be removed and sometimes up to $1–2$ cm of the anterior corpus callosum may need to be divided.

Surgical complications: Prolonged retraction on the cingulate gyrus may produce akinetic mutism that is usually temporary. The pericallosal arteries are small in caliber and may be atherosclerotic, which together increases the risk of occlusion of the parent artery with the aneurysm clip.

80.3 Posterior communicating artery aneurysms

80.3.1 General information

May occur at either end of p-comm; that is at the junction with the PCA, or more commonly at the junction with carotid (typically points laterally, posteriorly, and inferiorly). May impinge on the third nerve in either case and cause third nerve palsy (ptosis, mydriasis, “down and out” deviation) that, is not pupil sparing in 99% of cases. Surgical clipping may be more advantageous than endovascular coiling to treat oculomotor nerve palsies caused by pcomm aneurysms.$^{8,9}$

80.3.2 Angiographic considerations

Also see Table 102.2 in Endovascular section. Vertebral artery (VA) injection is necessary to help evaluate the p-comm artery:
1. if the p-comm is patent: determine if there is a “fetal circulation” where the posterior circulation is fed only through the p-comm
2. determine if the aneurysm fills from VA injection

If additional views are needed to better demonstrate aneurysm

Try paraorbital oblique 55° away from injection side, center beam 1 cm posterior to inferior portion of lateral rim of ipsilateral orbit, orient x-ray tube 12° cephalad.

80.3.3 Surgical treatment

Pterional approach

See Pterional craniotomy (p.1453) for positioning, etc. For the more common aneurysm at the ICA-p-comm junction, rotate head 15–30° from vertical (Fig. 94.5). Craniotomy is as shown in Fig. 94.7 (less frontal lobe needs to be exposed than for an ACoA aneurysm).

Microsurgical dissection

Ultimately, the major vector of retraction will be on tip of temporal lobe (less on frontal lobe than in ACoA aneurysm), but the initial approach will be more anterior to reduce risk of intra-operative rupture.

1. dissect down sylvian fissure, retract frontal lobe and come down on optic nerve
2. cautiously elevate temporal tip (aneurysm may be adherent to temporal tip and/or to tentorium),
   coagulate bridging temporal tip veins if necessary
3. incise arachnoid membrane along the optic nerve from anterior to posterior
4. open arachnoid and drain CSF to gain relaxation
5. start to dissect carotid at anterior margin (at junction with optic nerve) and work towards the poste-
   rior margin of carotid where the aneurysm is located (isolating the carotid gives proximal control)

The aneurysm dome usually points laterally, posteriorly and inferiorly, and is encountered before
and usually blocks visualization of the p-comm. The aneurysm frequently projects behind the tento-
rial edge which then obscures the dome.
Critical branches to preserve: anterior choroidal artery, posterior communicating artery (p-
comm). If necessary, the p-comm may be sacrificed (e.g. included in clip) without deleterious effect
in most cases if there is not a fetal circulation.

80.4 Carotid terminus (bifurcation) aneurysms

80.4.1 Angiographic considerations

See Table 102.2 in Endovascular section.

If additional views are needed to better demonstrate aneurysm. Try oblique 25° away from
injection side, center beam 3–4 cm above lateral aspect of ipsilateral orbital rim, orient x-ray tube in
Towne’s view. Also may try submentovertex view.

80.4.2 Surgical considerations

See Pterional craniotomy (p. 1453) for positioning, etc. (rotate head 30° from vertical, see Fig. 94.5.
Craniotomy is as shown in Fig. 94.7.

80.5 Middle cerebral artery (MCA) aneurysms

80.5.1 General information

The following considers MCA aneurysms of the M1-M2 junction (referred to as “trifurcation” region,
although this is not a true trifurcation (p. 76)).

80.5.2 Surgical treatment

Approaches
1. trans-sylvian approach through a pterional craniotomy: this is the most commonly used
   approach
2. superior temporal gyrus approach\(^{10}\):
   a) advantages: minimizes brain retraction, possible reduced vasospasm from manipulation of
      proximal vessels
   b) disadvantages: proximal control difficult, slightly larger bone flap, possible increased risk of
      seizures

Craniotomy vs. craniectomy

Primary decompressive craniectomy (vs. craniotomy) for poor-grade MCA aneurysm SAH (WFNS IV/ V)
with associated IPH (> 30cc) has not shown to provide any survival benefit and is not associated
with improved outcome.\(^{11}\)

Pterional approach

See Pterional craniotomy (p. 1453) for positioning, etc. (rotate head 45° from vertical, Fig. 94.5).

Craniotomy

Craniotomy is as shown in Fig. 94.7. Less frontal lobe needs to be exposed than for, e.g. an ACoA
aneurysm (distance “B” in Fig. 94.7 only needs to be \(\approx 1\) cm). The height “H” of the bony opening
should be \(\approx 5–6\) cm (larger than for circle of Willis aneurysms).
Microsurgical dissection
Dissect down sylvian fissure with major vector of retraction on tip of temporal lobe (less on frontal lobe than in ACoA aneurysm). Open arachnoid and drain CSF. Elevate temporal tip, coagulate bridging temporal tip veins, and expose the ICA for proximal control in the event of rupture.

Follow the ICA distally by splitting the sylvian fissure to expose the M1 (again, for proximal control). Although exposure for proximal control is helpful to have as a contingency, one may be able to avoid temporary clipping of the MCA in the event of intraoperative rupture by controlling bleeding with a large suction, and subsequent clip placement (since the blood flow through the MCA is not as voluminous as through the ICA, and the surgical access to these aneurysms is usually fairly unrestricted).

Critical branches to preserve: distal MCA branches, recurrent perforators from the origin of the major MCA branches.

80.6 Supraclinoid aneurysms
See reference.12

80.6.1 Applied anatomy
The carotid artery exits the cavernous sinus and enters the subarachnoid space at the dural constriction known as the carotid ring (AKA clinoidal ring). The supraclinoid portion of the carotid artery may be divided into the following segments13:
1. ophthalmic segment: the largest portion of the supraclinoid ICA. Lies between the take-off of the ophthalmic artery and the posterior communicating artery (PCoA) origin. The proximal portion of this (including the origin of the ophthalmic artery) is often obscured by the anterior clinoid process. Branches include:
   a) ophthalmic artery: usually originates from the supracavernous ICA just after the ICA enters the subarachnoid space; see variants (p. 79). Enters the optic canal positioned inferolateral to the optic nerve
   b) superior hypophyseal artery: the largest of several perforators supplying the dura of the cavernous sinus and the superior pituitary gland and stalk
2. communicating segment: from the PCoA origin to the origin of the anterior choroidal artery (AChA)
3. choroidal segment: from AChA origin to the terminal bifurcation of the ICA

80.6.2 Ophthalmic segment aneurysms (OSAs)
See reference.14

General information
Ophthalmic segment aneurysms (OSAs) OSAs include (NB: nomenclature varies among authors):
1. ophthalmic artery aneurysms:
2. superior hypophyseal artery aneurysms:
   a) paraclinoid variant: usually does not produce visual symptoms
   b) suprasellar variant: when giant, may mimic pituitary tumor on CT

Presentation (excluding incidental discovery)
Ophthalmic artery aneurysms
Arise from the ICA just distal to the origin of ophthalmic artery. They project dorsally or dorsomedially towards the lateral portion of the optic nerve.

Presentation:
1. \( \approx 45\% \) present as SAH
2. \( \approx 45\% \) present as visual field defect:
   a) as the aneurysm enlarges it impinges on the lateral portion of the optic nerve → inferior temporal fiber compression → ipsilateral monocular superior nasal quadrantanopsia
   b) continued enlargement → upward displacement of the nerve against the falciform ligament (or fold) → superior temporal fiber compression → monocular inferior nasal quadrantanopsia
   c) in addition to near-complete loss of vision in the involved eye, compression of the optic nerve near the chiasm may also produce a superior temporal quadrant defect in the contralateral
eye (junctional scotoma AKA “pie in the sky” defect) from injury to the anterior knee of Wilbrand (nasal retinal fibers that course anteriorly for a short distance after they decussate in the contralateral optic nerve)\(^{15}\)

3. \(\approx 10\%\) present as both

**Superior hypophyseal artery aneurysms**

Originate in the small subarachnoid pocket medial to the ICA near the lateral aspect of the sella. The direction of enlargement is dictated by the size of this pocket and the height of the lateral sellar wall, resulting in two variants: paraclinoid & suprasellar.

Suprasellar variant may actually grow to a size large enough to compress the pituitary stalk and cause hypopituitarism and “classic” chiasmal visual symptoms (bilateral temporal hemianopsia).

**Angiographic considerations**

Also see Table 102.2 in Endovascular section. A notch can often be observed in the in the anterior, superior, medial aspect of giant ophthalmic artery aneurysms due to the optic nerve.\(^{16}\)

If additional views are needed to better demonstrate aneurysm. Try oblique 25° away from injection side, center beam 3–4 cm above lateral aspect of ipsilateral orbital rim, orient x-ray tube in Towne’s view. Try submentovertex view.

**80.6.3 Surgical treatment**

See reference.\(^{12}\)

**Ophthalmic artery aneurysms**

If necessary, the ophthalmic artery may be sacrificed without worsening of vision in the vast majority. Clipping a contralateral ophthalmic artery aneurysm is not technically difficult, and is not uncommonly required as OSAs are often multiple.

The aneurysm arises from the superomedial aspect of the ICA just distal to the ophthalmic artery origin, and projects superiorly.

Cutting the falciform fold early decompresses the nerve, and helps minimize worsening of visual deficit from surgical manipulation.

For unruptured aneurysms, drill off anterior clinoid via an extradural approach before opening dura to approach neck; for ruptured aneurysms, this may not be as safe.

In most cases, a side-angled clip can be placed parallel to the parent artery along the neck of the aneurysm.

**Superior hypophyseal artery aneurysms**

If necessary, the superior hypophyseal artery on one side may be clipped without demonstrable deleterious effect (due to bilateral supply to stalk and pituitary). Clipping a contralateral superior hypophyseal aneurysm is not really feasible.

With a usual pterional approach, the carotid artery is usually encountered first, and with large aneurysms is usually bowed laterally towards the surgeon. Clinoidal removal is usually required. The entire ICA wall may appear to be involved, and it may necessitate temporary ICA clipping (with cerebral protection) to reconstitute the ICA using encircling clips parallel to the parent vessel.

**80.7 Posterior circulation aneurysms**

**80.7.1 General information**

See also basilar tip aneurysms (p.1218). Clinical syndrome of SAH in the posterior fossa is indistinguishable from that due to anterior circulation aneurysms except for possible increased tendency towards respiratory arrest and subsequent neurogenic pulmonary edema (p.1178).\(^{17}\) Vasospasm following posterior fossa SAH may be more likely to cause midbrain symptoms than vasospasm due to SAH elsewhere.

**80.7.2 Hydrocephalus**

In Yamaura’s series,\(^{18}\) 12% of patients required external ventricular drainage (EVD) following posterior fossa SAH to remove bloody CSF causing hydrocephalus, and 20% eventually required permanent ventricular shunt.
80.7.3 Vertebral artery aneurysms

General information

Traumatic vertebral artery aneurysms (VAA) (AKA dissecting aneurysms) are more common than non-traumatic VAAs. The following discussion concerns non-traumatic VAA.

Most VAAs arise at the VA-PICA junction. Other sites: VA-AICA, VA-BA.

Angiographic considerations

Also see Table 102.2 in Endovascular section. Angiography of VAA should assess the contralateral VA for patency in case of the need to trap the aneurysm. Alcock test (vertebral artery injection with carotid compression) may be used to assess patency of circle of Willis. Test occlusion with a balloon catheter can determine if patient will tolerate occlusion (a double lumen balloon will even allow measurement of distal back pressure).

PICA aneurysms

General information

For PICA anatomy, see Fig. 2.6. For arteriogram, see Fig. 2.7.

Comprise ≈ 3% of cerebral aneurysms. 3 common sites:

1. VA at the VA-PICA junction:
   a) saccular aneurysms: most commonly at the distal (superior) angle. An aneurysm in this location should be suspected with a CT showing blood predominantly in the 4th ventricle (aneurysmal dome may adhere to foramen of Luschka; rupture fills the ventricles with little subarachnoid blood visible on CT). The level is as varied as the PICA origin, and ranges from as low as the foramen magnum to as high as the ponto-medullary junction. Most VA-PICA aneurysms lie in the anterolateral portion of the medullary cistern, anterior to the first dentate ligament. However, the PICA origin may sometimes lie in the midline or across it
   b) fusiform aneurysms: usually the result of prior arterial dissection

2. PICA aneurysms distal to the VA-PICA junction: tend to be fragile and often develop multiple hemorrhages in a relatively short period, should be treated promptly, even when discovered incidentally

3. fusiform VA aneurysms involving PICA

Angiographic considerations

See Table 102.2 in Endovascular section.

Treatment

Options:

1. direct aneurysmal clipping is the preferred treatment
2. endovascular coil embolization: not as effective as clipping for relief of symptoms due to brainstem or cranial nerve compression
3. choices for unclippable and uncoilable aneurysms (e.g. fusiform, giant, or dissecting aneurysms) include:
   a) proximal (hunterian) VA ligation which must be distal to the PICA origin to prevent severe morbidity or mortality
   b) occlusion of the VA distal to the PICA origin (usually done endovascularly)
   c) midcervical VA occlusion (allows collateral flow through suboccipital muscular branches) e.g. endovascular Amplatz plug

Surgical clipping of VA-PICA junction saccular aneurysms

One approach to the VA-PICA junction is via a low extreme-lateral p-fossa approach. However, if the aneurysm is too far anterior to the brain stem, it may be totally out of vision or reach. Also, since these aneurysms usually project posteriorly and superiorly, the critical PICA will be directly in harms’ way. Direct lateral approach more directly exposes the aneurysm through a lateral suboccipital transcondylar approach.

Position: options include sitting position – less frequently used, see Sitting position (p.1445) – or lateral oblique (“park bench”).

SAH and Aneurysms
Lateral oblique position
Position: side of involved PICA is up, thorax elevated ≈ 15°. Head in-line with the thorax, neck slightly flexed, and slightly rotated 20° toward the floor (away from the side of the aneurysm). Upper shoulder depressed with adhesive tape. Lumbar spinal subarachnoid catheter placed, allows CSF drainage once dura is opened.

Options for skin incision:
- Avoid opening too far laterally, otherwise the muscle mass impedes surgeon’s vision. (p 1747)
  1. From just above superior nuchal line to C2 vertebra
     a) paramedian vertical incision
     b) midline vertical incision (hockey stick)
  2. “sigmoid” incision starting 2 cm medial to mastoid notch, and curving to midline at level of Cl arch

Cranietomy: lateral exposure of bone to the base of the mastoid, medially crossing the midline. Need not be quite as high as the transverse sinus. The foramen magnum is removed to its lateral margin. Removing the posterior arch of Cl from midline to the sulcus arteriosus (under VA) may help with proximal VA exposure but is not usually necessary.

Dural opening: K-shaped dural opening with a linear incision across the band at the foramen magnum (some patients have a sinus known as the arcuate sinus here that may require vascular clips).

Approach: first, gain proximal control of the VA where it first becomes intradural (in case of aneurysmal rupture). Retract cerebellum superiorly (caution: aneurysm dome may be adherent). Follow VA up from point where it enters dura; PICA origin then encountered usually just at neck of aneurysm (PICA origin may be confused for continuation of VA). Dissection must spare branches of pharyngeal filaments of spinal accessory nerve and lower filaments of vagus. May place temporary clip on VA proximal to PICA. Permanent clip usually placed between the fibers of IX & X above and XI below. It is better to leave a small residual aneurysm than to risk compromising PICA.

Postoperative care: when neuropraxia of the lower cranial nerves is likely (in cases of difficult dissection or traction applied during clipping) the patient is kept intubated overnight. Patients who do not tolerate extubation at this point are immediately reintubated and elective tracheostomy is scheduled. Tracheostomy is maintained until the neuropraxia resolves.

Surgical clipping of distal PICA aneurysms
Aneurysms distal to the lateral medullary segment are approached through a cranietomy that extends across the midline.

80.7.4 Verteobasilar junction aneurysms

General information
Saccular aneurysms located where the two vertebral arteries join often form at the location of a basilar artery fenestration (basilar fenestration aneurysm).

Angiographic considerations
See Table 102.2 in Endovascular section.
CT-angiogram may be helpful as an adjunct because it can opacify both vertebral arteries simultaneously (not generally feasible with catheter angiogram).

Surgical approaches
1. suboccipital approach: for most; performed in lateral oblique position
2. subtemporal-transventricular approach if the vertebrobasilar junction is high; performed in supine position

Suboccipital approach in lateral oblique position
NB: the side of approach must be chosen based on angiogram, as the extreme tortuosity of the VAs may cause the aneurysm of one VA to lie on the contralateral side of the brain stem.
Position: thorax elevated ≈ 15°. Head in-line with the thorax, neck slightly flexed, and slightly rotated away from side of aneurysm. Upper shoulder depressed with adhesive tape. Spinal subarachnoid catheter placed for CSF drainage, opened only once dura is opened.
80.7.5 AICA aneurysms

Angiographic considerations
See Table 102.2 in Endovascular section.

80.7.6 Basilar bifurcation aneurysms

General information
AKA basilar tip aneurysms. The most common posterior circulation aneurysm. Comprise \( \approx 5\% \) of intracranial aneurysms. Considered inoperable until Drake reported 4 cases in 1961,\(^{29}\) with larger series reported later.\(^{30}\)

Presentation
Most present with SAH indistinguishable from SAH due to anterior circulation aneurysmal rupture. Enlargement of the aneurysm prior to rupture may rarely compress the optic chiasm \( \rightarrow \) bitemporal field cut (mimicking pituitary tumor), or occasionally may compress the third nerve as it exits from the interpeduncular fossa \( \rightarrow \) oculomotor nerve palsy.\(^{17}\)

CT/MRI scan
May occasionally be seen on CT or MRI as round mass in region of suprasellar cistern. With SAH, tend to see blood in interpeduncular cistern with some reflux into 4th (and to a lesser extent, third and lateral) ventricle. Occasionally may mimic pretruncal nonaneurysmal SAH (p.1231).

Angiography
Also see Table 102.2 in Endovascular section. Dome usually points superiorly. Should evaluate flow through posterior communicating arteries (may require Ailcock test) in case trapping is required. Need to assess the height of the basilar bifurcation in relation to the dorsum sella (below).

Critical angiographic features to assess: On angiogram or CTA:
1. general features (p.1162)
2. orientation: determines whether surgery is an option. Posteriorly pointing aneurysms obscure perforators which may be adherent to the aneurysm, making surgery more difficult
3. patency of PCAs & SCAs
4. patency and size of p-comms
   a) diameter of p-comm >1 mm is needed to support collateral flow (expert opinion)
   b) to determine if the P1’s can be sacrificed
   c) P-comm patency and size is important for endovascular treatment as a potential route for deployment of horizontally oriented stent extending from P1 to contralateral P1\(^{31,32}\)
   d) which can facilitate temporary clipping, or sacrifice, or placement of stents.
5. height of the aneurysm relative to the posterior clinoid process which will affect the selection of surgical approach\(^{33,34}\) (the range of height of the posterior clinoid is 4–14 mm\(^{34}\))
   a) supraclinoidal: aneurysm neck >5 mm superior to posterior clinoid process
   b) clinoidal: aneurysm neck within 5 mm of posterior clinoid process
   c) infraclinoidal: aneurysm neck >5 mm inferior to posterior clinoid process

Surgical treatment
Timing
Initial experience tended to favor allowing basilar tip aneurysms to “cool-down” for \( \approx 10–14 \) days after SAH before attempting surgery to permit cerebral edema to subside. More recently, early surgery for these aneurysms has been advocated as for anterior circulation aneurysms (p.1199).\(^{35}\) However, some surgeons still recommend waiting \( \approx 1 \) week,\(^{26}\) and most would agree that if there are obvious technical difficulties because of size, configuration or location of the aneurysm, that early surgery may not be appropriate. Also, if during the craniotomy it becomes apparent that cerebral edema is impairing the exposure, the operation should be aborted and attempted again at a later date.

Approaches
1. right subtemporal craniotomy (classical approach of Drake): approached through the incisura or division of the tentorium. Most basilar tip aneurysms are probably best approached via pterional approach (see below) except for posteriorly pointing aneurysms
a) advantage:
- less distance to basilar tip
- may be better than pterional approach for aneurysms projecting posteriorly or posteroinferiorly

b) disadvantages:
- requires temporal lobe retraction (minimized with lumbar drainage, mannitol, and possibly zygomatic arch section)
- poor visualization of contralateral P1 segment and thalamoperforators

2. pterional approach (described by Yasargil): trans-Sylvian (see below)
a) advantages:
- little or no retraction on temporal lobe (unlike subtentorial approach)
- better visualization of both P1 segments and thalamoperforators
- other aneurysms, e.g. of the anterior circulation, can be dealt with at the same sitting

b) disadvantages:
- increases reach to aneurysm by ≈1 cm compared to subtentorial
- requires wide splitting of the sylvian fissure
- operating field is narrower than subtentorial approach
- perforators arising from the posterior aspect of P1 may not be visible

3. modified pterional craniotomy: may allow trans-Sylvian or subtentorial approach.

4. orbitozygomatic approach: allows access to portions of the basilar artery below the bifurcation.

Optional resection of the temporal tip will increase exposure of either approach. Unlike most anterior circulation aneurysms, securing proximal control is very difficult.

If the basilar bifurcation is high above the dorsum sella, then more retraction is required on a subtentorial approach than for a normal bifurcation height (near the dorsum sella). A high bifurcation is dealt with on a trans-Sylvian approach by opening the sylvian fissure more widely, or by a subfrontal approach through the third ventricle via the lamina terminalis. A low bifurcation may require splitting the tentorium behind the 4th nerve.

Pterional approach
See reference.

Risks include: oculomotor palsy in ≈30% (most are minimal and temporary).

Approach is from the right unless:
1. additional left sided aneurysm (e.g. p-comm aneurysm) which could be treated simultaneously by a left sided approach
2. aneurysm points to the right
3. aneurysm is located to the left of midline (the operation is more difficult when the aneurysm is even just 2–3 mm contralateral to the craniotomy)
4. patient has right hemiparesis or left oculomotor palsy

See Pterional craniotomy (p.1453) for general information. Rotate the head ≈30° off the vertical so that the malar eminence points directly upward (Fig. 94.5). Slight neck flexion is used for low-lying aneurysms, slight extension for high ones. Craniotomy is as shown in Fig. 94.7, with aggressive removal of the sphenoid wing. The sphenoid wing and the orbital roof may be reduced with a drill. The posterior clinoid can be removed to improve exposure.

Approach
The sylvian fissure is split until the take-off of the proximal M1 from the carotid terminus is identified. The approach is medial to the ICA (between the ICA and optic nerve) when this space is ≥5–10 mm. If the ICA is close to the optic nerve, an approach lateral to the ICA may be used, aided by medial retraction of the ICA/M1 segment (Fig. 94.8). Here, the exposure is limited by the height of the M1 branch above the skull base, and if the basilar tip height above the skull base greatly exceeds this, clipping via this approach is not feasible.

The 3rd nerve is identified. Also the p-comm and the anterior choroidal artery (AChA) are located as they arise from the posterior surface of the ICA (to differentiate between them: the p-comm origin is proximal to that of the AChA, p-comm courses perpendicular to Liliequist’s membrane whereas AChA courses obliquely into the crural cistern). The p-comm is followed posteriorly through Liliequist’s membrane which is opened revealing the preoptic cistern. The p-comm is followed until it joins the PCA at the P1/P2 junction. If p-comm is absent, follow the third nerve back to find where it
emerges between PCA and SCA. P1 is followed proximally to the basilar bifurcation region where the contralateral P1 and both SCAs are identified. Caudal dissection of Liliequist’s membrane exposes the interpudendular cistern with proximal BA (this exposure is critical for proximal control of BA in the event of aneurysmal rupture).

Thalamoperforating arteries (ThPAs) arise from the distal p-comm and proximal PCA, and often compromise the access. Early poor results with clipping of basilar tip aneurysms has been attributed to sacrificing these vessels, which produces lacunar infarcts in the thalamus, midbrain, subthalamic, and pretectal regions. If hypoplastic, the p-comm may be divided between clips to improve exposure (preserving the ThPAs which will then arise from the stumps). Similarly, a hypoplastic P1 may be divided if the PCA fills from the p-comm. If the ThPAs make it impossible to clip the aneurysm, some (preserving the ThPAs which will then arise from the stumps). Similarly, a hypoplastic P1 may be divided between clips to improve exposure.

Outcomes

If the aneurysm cannot be treated with endovascular technique, then the surgical option can be considered. Overall mortality is 5% and morbidity is 12% (mostly due to injury to perforating vessels).21

80.7.7 Basilar trunk aneurysms

Most aneurysms of the basilar trunk are fusiform in morphology. Surgical access for these is extremely difficult.

81 Special Aneurysms and Non-Aneurysmal SAH

81.1 Unruptured aneurysms

81.1.1 General information

Unruptured intracranial aneurysms (UIA) includes incidental aneurysms (those that do not produce any symptoms and are discovered incidentally) and aneurysms that produce symptoms other than those due to hemorrhage (e.g. pupillary dilatation due to third nerve compression). UIA merit consideration for treatment since the outcome from SAH with or without surgery is poor even under the best of circumstances. About 65% of patients die from the first SAH, and even in patients with no neurologic deficit after aneurysm rupture, only 46% fully recover, and only 44% return to their former jobs. However, the risk of aneurysmal rupture without intervention should be weighed against the risks of surgical clipping or endovascular treatment. Estimated prevalence of incidental aneurysms is 5–10% of the population.

81.1.2 Presentation

See items other than those listed under “rupture” in Presentation of aneurysms (p. 1191).

81.1.3 Natural history

Risk of bleeding from UIA differs from aneurysms that have ruptured. True risk is not known with certainty. Early studies found annual bleeding rate of 6.25% whereas later reports estimate lifetime risk for a 20-year-old with an UIA to be 16% which drops off to 5% for a 60-year-old. A more recent study estimates the annual rupture rate to be 1% The International Study of Unruptured aneurysms (ISUIA) was the first large-scale, prospective study evaluating the natural history of unruptured aneurysms as well as the risks of treatment of unruptured aneurysms. The authors concluded that rupture rate was related to size and location of the aneurysm, and that risk is increased with previous aSAH from a separate aneurysm (see below). However, there were important limitations of ISUIA (see Table 81.1).

Σ

There appears to be 2 distinct types of aneurysms: those that rupture, and those that tend to remain stable. Most UIAs seen in the clinic fall into the latter group

Spontaneous thrombosis of unruptured aneurysms may occur rarely (p. 1194).

Additional retrospective and prospective studies have been conducted to assess the natural history of unruptured aneurysms. Overall, several variables have been identified as risk factors for rupture:

1. patient factors
   a) history of previous aSAH from a separate aneurysm
   b) multiple aneurysms
   c) age: there is conflicting evidence, as some studies have found an inverse relationship between age and rupture risk, while others have found an increased risk of rupture for those aged 40 or older, or no effect of age on rupture risk
   d) medical conditions:
      ● hypertension
      ● smoking
   e) geographic location: North America/Europe < Japan < Finland

Table 81.1 Main methodological limitations of ISUIA study

- Patients were not randomized to surgery (vs. no surgery), and there were substantial differences between treated and untreated groups
- Follow-up was < 5 years in of 50% of patients
- Selection bias: low recruitment numbers from each center
f) gender?: Risk of rupture was greater amongst women compared to men in one study, but only approached statistical significance.

g) family history?: In the Familial Intracranial Aneurysm study, rupture rate in patients with unruptured aneurysm and first-degree relative with intracranial aneurysm was 17% higher than that for patients with unruptured intracranial aneurysm in ISUIA (after matching for aneurysm size and location) – although conclusions are limited secondary to small number of ruptures in the study. Other studies have failed to demonstrate an increased risk in this subgroup.

2. aneurysm characteristics
   a) size: risk of rupture appears critically dependent on aneurysm diameter. ISUIA estimated the annual risk of rupture of aneurysms <10 mm to be 0.05% /year, however a number of other studies have demonstrated a rupture risk closer to =1% /year for aneurysms <10 mm. Furthermore, the Small Unruptured Intracranial Aneurysm Verification Study demonstrated that the rupture risk of smaller aneurysms (<5 mm) is not trivial, and estimated to be ≈0.5% /year. A more recent retrospective review demonstrated the majority (62%) of ruptured aneurysms to be <7 mm, with the majority of these being anterior communicating aneurysms. Some speculate that this may be due to a shrinkage of aneurysms following rupture. Larger aneurysms (10-25 mm) are estimated to have ≈3-18% /year risk, while giant aneurysms (≥25 mm) have a risk of ≥8-50%/year.
   b) location: ISUIA showed an increase rupture risk for pcomm and posterior circulation aneurysms. Ishibashi et al. also demonstrated increased risk amongst posterior circulation aneurysms. Conversely, some studies found an increased risk of rupture with anterior communicating aneurysms. In one such study, using the values shown in Table 81.3, the result obtained was that a life expectancy of 12 more years is the break-even point, i.e. if the patient is not expected to live for 12 more years, then non-surgical management is a better choice than surgery (this result involves numerous assumptions and estimations; e.g. 5% "risk aversiveness" (intermediate) relates to patient’s fears of immediate surgical risk vs. risk of rupture spread over many years). Another analysis of various scenarios for a 50 year old female found that treatment was cost-effective for UIAs that were symptomatic, ≥10 mm diameter, or with a previous history of SAH.
   c) morphology: presence of a daughter sac, bottleneck shape and increased ratio of size of aneurysm to parent vessel have all been associated with increased risk of rupture.

Estimation of absolute risk of aneurysm rupture in a patient based on a combination of risk factors is complex. Recently, a scoring system (PHASES) was developed by pooling patient data from six prospective studies, to help estimate 5-year rupture risk by risk factor status. The predictors comprising the PHASES aneurysm rupture risk score and the predicted 5-year cumulative risk of aneurysm rupture based on score is summarized below (Table 81.2). Further studies are needed however to externally validate the score.

81.1.4 Management

Cumulative rupture risk

To understand the calculation of cumulative risk for aneurysmal rupture, see discussion of this issue related to AVMs which is also relevant to aneurysms (p.1240).

Decision analysis

Decision analysis is a means of mathematically modeling outcomes of various decision options using probabilities and assigning “desirability factors” to the outcomes. This analysis requires data about the natural history (see above), life expectancy, and morbidity and mortality of SAH and aneurysm surgery. Although it is only a model, it does yield some insights in some complicated decisions.

In one such study, using the values shown in Table 81.3, the result obtained was that a life expectancy of 12 more years is the break-even point, i.e. if the patient is not expected to live for 12 more years, then non-surgical management is a better choice than surgery (this result involves numerous assumptions and estimations; e.g. 5% “risk aversiveness” (intermediate) relates to patient’s fears of immediate surgical risk vs. risk of rupture spread over many years). Another analysis of various scenarios for a 50 year old female found that treatment was cost-effective for UIAs that were symptomatic, ≥10 mm diameter, or with a previous history of SAH.

Management recommendations

Decisions are based on natural history data compared with morbidity and mortality of intervention (surgery/endovascular), with recommendations being based mainly on expert opinion as high level evidence is lacking. Size, patient age and location appear to be the most important factors in determining whether to treat and by which means to treat an unruptured aneurysm (in a patient without prior SAH). In addition, treatment should be recommended for patients with a history of aSAH, strong family history, symptomatic aneurysms, and for enlargement or change in configuration of aneurysms.
Numerous recommendations have been made for a critical size above which an unruptured aneurysm should be considered for surgery, and have included 3 mm, 5 mm, 7 mm, and 9 mm. The most recent American Heart Association guidelines did not advocate for repair of small incidental aneurysms (<10 mm) in patients with no history of subarachnoid hemorrhage, but this report was prior to more recent prospective trials. In addition, the patient’s expected longevity must also be taken into account, and therefore special consideration for treatment should be

Table 81.2 Predictors comprising the PHASES aneurysm rupture risk score; predicted 5-year cumulative risk of aneurysm rupture based on score.
given to young patients in this group. In all treatment decisions, coexisting medical conditions must also be taken into account.

One recent proposed strategy in management is summarized here:

1. Large and/or symptomatic aneurysms (esp. in young pts) → intervention

2. Patients <60 years old:
   a) <7 mm
      ● anterior circulation, NO risk factors → medical management or intervention
      ● pcomm/posterior circulation, symptomatic aneurysm, strong family hx → intervention
   b) >7 mm → intervention (surgery or endovascular based on size, location)

3. Patients >60 years old:
   a) <7 mm
      ● no family hx and asymptomatic → medical management
      ● + risk factors → intervention
   b) 7-12 mm
      ● anterior circulation → medical management or intervention
      ● pcomm/posterior circulation → intervention
   c) >12 mm → Intervention

Recommended follow-up for UIAs treated conservatively

Annual follow-up with MRA/CTA is recommended for most incidental aneurysms that are not treated. Intervention is indicated for any documented growth. If no growth, may consider repeat imaging at a reduced frequency.

Background: The morbidity from catheter arteriograms is probably too high to recommend them for this purpose. CTA is more accurate than MRA, but involves iodine contrast and radiation. A TOF-MRA (not gadolinium-MRA) has no known risks and does not involve radiation, but has lower spatial resolution.

Unfortunately, most aneurysms rupture without demonstrable enlargement on follow-up. Aneurysms do not grow at a constant rate, and it may take several years to appreciate a millimeter of increased size on MRA.

Studies have identified risk factors for growth, including size, location (MCA, basilar bifurcation), >1 aneurysm, family history of SAH and smoking.

Risk of rupture in setting of growth is hard to estimate, given most aneurysms that increase in size are subsequently treated. In one study, the rupture rate was 2.4%/year for aneurysms showing growth (vs. 0.2%/year in those without growth). In another study of 18 Japanese patients, rupture risk after growth was 18.5%/year.

Unruptured cavernous carotid artery aneurysms (CCAAs)

Cavernous carotid artery aneurysms (CCAAs) have a unique risk profile among intracranial aneurysms. Most develop on the horizontal segment of the artery.

Presentation:
1. CCAAs may be discovered incidentally
   a) on arteriography for other reason

| Table 81.3 Data used in decision analysis of management of unruptured aneurysms |
|---------------------------------|-----------------|------------------|
| annual risk of rupture*        | Typical value   | Range            |
| 3 month mortality of SAH       | 55%             | 50–60%           |
| serious morbidity after SAH    | 15%             | 10–20%           |
| surgical morbidity & mortality | 2% & 6%         | 4–10%            |

*a this is an intermediate risk for aneurysms 6–10 mm diameter (NB: size may change; small aneurysms may grow*
b) on MRI
c) occasionally on CT

2. when symptomatic:
   a) usually present with:
      • headache
      • cavernous sinus syndrome (p.1401): primarily produces diplopia (due to ophthalmoplegia). Classically the third nerve palsy from enlarging CCAA will not produce a dilated pupil because the sympathetics which dilate the pupil are also paralyzed36(p 1492)
      • those that expand through the carotid ring into the subarachnoid space may cause monocular blindness from strangulation of the optic nerve37
   b) rarely, pain (retro-orbital or pain mimicking trigeminal neuralgia38,39) or a carotid-cavernous fistula (CCF) are the sole manifestation
   c) when CCAAs rupture, they usually produce a CCF
d) life threatening complications are rare, but may be more common with giant intracavernous aneurysms.40 Manifestations include:
      • SAH40,41: primarily with CCAAs that straddle the carotid ring (subarachnoid extension of CCAAs may be indicated by “waisting” of the aneurysm on angiography42)
      • arterial epistaxis from rupture into sphenoid sinus; usually with traumatic aneurysms (p.1227); subarachnoid extension of CCAAs may be indicated by “waisting” of the aneurysm on angiography42
      • emboli

Indications for treatment:
1. unruptured CCAAs: the natural history is not precisely known
   a) symptomatic: patients with intolerable pain or visual problems43
   b) giant aneurysms: especially those that straddle the clinoidal ring (subarachnoid extension of CCAAs may be indicated by “waisting” of the aneurysm on angiography42)
   c) aneurysms that enlarge on serial imaging
   d) controversial: incidental aneurysms in the distribution of a stenotic carotid artery for which carotid endarterectomy is indicated. There has been no evidence that doing the endarterectomy increases the risk of rupture, and, as indicated above, most ruptures are not life threatening and so the carotid disease should be treated according to its own merits
2. ruptured CCAAs:
   a) emergent treatment for cases with epistaxis or SAH
   b) urgent treatment for CCFs with severe eye pain or threat to vision

Treatment options for CCAAs:
   Treatment of small incidental intracavernous CCAAs is not generally indicated.25
   For other unruptured CCAAs, options include detachable coils in an attempt to thrombose the aneurysm (p.1194). This results in reduction of mass effect in ≈ 50%. Open surgical treatment is rarely appropriate. Aneurysms that rupture and produce a carotid-cavernous fistula may be treated by endovascular occlusion (p.1256).

81.2 Multiple aneurysms

Multiple aneurysms are present in 15–33.5% of cases of SAH.2 In one study of multiple factors, hypertension was found to be the most important one associated with multiplicity.44 When a patient presents with SAH and is found to have multiple aneurysms, the following may be clues as to which aneurysm has bled:
1. epicenter (center of greatest concentration) of blood on CT or MRI45,46
2. area of focal vasospasm on angiogram
3. irregularities in the shape of the aneurysm (so-called “Murphy’s test”)
4. if none of the above help, then suspect the largest aneurysm
5. NB: in one series, the most common cause of post-op bleeding in 93 patients with multiple aneurysms was felt to be from rebleeding of the original aneurysm that ruptured that was actually missed on initial angiogram47

81.3 Familial aneurysms

81.3.1 General information

The role of inheritance in the development of intracranial aneurysms (IA) is well established for disorders such as polycystic kidney disease, and connective tissue disorders such as Ehlers-Danlos
type IV, Marfan syndrome, and pseudoxanthoma elasticum (p. 1193). Overall, it is not uncommon for patients with aSAH to have a family history. In one study of patients with subarachnoid hemorrhage,48 9.4% had a first-degree relative with aSAH or intracranial aneurysm and 14% had a second-degree relative with these diagnosis In families with two or more affected members, the age-adjusted prevalence of intracranial aneurysm among first-degree relatives was 9.2% in those aged 30 years or older.49,50

Additional cases of IAs in identical twins51,52 as well as familial aggregations of IAs without a recognized inherited disorder have also been reported but are felt to be rare (it has been estimated that <2% of IAs are familial53). Most reported cases consist of only 2 family members with IAs, and these are most commonly siblings.54 In fact, siblings of an affected aSAH patient have a higher risk of aneurysm, than do children of an affected patient.30 Analysis of case reports reveals that when IAs occur in siblings they tend to occur at identical or mirror image sites, and in comparison to sporadic IAs, familial IAs tend to rupture at a smaller size and at a younger age, and that the incidence of anterior communicating artery aneurysms is lower.55 It has been postulated that IAs occurring in siblings may represent a distinct population of IAs.56

81.3.2 Screening recommendations
The indications and best method for investigation of asymptomatic relatives of a patient found to harbor an intracranial aneurysm are controversial. Negative studies do not guarantee that at a later date an aneurysm will not be discovered that either subsequently developed or expanded, or was simply not detected on the initial study.57,58,59 Cerebral angiography is the most sensitive study; however, the risk and expense may not justify its use as a screening test in many cases. Furthermore, there is some evidence that aneurysms that rupture tend to do so shortly after their formation29 which would reduce the value of screening.

81.3.3 Genetics
A large meta-analysis identified 19 single nucleotide polymorphisms associated with sporadic intracranial aneurysms.60 The strongest associations were found on chromosomes 9 (CDKN2B; antisense inhibitor gene), 8 (SOX17; transcription regulator gene), and 4 (EDNRA gene). Screening with either MRA or CTA is typically recommended for first-degree relatives (especially siblings) of affected family members when two or more members of the family have an intracranial aneurysm or aSAH.30 The overall need for screening second-degree relatives is less clear. Screening of first-degree relatives is not typically recommended if only one family member is affected.25,58 In patients with coarctation of the aorta, screening is typically recommended. Finally, patients with ADPKD who have a family history of intracranial aneurysm or aSAH should be screened. Findings suspicious for intracranial aneurysms should be followed-up with four vessel arteriography to confirm suspected lesions (MRA has a high false-positive rate of ≈ 16%49) and to rule-out additional aneurysms.

81.4 Traumatic aneurysms
81.4.1 General information
Traumatic aneurysms (TAs) comprise <1% of intracranial aneurysms.61,62 Most are actually false aneurysms, AKA pseudoaneurysms (a rupture of all the vessel wall layers with the “wall” of the aneurysm being formed by surrounding cerebral structures63). They may occur rarely in childhood. The mechanism of injury usually falls into one of the following groups64:

Those arising from penetrating trauma. Usually from gunshot wounds, although penetration with a sharp object (which is less common) may be more prone to cause traumatic aneurysms.65

Those arising from closed head injury. More common. Theories of pathogenesis include traction injury to the vessel wall or entrapment within a fracture. Tend to occur either:
1. peripherally
   a) distal anterior cerebral artery aneurysms: secondary to impact against the falx centralis
   b) distal cortical artery aneurysms: often associated with an overly thin skull fracture, sometimes a growing skull fracture
2. at the skull base, usually involving the ICA in one of the following sites:
   a) petrous portion (virtually always associated with basal skull fractures):
   b) cavernous carotid artery (virtually always associated with basal skull fractures):
• aneurysm enlargement may cause a progressive cavernous sinus syndrome
• rupture may lead to a posttraumatic carotid-cavernous fistula (p. 1256) or to massive epis-
taxis in the presence of a sphenoid sinus fracture\textsuperscript{66,67,68}
c) supraclinoid carotid artery

Iatrogenic. Following surgery in or around the skull base, the sinuses, or orbits (including following transsphenoidal surgery\textsuperscript{69}). The first such case was described in 1950

81.4.2 Presentation
1. delayed intracranial hemorrhage (subdural, subarachnoid, intraventricular, or intraparenchy-
mal): the most common presentation. TAs tend to have a high rate of rupture
2. recurrent epistaxis
3. progressive cranial nerve palsy
4. enlarging skull fracture
5. may be incidental finding on CT scan
6. severe headache

81.4.3 Treatment
Although there are case reports of spontaneous resolution, treatment is usually recommended. ICA
aneurysms at the skull base should undergo trapping or endovascular embolization. Peripheral
lesions should be treated surgically with clipping of aneurysm neck, excision of the aneurysm, coil-
ing, or wrapping if no other method is feasible.

81.5 Mycotic aneurysms

81.5.1 General information
The name “mycotic” originated with Osler in whose time the term referred to any infectious proc-
ess\textsuperscript{70} rather than the current usage which infers a fungal etiology. Currently accepted terminology
favors infectious aneurysm (or bacterial aneurysm). Infectious aneurysms can, however, also occur
with fungal infections.\textsuperscript{71} Tend to form in distal (often unnamed) vessels.

81.5.2 Epidemiology and pathophysiology
1. comprise \approx 4\% of intracranial aneurysms
2. occurs in 3–15\% of patients with subacute bacterial endocarditis (SBE)
3. most common location: distal MCA branches (75–80\%)
4. at least 20\% have or develop multiple aneurysms
5. increased frequency in immunocompromised patients (e.g. AIDS) and drug users
6. most probably start in the adventitia (outer layer) and spread inward

81.5.3 Evaluation
Blood cultures and LP may identify the infectious organism. Table 81.4 shows typical pathogens
recovered. Patients with suspected infectious aneurysm(s) should undergo echo-cardiography to
look for signs of endocarditis.

81.5.4 Treatment
These aneurysms usually have fusiform morphology and are usually very friable, therefore surgical
treatment is difficult and/or risky. Most cases are treated acutely with antibiotics which are contin-
ued 4–6 weeks. Serial angiography (at 7–10 days and 1.5, 3, 6 and 12 months, even if aneurysms
seem to be getting smaller, they may subsequently increase\textsuperscript{73} and new ones may form) helps docu-
ment effectiveness of medical therapy (serial MRA may be a viable alternative in some cases). Aneu-
rysms may continue to shrink following completion of antibiotic therapy.\textsuperscript{74} Delayed clipping may be
more feasible; indications include:
1. patients with SAH
2. increasing size of aneurysm while on antibiotics\textsuperscript{75} (controversial, some say not mandatory\textsuperscript{74})
3. failure of aneurysm to reduce in size after 4–6 weeks of antibiotics\textsuperscript{75}
Patients with SBE requiring valve replacement should have bioprosthetic (i.e. tissue) valves instead of mechanical valves to eliminate the need for risky anticoagulation.

81.6 Giant aneurysms

81.6.1 General information

Definition: > 2.5 cm (≈ 1 inch) diameter. Two types: saccular (probably an enlarged “berry” aneurysm) and fusiform. Comprise 3–5% of intracranial aneurysms; peak age of presentation 30–60 years; female:male ratio = 3:1.

Drake’s series of 174 giant aneurysms\(^76\): 35% presented as hemorrhage, with 10% showing some evidence of remote bleeding. The bleeding rate is unknown, but is probably less than the ≈ 2%/year for non-giant aneurysms.

May also present as TIAs (by reducing flow or by emboli) or as a mass. About one third have a neck amenable to clipping.

81.6.2 Evaluation

General information

Drake contended that even after thorough radiographic evaluation, actual operative visualization is the only way to definitively assess the aneurysm and its branches. 3D-CTA can add substantial information that rivals and may exceed direct visualization.

Angiogram

Often underestimates the size of the lesion secondary to thrombosed regions of the aneurysm that do not fill with contrast. CT or MRI is required to visualize the thrombosed portion.

CT scan

Frequently have a significant amount of edema surrounding the aneurysm. May see contrast enhancement of the brain surrounding the aneurysm; probably due to increased vascularity secondary to inflammatory reaction to the aneurysm.

MRI scan

Turbulence within → complicated signal on TIWI. Pulsation artifact (linear distortion radiation through aneurysm) on MRI helps differentiate giant aneurysms from solid or cystic lesions.

81.6.3 Treatment

Options include:
1. direct surgical clipping: usually possible in only ≈ 50% of cases
2. vascular bypass of aneurysm with subsequent clipping

| Table 81.4 Pathogens implicated in mycotic aneurysms\(^72\) (p 933–40) |
|-----------------|---------|--------------------------------|
| Organism        | %       | Comment                        |
| streptococcus   | 44%     | S. viridans (classic cause of SBE) |
| staphylococcus  | 18%     | S. aureus (cause of acute bacterial endocarditis) |
| miscellaneous   | 6%      | (pseudomonas, enterococcus, corynebacteria...) |
| multiple        | 5%      |                                  |
| no growth       | 12%     |                                  |
| no info         | 14%     |                                  |
| total           | 99%     |                                  |

Patients with SBE requiring valve replacement should have bioprosthetic (i.e. tissue) valves instead of mechanical valves to eliminate the need for risky anticoagulation.
3. trapping
4. proximal arterial ligation (hunterian ligation)
   a) for vertebral-basilar aneurysms\textsuperscript{77}: results in improvement of cranial nerve deficit in $\approx 95\%$ of patients. A reasonable alternative in the presence of an adequately sized contralateral VA that unites with the VA to be ligated
5. wrapping (p.1194)
6. endovascular treatment

81.7 Cortical subarachnoid hemorrhage

Cortical SAH (cSAH) appears as SAH over the convexity. Trauma is the most common cause. Nontraumatic etiologies are shown below.

Etiologies of nontraumatic cSAH\textsuperscript{75}:
- pial AVMs
- dural AV fistulas
- cerebrovascular arterial dissection
- dural or cortical venous thrombosis
- vasculitis
- Reversible cerebral vasoconstriction syndrome (RCVS), AKA Call-Fleming syndrome,\textsuperscript{79} a group of disorders sharing the cardinal clinical and angiographic features of reversible segmental multifocal cerebral vasoconstriction with severe headaches, focal ischemia, and/or seizures. May present as a hemorrhage restricted to a cortical sulcus
- PRES
- Cerebral amyloid angiopathy (CAA)
- Coagulopathies
- Brain tumors (primary or metastatic)

81.8 SAH of unknown etiology

81.8.1 General information

Incidence: traditionally quoted as 20–28\% of all SAH, but this includes data from older series (some did not perform true pan-angiography, and/or CT was not available to R/O intracerebral hemorrhage). Recent estimates of incidence: 7–10\% This is a heterogeneous category, and a better term might be “angiogram-negative SAH”; see requirements to be met before considering an arteriogram to be negative (p.1161). The quantity of blood on CT may predict the chances of an arteriogram disclosing a cerebral aneurysm.\textsuperscript{80,81,82,83}

Patients with angiogram-negative SAH tend to be younger, less hypertensive, and more commonly male than those with positive angiography.\textsuperscript{81}

Possible causes of SAH with a negative angiogram include:

- Aneurysm that fails to be demonstrated in initial angiogram:
  1. inadequate angiography, causes include:
     a) incomplete angio: (p.1161)
        - must see both PICA origins (1–2\% of aneurysms occur here)
        - need to cross-fill through the ACoA (p.1161)
     b) degradation of images due to
        - poor patient cooperation (e.g. from agitation). Either sedate patient (use caution in non-intubated patients) or repeat the study at a later time when patient more cooperative
        - poor quality equipment providing substandard images
  2. obliteration of aneurysm by the hemorrhage
  3. thrombosis of the aneurysm after SAH (p.1194)
  4. aneurysm too small to be visualized\textsuperscript{84}: although “microaneurysms” may be a source of SAH, their natural history and optimal treatment are unknown
  5. lack of filling of aneurysm due to vasospasm (of parent artery or of aneurysmal orifice)

Nonaneurysmal SAH from source that fails to show up on angiography. See for etiologies of SAH other than aneurysm (p.1156) (many of which may not be demonstrated on angiography), including:

- angiographically occult (or cryptic) vascular malformation (p.1246)
- pretruncal nonaneurysmal SAH: see below
81.8.2 Risk of rebleeding

Overall rebleed rate is 0.5%/yr, which is lower than with aneurysmal SAH or rebleeding from AVMs. There is also a smaller risk of delayed cerebral ischemia (vasospasm). Neurological outcome is likewise better.

81.8.3 Management

General measures

These patients are still at risk for the same complications of SAH as with aneurysmal SAH: vasospasm, hydrocephalus, hyponatremia, rebleeding, etc. (p.1164) and (should be managed as any SAH (p.1163). Some subgroups may be at lower risk for complications and may be managed accordingly (e.g. below).

Repeat angiography

Yield of positive second angiogram after technically adequate negative study: 1.8–9.8%⁷ in early (pre-CT) studies, 2–24% quoted more recently.⁸⁴,⁸⁶,⁸⁷ CT scan findings are helpful in the decision to repeat angiography.⁸⁸ 70% of cases with diffuse SAH and thick layering of blood in the anterior interhemispheric fissure were associated with an ACoA aneurysm that showed up on repeat angiography.⁸² The absence of blood on CT (performed within 4 days of SAH), or thick blood in the perimesencephalic cisterns alone (see below) were unlikely to be associated with a missed aneurysm.

Recommendations regarding repeat angio:
1. repeat angio after ≈10–14 days (allows vasospasm & some clot to resolve; note: between 5–10 days there is decreased chance of seeing an aneurysm because of vasospasm; angiography at ≈day 10 permits surgery to be done if needed ≈at day 14 which is about the earliest time after the “no-op” window of day 3–12)
   a) technically adequate 4 vessel angiogram is negative, and evidence for SAH is strong
   b) original angio was incomplete or if there are suspicious findings
2. if CT localizes blood clot to particular area, place special attention to this area on repeat angio
3. do not repeat angio for classic pretruncal SAH (see below) or if no blood on CT
4. patients are usually kept in the hospital 10-14 days while waiting for repeat angio (to watch for and manage complication of SAH or rebleeding)

Third arteriogram:
If the 1st 2 arteriograms are negative, and the history is suggestive of aneurysmal SAH, a 3rd arteriogram 3–6 months after SAH has ≈1% chance of showing a source of bleeding.

Other studies

1. imaging studies of the brain: MRI (with MRA if available) or CT (with angio-CT if available). This may visualize an aneurysm that fails to show up on angiography, and may identify other sources of SAH such as angiographically occult vascular malformation (p.1246), tumor...
2. tests to rule-out spinal AVM: a rare cause of intracerebral SAH (p.1140)
   a) spinal MRI: cervical, thoracic and lumbar
   b) spinal angiography: too difficult and risky to be justified in most cases of angio negative SAH.
   Consider in cases with high suspicion of spinal source

Surgical exploration

Advocated by some for cases of SAH with CT findings compatible with an aneurysmal source in which a suspicious area is demonstrated angiographically⁸⁴ with careful explanation to the patient and family of the possibility of negative operative findings.

81.9 Pretruncal nonaneurysmal SAH (PNSA H)

81.9.1 General information

Née perimesencephalic nonaneurysmal SAH.⁸⁹ The suggestion to change the name to pretruncal nonaneurysmal SAH was proposed because neuroimaging has shown the true anatomic localization of the blood to be in front of the brain stem (truncus cerebri) centered in front of the pons rather
than perimesencephalic. The existing literature on PNSAH is somewhat limited by the lack of a rigorous anatomic definition, with criteria of blood pattern differing amongst studies. Blood often extends into the interpeduncular or premedullary cisterns. It has also sometimes been referred to as the "Dutch disease" due to the initial profusion of information in that literature.

A distinct entity considered to be a benign condition with good outcome and less risk of rebleeding and vasospasm than other patients with SAH of unknown etiology (no rebleeding occurred in 37 patients with PNSAH and 45 months mean follow-up, nor in 169 patients with 8–51 months follow-up); vasospasm has been reported in only 3 patients and may have been related to cerebral angiography rather than the PNSAH, and although it is low, the incidence of angiographic vasospasm may be higher than originally thought.

The actual etiology has yet to be determined (there are 3 case reports of patients explored surgically with no abnormal findings and one case where a pontine abnormality resembling a capillary telangiectasia was demonstrated on MRI), but it may be secondary to rupture of a small perimesencephalic vein or capillary. Studies have shown an association with abnormal venous anatomy, including primitive variants of the basal vein of Rosenthal, which some authors have hypothesized results in hemorrhage secondary to central cerebral venous hypertension. Other proposed etiologies include a ruptured perforating artery, cavernous malformation, intraluminal basilar dissection, and capillary telangiectasia.

81.9.2 Presentation

Patients may present with severe paroxysmal H/A, meningismus, photophobia, and nausea. Loss of consciousness is rare. These patients are usually not critically ill (all were grade 1 or 2 (H&H or WFNS grading scale)), however, complications such as hyponatremia or cardiac abnormalities may still occur. Preretinal hemorrhages and sentinel H/A have not occurred. CT and/or MRI demonstrate characteristic findings (see below) although it may initially be missed on CT, and LP may yield bloody CSF. By definition, all have negative angiography.

81.9.3 Epidemiology

PNSAH has been reported to comprise 20–68% of cases of angiogram-negative SAH depending on the timing of CT, adequacy of angiography, and the definition of PNSAH. However, the true incidence is probably more in the range of 50–75%.

The reported age range is 3–70 years (mean: 50 yrs), 52–59% are male, and pre-existing HTN was present in 3–20% of patients.

81.9.4 Relevant anatomy

Posterior fossa cisterns:

The perimesencephalic cisterns include: interpeduncular, crural, ambient and quadrigeminal cisterns. The preptontine cistern lies immediately anterior to the pons.

Liliequist’s membrane (LM) is basically considered to separate the interpeduncular cistern from the chiasmatic cistern (forming a competent barrier in only 10–30% of the population). In further detail, the superior leaflet of LM (diencephalic membrane) separates the interpeduncular cistern from the chiasmatic cistern medially and from the carotid cisterns laterally. The inferior leaflet (the mesencephalic membrane) separates the interpeduncular from the preptontine cistern.

The diencephalic membrane is thicker and is more often competent, effectively isolating the chiasmatic cistern. However, the carotid cisterns often communicate with the crural cisterns and in turn with the interpeduncular cistern.

Thus, blood in the carotid or preptontine cistern is compatible with a low-pressure pretrunca1 source of bleeding, however, blood in the chiasmatic cistern should raise concern about aneurysmal rupture.

81.9.5 Diagnostic criteria

Without knowledge of the actual substrate of PNSAH, the following suggested diagnostic criteria must be viewed as empiric (adapted):

1. CT or MRI scan performed ≤2 days from ictus meeting the criteria shown in Table 81.5 (later scans render the diagnosis unreliable, e.g. washout could cause an aneurysmal SAH to fit the criteria). This criteria implies that blood should be contained inferior to Liliequist’s membrane (LM) (i.e. perimesencephalic and/or preptontine cisterns). Extension into the suprasellar cistern is
common. Significant amounts of blood penetrating LM to the chiasmatic, sylvian, or interhemispheric cisterns should be viewed with suspicion

2. a negative high-quality 4-vessel cerebral angiogram (radiographic vasospasm is common, and does not preclude the diagnosis nor does it mandate repeat angiography). NB: ≈ 3% of patients with a ruptured basilar bifurcation aneurysm meet the criteria of Table 81.5, therefore an initial arteriogram is mandatory

3. appropriate clinical picture: no loss of consciousness, no sentinel H/A, SAH grade 1 or 2 (Hunt and Hess or WFNS grading scale) (p. 1162), and absence of drug use. Variance from this should raise suspicion of alternate pathogenesis

Recently, a more stringent set of anatomic criteria (see Table 81.6) was tested and found to result in excellent inter-observer agreement (97.2%) in PNSAH. Additionally, no aneurysms were identified on formal angiography when the anatomical criteria were met.108

### 81.9.6 Repeat angiography

Controversial. Angiography carries ≈ 0.2–0.5% risk of permanent neurologic deficit in this population.57 Most experts agree that repeat angiography is not indicated in patients meeting the criteria of PNSAH6,105 (although others recommend repeat angiography in all surgical candidates84,109). One should probably repeat the study if any uncertainty exists or if there is a history of a condition associated with increased risk of cerebral aneurysms.93

### 81.9.7 Treatment

Optimal treatment is not known with certainty. The low risk of rebleeding and delayed ischemia suggests that extreme measures are not indicated. The following recommendations are made37,93 (period not specified):

1. symptomatic treatment
2. cardiac monitoring
3. electrolyte monitoring for hyponatremia
4. follow patient clinically (and if appropriate, with repeat imaging studies) to rule-out hydrocephalus (transient ventricular enlargement is common, however, hydrocephalus requiring shunting is rare (only ≈ 1%47)
5. not recommended
   a) hyperdynamic therapy
   b) calcium channel blockers: use has not been investigated in PNSAH, but is probably not warranted due to low incidence of vasospasm and should be discontinued when normal angiographic findings are documented93
   c) activity restrictions (except in cases of increasing H/A with mobilization)
   d) anticonvulsants
   e) reduction of blood pressure below normal
   f) surgical exploration

82 Vascular Malformations

82.1 General information and classification

This designation encompasses a number of non-neoplastic vascular lesions of the CNS. The four types originally described by McCormick in 1966 are shown in Table 82.1.

Possible additional categories:
1. direct fistula AKA arteriovenous fistula (AV-fistula, not AVM). Single or multiple dilated arteries that connect directly to a vein without a nidus. These are high-flow, high-pressure. Low incidence of hemorrhage. Usually amenable to interventional neuroradiological procedures. Examples include:
   a) vein of Galen malformation (aneurysm) (p.1255)
   b) dural AVM (p.1251)
   c) carotid-cavernous fistula (p.1256)
2. mixed or unclassified angiomas: 11% of AOVMs

82.2 Arteriovenous malformation (AVM)

82.2.1 General information

Key concepts
- dilated arteries and veins with dysplastic vessels. Arterial blood flows directly between them with no capillary bed and no intervening neural parenchyma in nidus
- AVMs are medium-to-high pressure and high-flow
- usually presents with hemorrhage, less often with seizures
- these usually are congenital lesions with a lifelong risk of bleeding of ≈ 2–4% per year
- demonstrable on angiography, MRI, or CT (especially with contrast)
- main treatment options: stereotactic radiosurgery (usually for deep lesions <3 cm dia) or surgical excision

82.2.2 Description

An abnormal collection of blood vessels wherein arterial blood flows directly into draining veins without the normal interposed capillary beds. There is no brain parenchyma contained within the nidus. AVMs are usually congenital lesions, that tend to enlarge somewhat with age and often progress from low flow juvenile lesions at birth to medium-to-high flow high-pressure lesions in adulthood. AVMs appear grossly as a “tangle” of vessels, often with a fairly well-circumscribed center (nidus), and draining “red veins” (veins containing oxygenated blood). May be classified as:
1. parenchymal AVMs (discussed below). Subclassified as:
   a) pial
   b) subcortical
   c) paraventricular
   d) combined

Table 82.1 4 classic types of vascular malformation

</tr>
</tbody>
</table>

*Sometimes referred to as “pial AVM” to distinguish it e.g. from dural AVM
2. pure dural AVM (p.1251)
3. mixed parenchymal and dural (rare)

82.2.3 Epidemiology
Prevalence: probably slightly greater than the usually quoted 0.14%.
Slight male preponderance. Congenital (therefore risk of hemorrhage is lifelong).
A few types are known to be hereditary. Other types are part of known hereditary syndromes:
15–20% of patients with Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia) have
cerebral AVMs.

82.2.4 Comparison to aneurysms
See reference.\(^3\)
AVM: aneurysm ratio in U.S. is 1:5.3 (pre-CT era data). The average age of patients diagnosed with
AVMs is ≈ 33 yrs, which is ≈ 10 yrs younger than aneurysms.\(^4\) 64% of AVMs are diagnosed before age
40 (c.f. 26% for aneurysms).

82.2.5 Presentation
General information
1. hemorrhage (most common): 50% (61% quoted elsewhere,\(^3\) compared to 92% for aneurysms)
   (see below)
2. seizures
3. mass effect: e.g. trigeminal neuralgia due to CPA AVM
4. ischemia: by steal
5. H/A: rare. AVMs may occasionally be associated with migraines. Occipital AVMs may present with
   visual disturbance (typically hemianopsia or quadrantanopsia) and H/A that are indistinguishable
   from migraine\(^6\)
6. bruit: especially with dural AVMs (p.1251)
7. increased ICP
8. findings limited almost exclusively to peds, usually with large midline AVMs that drain into an
   enlarged vein of Galen (“vein of Galen malformation” (p.1255)):
   a) hydrocephalus with macrocephaly: due to compression of Sylvian aqueduct by enlarged vein
      of Galen or to increased venous pressure
   b) congestive heart failure with cardiomegaly
   c) prominence of forehead veins (due to increased venous pressure)

Hemorrhage
General information
Peak age for hemorrhage is between 15–20 yrs.\(^3\) The reported morbidity and mortality from AVM
hemorrhage varies widely. An estimate is 10% mortality, 30–50% morbidity\(^7\) (neurological deficit)
from each bleed. For a discussion of hemorrhage during pregnancy, also see Pregnancy & intracranial
hemorrhage (p.1169).

Hemorrhage location with AVMs
1. intraparenchymal (CH): 82% (the most common site of bleeding)\(^8\)
2. intraventricular hemorrhage:
   a) usually accompanied by ICH as the result of rupture of the ICH into the ventricle
   b) pure IVH (with no ICH) may indicate an intraventricular AVM
3. subarachnoid: SAH may also be due to rupture of an aneurysm on a feeding artery; common with
   AVMs (p.1156)
4. subdural: uncommon. May be the source of a spontaneous SDH (p.904)

Hemorrhage rate related to AVM size
Small AVMs tend to present more often as hemorrhage than do large ones.\(^9,10\) It was postulated that
larger AVMs presented as seizure more often simply because their size made them more likely to
involve the cortex. However, small AVMs are now thought to have much higher pressure in the feeding
arteries\(^10\) (see Table 82.2). Conclusion: small AVMs are more lethal than larger ones.
Hemorrhage rate related to Spetzler-Martin grade

Controversial. Some studies show increased risk with Spetzler-Martin (S-M) grade 4–5 AVMs (p.1242)\(^\text{11}\) (high grade), others show the opposite effect as:

- S-M grade 1–3: annual risk of hemorrhage is 3.5%.
- S-M grade 4–5: annual risk of hemorrhage is 2.5%.

Hemorrhage rate based on nidus depth, venous drainage and prior bleed

Breakdown of the risk of bleeding based on history of prior bleeding, venous drainage pattern, and nidus location using data from Stapf et al. is shown in Table 82.3.

Annual and lifetime risk of hemorrhage and recurrent hemorrhage

The average risk of hemorrhage from an AVM is \(\approx 2–4\%\) per year\(^\text{13}\) (reminder: risk varies by AVM size, see above). The risk of bleeding over the remainder of one’s life is given by Eq (82.1); this analysis includes a number of assumptions, among them: a constant risk of rebleeding even early after an initial bleed, no change in risk during the lifetime (which may not be true in pregnancy), no difference in risk for various AVM locations or age groups.

risk of bleeding at least once\(^{\text{b}}\)=\(\frac{1}{\text{expected years of remaining life}}\)

\[\text{risk of bleeding at least once} = \frac{1}{\text{expected years of remaining life}}\]

where the annual risk of not bleeding is equal to 1 – the annual risk of bleeding. For example, if a 3% annual risk of bleeding is used as an average, and the remaining life expectancy is 25 years, the result is as illustrated in Eq (82.2).

\[\text{risk of bleeding at least once in 25 years} = \frac{1}{0.97^{25}} \approx 0.53\]

A simple to apply first approximation to Eq (82.1) is shown in Eq (82.3).

\[\text{risk of bleeding at least once} \approx 105 \times \text{age in years}\]

*Note: Eq (82.3) assumes a 3% per year bleeding rate.

Table 82.4 shows the risk for various ages using Eq (82.1) (longevity is taken from insurance life-tables).

82

Vascular Malformations
A study of 166 symptomatic AVMS with long average follow-up (mean: 23.7 yrs) found the risk of major bleeding was constant at 4% per year, and that this was independent of whether the AVM presented with or without hemorrhage. The mean time between presentation and hemorrhage was 7.7 yrs. The mortality rate was 1% per year, and the combined major morbidity and mortality rate was 2.7% per year.

Older studies may suffer from smaller numbers or short follow-up (mean: 6.5 yrs). These studies suggested a higher risk of (re)bleeding depending on whether the initial presentation was hemorrhage (≈3.7% per year) vs. seizure (1–2% per year). Crawford found that none of 8 incidental (asymptomatic) AVMs bled in 20 yrs follow-up; all died of unrelated causes.

The hemorrhage risk (but not the rate) may be higher in pediatrics or with posterior-fossa AVMs.

Rebleeding
The literature contains conflicting information. Reported rebleeding rate in the first year after hemorrhage was 6% in one series,15 18% in another series13 which declined to 2% per year after 10 years, and in another large series4 the annual rate was 4% and did not vary regardless of presentation as discussed above.

Seizures
The younger the patient at the time of diagnosis, the higher the risk of developing convulsions. 20 yr risk: diagnosis at age 10–19 → 44% risk; age 20–29 → 31% age 30–60 → 6% Patients presenting with hemorrhage have 22% risk of developing epilepsy in 20 yrs. No AVM found incidentally or presenting with neuro deficit developed seizures.

AVMs and aneurysms
7% of patients with AVMs have aneurysms. 75% of these are located on major feeding artery (probably from increased flow). These aneurysms may be classified into 1 of 5 types shown in Table 82.5. Aneurysms also may form within the nidus or on draining veins. When treating tandem AVMs and aneurysms, the symptomatic one is usually treated first (when feasible, both may be treated at the same operation). If it is not clear which bled, the odds are that it was the aneurysm. Although a significant number (>66%) of related aneurysms will regress following removal of the AVM, this does not always occur. In one series, none of the 9 associated aneurysms ruptured or enlarged following AVM removal.

82.2.6 Evaluation

CT
Unenhanced brain CT is the best study to rule-out acute hemorrhage. Can also demonstrate calcifications within the lesion. Adding a contrast CT will show enhancement within the vessels, and can delineate the nidus (dense central area of an AVM). See below for CTA.

MRI
Characteristics of AVM on MRI:
1. flow void on T1WI or T2WI within the AVM
2. feeding arteries
3. draining veins
4. increased intensity on partial flip-angle (to differentiate signal dropout on T1WI or T2WI from calcium)
5. significant edema around the lesion may indicate a tumor that has bled rather than an AVM
6. gradient echo sequences (GRASS…) help demonstrate surrounding hemosiderin which suggests a previous significant hemorrhage
7. a complete ring of low density (due to hemosiderin) surrounding the lesion suggests AVM over neoplasm

82.2.7 CT angiography (CTA)

MR angiography (MRA)

Angiography
Characteristics of AVM on angiography:
1. tangle of vessels
2. large feeding artery
3. large draining veins
4. draining veins are visualized in the same images as arteries (arterial phase)

Most, but not all AVMs show up on angiography; see Angiographically occult vascular malformations (p.1246). Fewer cavernous malformations and venous angiomas do.

Grading

Spetzler-Martin grade of AVMs
Grade = sum of points from Table 82.6, ranges from 1 to 5. A separate grade 6 is reserved for untreatable lesions (by any means: surgery, SRS…), resection of these would almost unavoidably be associated with disabling deficit or death. This scale has been shown to have good prognostic predictability.\(^\text{17}\) May not be applicable to pediatrics (AVMs are immature and change with time; AVMs mature at \(\approx\) age 18 yrs and tend to become more compact).

Outcome based on Spetzler-Martin grade: 100 consecutive cases operated by an expert (Spetzler) had the outcomes shown in Table 82.7 (no deaths).

Spetzler has since published a 3-tiered management recommendation scheme\(^\text{19}\) as follows:

- Class A (S-M Grade I & II): surgical resection

| Table 82.5 Categories of aneurysms associated with AVMs\(^\text{16}\) |
|-----------------|------------------|
| Type | Aneurysm location |
| I | proximal on ipsilateral major artery feeding AVM |
| IA | proximal on major artery related but contralateral to AVM |
| II | distal on superficial feeding artery |
| III | proximal or distal on deep feeding artery (“bizarre”) |
| IV | on artery unrelated to AVM |

*excludes intra-nidal and venous aneurysms
Class B (S-M Grade III): multimodality treatment
Class C (S-M Grade IV & V): follow clinically and repeat angiogram every 5 years. Treatment only for progressive neurologic deficit, steal-related symptoms, or aneurysms identified on surveillance angiograms

82.2.8 Treatment

General information

Options and some pros and cons of each include:

1. surgery: the treatment of choice for AVMs. When surgical risk is unacceptably high, alternative procedures (e.g. SRS) may be an option
   a) pros: eliminates risk of bleeding almost immediately. Seizure control improves
   b) cons: invasive, risk of surgery, cost (high initial cost of treatment may be offset by effectiveness or may be increased by complications)

2. radiation treatment
   a) conventional radiation: effective in \( \approx 20\% \) or less of cases. Therefore not considered effective therapy
   b) stereotactic radiosurgery (SRS): accepted for some small (\( \leq 2.5-3 \) cm nidus), deep AVMs; see Stereotactic radiosurgery & radiotherapy (p. 1564)

</tbody>
</table>

\( ^a \) minor deficit: mild brainstem deficit, mild aphasia, mild ataxia

\( ^b \) major deficit: hemiparesis, increased aphasia, homonymous hemianopsia
• pros: done as an outpatient, non-invasive, gradual reduction of AVM flow, no recovery period
• cons: takes 1–3 years to work (latency period). During that time there is a risk of bleeding, controversial whether it is increased or decreased; limited to lesions with nidus ≤3 cm

3. endovascular techniques: e.g. embolization (see below)
   a) pros: facilitates surgery
   b) cons: sometimes inadequate by itself to permanently obliterate AVMs, induces acute hemodynamic changes, may require multiple procedures, embolization prior to SRS reduces the obliteration rate from 70% (without embolization) to 47% (with embolization)22

4. combination techniques: e.g. embolization to shrink nidus then stereotactic radiosurgery

Considerations to take into account in managing AVMs:
1. associated aneurysms: on feeding vessels, draining veins or intra-nidal
2. flow: high or low
3. age of patient
4. history of previous hemorrhage
5. size and compactness of nidus
6. availability of interventional neuroradiologist
7. general medical condition of the patient

Embolization
Used as an initial procedure, embolization facilitates surgery23 and possibly SRS. It is usually inadequate by itself to treat conventional AVMs (may recanalize later). See AVM embolization (p.1589) in Endovascular neurosurgery section.

Surgical treatment
Pre-op medical management
Before direct surgical treatment, patient should ideally be pre-treated with propranolol 20 mg PO QID for 3 days to minimize post-op normal perfusion pressure breakthrough (postulated cause of postoperative bleeding and edema,24 see below). Labetalol has also been used perioperatively to keep MAP 70–80 mm Hg.25

Booking the case: Craniotomy for AVM

Also see defaults & disclaimers (p.27).
1. position: (depends on location of AVM), radiolucent headholder
2. pre-op embolization (by neuroendovascular interventionalist): typically 24–48 hours pre-op
3. intraoperative angiography (optional)
4. equipment
   a) microscope (with ICG capability if used)
   b) image-guided navigation: primarily for the bone flap placement
5. blood availability: type and cross 2 U PRBC
6. post-op: ICU
7. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery to open the skull and remove the abnormal tangle of blood vessels in the brain, intraoperative angiography
   b) alternatives: stereotactic radiosurgery, endovascular techniques (not considered definitive treatment for most AVMs, but often used as an adjunct)
   c) complications: usual craniotomy complications (p.28) plus stroke (the main concern), bleeding intra-op (requiring transfusion) and post-op, neurologic deficit related to the area of AVM location, failure to be able to remove entire AVM, recurrence in future

Basic tenets of AVM surgery
1. wide exposure
2. occlude feeding (terminal) arteries before draining veins (lesions with a single draining vein can become impossible to deal with if premature blockage of the draining vein occurs, e.g. by kinking, coagulation)
3. excision of whole nidus is necessary to protect against rebleeding (occluding feeding arteries is not adequate)
4. identify and spare vessels of passage and adjacent (uninvolved) arteries
5. dissect directly on nidus of AVM, work in sulci and fissures whenever possible
6. in lesions that are high-flow on angiography, consider preoperative embolization
7. lesions with supplies from multiple vascular territories may require staging
8. clip accessible aneurysms on feeding arteries

Delayed postoperative deterioration
May be due to any of the following:
1. normal perfusion pressure breakthrough\textsuperscript{24}, characterized by post-op swelling or hemorrhage. Thought to be due to loss of autoregulation, although this theory has been challenged.\textsuperscript{26} Risk may be reduced by pre-op medication (see above)
2. occlusive hyperemia\textsuperscript{27}; in the immediate post-op period probably due to obstruction of venous outflow from adjacent normal brain, in a delayed presentation may be due to delayed thrombosis of draining vein or dural sinus.\textsuperscript{28} Risk may be elevated by keeping the patient “dry” post-op
3. rebleeding from a retained nidus of AVM
4. seizures

82.2.9 Follow-up of treated AVMs
When satisfactory complete angiographic obliteration of an AVM has been accomplished, recommended follow-up is with catheter angiogram (not CTA or MRA) at 1 & 5 years post treatment.

82.3 Venous angiomas
82.3.1 General information

Key concepts
- a vascular malformation that is part of the venous drainage of the involved area with intervening brain present. Therefore direct treatment is rarely indicated
- low-flow, low-pressure
- usually demonstrable on angiography as a starburst pattern
- rarely symptomatic: seizures rare, hemorrhage even more uncommon. Venous infarcts may occur (controversial)
- may have an associated cavernous malformation (p.1247) which is more likely to be symptomatic

AKA venous malformation or (developmental) venous anomaly (DVA). A tuft of medullary veins that converge into an enlarged central trunk that drains either to the deep or superficial venous system. The veins lack large amounts of smooth muscle and elastic. No abnormal arteries are found. There is neural parenchyma between the vessels. Most common in regions supplied by the MCA\textsuperscript{29} or in the region of the vein of Galen. They may be associated with a cavernous malformation (p.1247). Non hereditary. These are low-flow and low-pressure.

Most are clinically silent, but rarely seizures and even less frequently hemorrhage may occur. Venous infarcts have been described, but may be coincidental. If symptoms are present, look for an associated cavernous malformation (GRASS MRI images may reveal some cavernous malformations that might otherwise be occult).

82.3.2 Imaging

MRI
There may be some T2 hyperintensity on FLAIR.

Angiogram
Occasionally may be angiographically occult, however, they classically produce a distinct caput medusae (other descriptive terms include: a hydra, spokes of a wheel, a spider, an umbrella, a
mushroom, or a sunburst or starburst. Other angiographic characteristics: appears as a long draining vein (longer than a normal vein) draining an excessive amount of brain tissue (it is theorized that venous restrictive disease occurs because of the length), arterial phase should show no AV shunting (characteristic of AVM).

82.3.3 Treatment
In general, these should not be treated as they are the venous drainage of the brain in that vicinity. If surgery is indicated for associated cavernous malformations, the angioma should be left alone. Surgery for the angioma itself is reserved only for documented bleeding or for intractable seizures that can be definitely attributed to the lesion.

82.4 Angiographically occult vascular malformations
82.4.1 General information
Terminology is controversial. The term “cryptic cerebrovascular malformations” was originally applied to angiographically and clinically silent lesions regardless of size. Recommendation: use the term “angiographically occult (or cryptic) vascular malformations” (AOVM) to refer to cerebrovascular malformations that are not demonstrable on technically satisfactory catheter cerebral angiography (i.e. good quality films, with subtraction views, and the following as appropriate: magnification, angiotomography, rapid serial angiograms or delayed films). Many lesions have large patent vessels at surgery in spite of negative angiography. Other imaging modalities (i.e. CT, MRI) may be able to reveal these lesions. Although often used interchangeably, the term “occult malformation” (omitting the word “angiographically”) is suggested for use with lesions that also do not appear on these other imaging modalities.

The reasons for a vascular lesion being angiographically cryptic include:
1. lesion that have hemorrhaged
   a) the bleeding may obliterate the lesion: difficult to substantiate
   b) the clot may temporarily compress the lesion which may re-open after weeks to months as clot dissolves
2. sluggish flow
3. small size of the abnormal vessels
4. may require very late angiographic films (i.e. delayed films) to visualize due to late filling

82.4.2 Epidemiology
Incidence of AOVM has been estimated as ≈ 10% of cerebrovascular malformations. AOVMs were found at necropsy in 21 (4.5%) of 461 patients with spontaneous intracranial hemorrhage (ICH), but refinements in angiography have occurred since this 1954 report. The average age at diagnosis in one literature review was 28 yrs.

82.4.3 Presentation
AOVM most often present with seizures or H/A. Less commonly they may present with progressive neurologic symptoms (usually as a result of spontaneous ICH). They may also be discovered incidentally.

The natural history of this group of lesions is not accurately known.

82.5 Osler-Weber-Rendu syndrome
82.5.1 General information
AKA hereditary hemorrhagic telangiectasia (HHT), AKA capillary telangiectasia: slightly enlarged capillaries with low flow. Cannot be imaged on any radiographic study. Usually incidentally found at necropsy without clinical significance (risk of hemorrhage is very low, except possibly in brain stem). Has intervening neural tissue (unlike cavernous malformations). Usually solitary, but may be multiple when seen as a part of a syndrome: Osler-Weber-Rendu (see below), Louis-Barr (ataxia telangiectasia), Myburn-Mason, Sturge-Weber.

Associated cerebrovascular malformations (CVM) include: telangiectasias, AVMs (the most common CVM, seen in 5–13% of HHT patients), venous angiomas and aneurysms. Patients are also
prone to pulmonary arteriovenous fistulas with associated risk of paradoxical cerebral embolism which predisposes to embolic stroke and cerebral abscess formation (p.320).

82.5.2 Epidemiology
Rare autosomal dominant genetic disorder of blood vessels affecting ≈ 1 in 5,000 people. 95% have recurrent epistaxis.

82.5.3 Imaging
CT
May show a well demarcated homogeneous or mottled high density (high density due to hematoma, calcification, thrombosis, hemosiderin deposition, alterations in BBB, and/or increased blood volume) with some form of contrast enhancement (around or within lesion) in 17 of 24 patients. Surrounding edema or mass effect is rare (except in cases that have recently hemorrhaged).

MRI
May demonstrate previous hemorrhage(s), (may be important when the presence of multiple occurrences affects therapeutic choices). T2WI finding: reticulated core of increased and decreased intensity, a prominent surrounding rim of reduced intensity may be present (due to hemosiderin laden macrophages from previous hemorrhages). GRASS image demonstrates flow related enhancement in ≈ 60% of cases, which allows signal dropout from flowing blood on other sequences to be differentiated from that due to calcium (and thus, bone) or air (limitations: hemosiderin causes signal dropout, and slow in-plane flow does not enhance).

82.5.4 Treatment
Surgery is indicated mainly for evacuation of hematoma or diagnosis, especially when favorably located. Also consider surgery for recurrent hematomas (rupture has been reported even after normal angiography) or medically intractable seizures. Stereotactic radiosurgery has not had a satisfactorily high enough benefit to risk ratio to justify its use.

82.6 Cavernous malformation
82.6.1 General information
AKA: cavernous hemangioma, cavernoma, cavernous angioma, angioma, and in medical jargon “cav-mal.” A well-circumscribed, benign vascular hamartoma consisting of irregular thick and thin walled sinusoidal vascular channels located within the brain but lacking intervening neural parenchyma, large feeding arteries, or large draining veins. Usually 1–5 cm in size. May hemorrhage, calcify, or thrombose. Occur rarely in the spinal cord. Caverns are filled with blood in various stages of thrombus formation/organization/dissolution. Frequently associated with venous angiomas (p.1245). Capillary telangiectasias may be found adjacent to lesions and may represent a precursor. Stain positive for angiogenesis factor. Lesions may arise de novo and may grow (although slower than hemangioblastomas), shrink, or remain unchanged with time.
82.6.2 Pathology
Gross appearance resembles a mulberry (facetiously dubbed a “hemorrhoid of the brain”). Light microscopy: stains for von Willebrand’s factor. Smooth muscle layer is absent (except for some tiny portions). EM: shows abnormal gaping of the tight junctions between endothelial cells\(^{44}\) (may permit leakage of blood) and sparse or poorly characterized subendothelial smooth muscle cells.\(^{54}\)

82.6.3 Epidemiology
Cerebral cavernous malformations (CM) comprise 5–13% of CNS vascular malformations, and develop in 0.02–0.13% of the population (based on large autopsy\(^{45}\) and MRI\(^{46}\) series). 48–86% are supratentorial, 4–35% brainstem, 5–10% basal ganglia.\(^{47}\) Multiple in 23\(^{48}\) to 50\(^{49}\) of cases, and multiplicity may be more common in hereditary cases.\(^{50}\)

Spinal CMs: CMs rarely may occur in spinal cord. XRT appears to be a risk factor,\(^{51}\) (e.g. following craniospinal XRT\(^{52}\) for medulloblastoma) especially for spinal CMs. 42% of patients with spinal CMs also harbor \(\geq 1\) intracranial CM.\(^{53}\)

82.6.4 Genetics
Two types: sporadic and hereditary. The latter may be inherited in a Mendelian autosomal dominant pattern with variable expressivity.\(^{54}\) There appears to be at least 3 gene loci (see Table 82.8). Multiple lesions are more common in the familial form.\(^{56}\)

82.6.5 Presentation/natural history
See references.\(^{55,56,57}\)

General information
Seizures (60%), progressive neurologic deficit (50%), hemorrhage (20% usually intraparenchymal; note: here, hemorrhage is defined as symptomatic, radiologically proven extralesional bleeding), hydrocephalus, or as an incidental finding (over 50% in one series).

Hemorrhage
Risk is not well delineated. Even the definition of hemorrhage is controversial since, by definition, all CMs have surrounding hemosiderin indicative of small leaks. The Angioma Alliance\(^{58}\) definition of hemorrhage: acute or subacute symptoms (any of: headache, seizure, impaired consciousness, or new/worsened focal neurological deficit referable to the anatomic location of the CM) accompanied by radiological, pathological, surgical, or rarely only cerebrospinal fluid evidence of recent extra- or intralesional hemorrhage. This definition does not include either an increase in CM diameter without other evidence of recent hemorrhage, nor the presence of a hemosiderin halo. Risk of significant hemorrhage is much less than with AVMs. CMs are prone to recurrent small hemorrhages that are rarely devastating. Hemorrhage rate tends to be low in cohort studies \(\approx 2.6–3.1\%\text{yr}\); appears higher in females (4.2\%\text{yr}) than males (0.9\%\text{yr}).\(^{46}\) Bleeding risk is not related to the size of the CM. Controversial if hemorrhage increases the risk of future bleeding: it did not in one study\(^{46}\) whereas another study\(^{59}\) found only a 0.6\%\text{yr} risk of bleeding in lesions without prior hemorrhage. Some CMs behave benignly after an initial hemorrhage. Others behave more malignant with (>2 hemorrhages) with increasingly more detrimental outcome. Pregnancy and parturition are not known to be risk factors for hemorrhage.\(^{54}\)

</tbody>
</table>
The bleeding rate is variable & the criteria for what constitutes “bleeding” has not been uniform. Each patient appears to have their own natural history it is difficult to assign a risk of hemorrhage for any individual patient.

Seizures
The rate of new-seizure onset is 2.4%/yr.46

82.6.6 Evaluation
CT
Not sensitive: CT misses many small lesions, some large ones, and even some that have bled. Not specific: CT findings may overlap with low grade tumors, hemorrhages, granulomas.

MRI
Gradient-echo T2WI MRI is the most sensitive test due to high sensitivity to susceptibility artifact. Findings are similar to AVM in general (mixed signal core with low signal rim – sometimes described as “popcorn” pattern; see above). The diagnosis is strongly suggested by finding multiple lesions with these characteristics and a positive family history.49 A venous malformation may be seen adjacent to a solitary CM, but not with multiple CMs.60 Diffusion tensor imaging/white matter tractography61 and pre-op 3D-constructive interference in steady-state (CISS) MRI62 may improve localization, approach, and post-op outcomes.

Angiography
Does not demonstrate lesion. MRI appearance is nearly pathognomonic, and angiography is not necessary in classically appearing cases. Angiography may be needed to R/O other diagnoses in questionable cases.

Familial considerations
First degree relatives of patients with more than one family member having a cavernous malformation should have MRI screening and appropriate genetic counselling.

82.6.7 Treatment/management
Overview
Options:
1. observe
2. surgical excision
3. XRT or stereotactic radiosurgery.63,64,65,66 Controversial: results appear comparable to natural history

No randomized prospective study has been done. Determining treatment response is difficult since no imaging study can prove elimination of the lesion. Therefore it has been suggested that recurrent hemorrhage rate be followed as an endpoint.

Recommendations
Incidental lesions
Asymptomatic, incidentally discovered CMs should be managed expectantly with serial imaging studies for about 2–3 years (to rule-out frequent subclinical bleeds); additional studies thereafter based on clinical grounds. However, some experts recommend removal for single, easily accessible incidental CMs in non-eloquent brain.67
Since the radiographic appearance is almost pathognomonic, biopsy or excision solely to verify the diagnosis is rarely appropriate.

**Brainstem CMs**

Surgery is almost never indicated for brainstem CMs that have not bled. With a bleed rate of 2–6%, Gross et al.\(^6^8\) suggest operative management for a history of \(>2\) prior hemorrhages and “pial/ependymal representation” on T1WI MRI.

Bleeds that do not come to the surface cannot be removed without creating neurologic deficit (worsening of neurologic outcome was 9% vs. 29% in superficial vs. deep brainstem CM resections, respectively\(^6^9\)). The approach is chosen to expose the site where the bleed comes closest to the surface. Spetzler says brainstem CMs are almost always associated with a venous angioma (which, again, must be preserved since it provides the venous outflow). Outcome was worse with surgery through the floor of the 4th ventricle than with a lateral approach. Significant short-term neurologic deficit is expected with brainstem CM resection.\(^6^8\)

**Spinal cord CMs**

Managed essentially the same as brainstem CMs.

**Cranial nerve CMs**

Many case reports and reviews document CMs of cranial nerves (rarely extra-axial) with various presentations.\(^7^0,7^1,7^2\) Case reports suggest patients may benefit from early surgical decompression from hemorrhagic chiasmal cavernomas since they are at risk for recurrent micro-hemorrhages.\(^7^3\)

**Surgery**

**General information**

Indications for surgery for intracranial CMs:

1. Accessible lesions with
   a) Focal deficit
   b) Or symptomatic hemorrhage
   c) Or seizures:
      - New onset seizures (p.461): there is a suggestion that removing CMs before “kindling” occurs may have a better chance of preventing future seizures
      - Difficult to manage seizures

2. Less accessible lesions that repeatedly bleed with progressive neurologic deterioration may be considered for excision, even in delicate regions such as the brain stem\(^7^4,7^5,7^6\) or spinal cord

**Surgical technique**

Goal of surgery: complete removal of the malformation. Since CMs are not particularly bloody, piecemeal excision is an option; especially important in brainstem lesions.

Stereotactic localization or intraoperative ultrasound may be particularly helpful in localizing. When operating on CMs that have bled, one usually encounters a cavity containing the CM and blood degradation products.\(^7^7\) Initial dissection is directed at separating the lesion from the adjacent brain. Although bleeding is usually not a problem, it occasionally may be brisk if the CM is entered before the dissection and devascularization is complete. Once the dissection is complete, the contents of the CM capsule may be removed piecemeal to minimize the parenchymal opening (especially important in the brainstem). For supratentorial CMs presenting with seizures, it is desirable to also remove the hemosiderin-stained brain immediately surrounding the CM.

Keep in mind the relatively common association of CMs with venous angiomas (p.1245), which if encountered should not be removed as they represent the venous drainage of the area.

**Brainstem CMs**

The use of retractors is to be avoided; cottonoids and exploitation of hematoma cavity may be used to gain access. Brainstem CMs may be extremely adherent to brain parenchyma\(^7^6\) unlike supratentorial CMs. Bipolar cautery: use on low power with constant irrigation to reduce thermal injury. Unlike supratentorial CMs with seizures (where you want to remove adjacent hemosiderin-stained brain), just remove the CM itself.

**Post-op follow-up**

Follow-up MRI \(\approx 3\) months post-op is recommended. It never looks “normal” but can determine if removal was complete.
Stereotactic radiosurgery (SRS)

Some non-controlled studies have shown a possible reduction in recurrent hemorrhage rate following a 2 year latency period after SRS, however, radiation induced morbidity was significant. Other series have failed to show reduction. Findings may reflect the natural history of CMs with temporal clustering of hemorrhagic events with decrease in hemorrhage rates after 28 months.

Evidence suggests that SRS is not an alternative to surgery and should not be considered for the treatment of CMs.

82.6.8 Prognosis

When CMs can be completely removed, the risk of further growth or hemorrhage is essentially permanently eliminated (however, recurrence of symptoms has been reported after partial and even seemingly-complete removal).

For CMs treated surgically, patients need to be aware that post-op neurologic worsening is very common, especially with brainstem CMs. Worsening may be transient, but may take months to resolve.

82.7 Dural arteriovenous fistulae (DAVF)

82.7.1 General information

AKA dural AVMs (DAVM). Vascular abnormality in which an arteriovenous shunt is contained within the leaflets of the dura mater, exclusively supplied by branches of the internal/external carotid or vertebral arteries. Because they are considered acquired rather than congenital lesions, the term fistula is preferred over malformation, although the latter term has also been used in the literature. Multiple fistulas may be found in up to 8% of cases. Usually found adjacent to dural venous sinuses. Common locations:
1. transverse/sigmoid: the most common (63% of cases) with a slight left-sided predominance
2. tentorial/petrosal
3. anterior fossa/ethmoidal
4. middle fossa/Sylvian
5. cavernous sinus (carotid-cavernous fistula – CCF)
6. superior sagittal sinus
7. foramen magnum

82.7.2 Etiology

Evidence suggests that most DAVFs are acquired, idiopathic lesions, and they have a well-recognized association with venous sinus thrombosis, although their exact pathogenesis is not fully understood. Theories include:
1. venous sinus occlusion awakens dormant embryonic dural arteriovenous channels
2. venous hypertension/thrombosis promotes local angiogenesis and the de novo formation of DAVF
3. the DAVF may arise first and itself result in venous sinus thrombosis

82.7.3 Epidemiology

DAVFs comprise 10–15% of all intracranial AVMs, 61–66% occur in females, and patients are usually in their 40s or 50s. They occur rarely in children, and when they do they tend to be complex, bilateral dural sinus malformations.

82.7.4 Presentation

Common findings are listed in Table 82.9. Pulsatile tinnitus is the most common presenting symptom of a DAVF. Cortical venous drainage with resultant venous hypertension can produce IC-HTN,
and this is the most common cause of morbidity and mortality and thus the strongest indication for DAVF treatment. DAVFs may also cause global cerebral edema or hydrocephalus due to poor cerebral venous drainage or by impairing the function of the arachnoid granulations, respectively. Other DAVF symptoms/signs include headaches, seizures, cranial nerve palsies, and orbital venous congestion.

82.7.5 Evaluation

General information

Brain CT or MRI without contrast are often normal. CTA may reveal dilated tortuous vessels corresponding to enlarged arterial feeders or ectatic draining veins. MRA may reveal dilated pial vessels, early prominent venous sinus filling, sinus enlargement or occlusion, and white matter edema related to venous hypertension. Full 6 vessel cerebral angiography (bilateral ICAs, bilateral ECAs, bilateral vertebral arteries) is required to establish the diagnosis and to plan treatment.

Angiographic classification

Several classification systems have been described to characterize DAVFs. The Borden\textsuperscript{92} (Table 82.10) and the Cognard\textsuperscript{93} (Table 82.11) systems have emerged as the most commonly utilized contemporary grading schemes. See Tables. Cortical venous drainage is the defining angiographic feature that distinguishes benign (low-grade) from aggressive (high-grade) fistulas. (Borden I, Cognard I, and Cognard IIa are low-grade, all others are high-grade.)

Borden classification system

The Borden classification\textsuperscript{92} is shown in Table 82.10.

Cognard angiographic classification

The Cognard system\textsuperscript{93} is shown in Table 82.11. This system is generally most applicable to DAVFs involving the transverse sinus.

Cognard found 54\% had no cortical venous reflux (Types I and IIa) and usually exhibit benign behavior.
Key determinant: in the Cognard system, the pattern of venous drainage is the most critical factor. As a general rule, lesions with retrograde flow in the cortical veins (IIb, Ila+b, III & IV – red frames in Table 82.11) are high risk (for bleeding or intracranial hypertension...).

82.7.6 Natural history

The concept of benign vs aggressive DAVF behavior based on the absence or presence, respectively, of cortical venous drainage was validated by data reported by University of Toronto group. Over a 3 year period, 98% of benign lesions (no cortical venous drainage) remained benign.94 On the other hand, over a 4 year period, annual rates of hemorrhage, non-hemorrhagic neurologic deficit, and mortality were 8.1%, 6.9%, and 10.4% for aggressive lesions (with cortical venous drainage).95

In a meta-analysis of 377 cases,96 three DAVF locations were associated with particularly aggressive behavior (aggressive:benign ratio) – tentorial (31:1), middle fossa/sylvian (2.5:1), anterior fossa/ethmoidal 2:1:1.

82.7.7 Management

General information

Lesions with cortical venous drainage should generally be treated. Lesions without cortical venous drainage should be followed radiographically and clinically (2% may evolve to develop cortical venous drainage). A change in a bruit (either worsening, or disappearance) should prompt restudy.

Indications for intervention:
1. presence of cortical venous drainage
2. neurologic dysfunction
3. hemorrhage
4. orbital venous congestion
5. refractory symptoms (headache, pulsatile tinnitus)

Manual carotid self compression

Advocated by some, the thrombosis rate of ≈22% and clinical improvement rate of 33%97 may mimic the natural course. Patients are advised to compress with the hand that would be affected by ischemia if it were to occur (e.g., with a left-sided DAVF, the right hand should be used to compress the left carotid artery). That way, the hand would fall away if ischemia develops. Recommendations vary, one option: start with 10 minutes once a day, gradually increase frequency and duration.

Endovascular embolization

May be performed transarterial or transvenous. Before the availability of liquid embolic agents (Onyx and NBCA), treatment was directed at the venous drainage (unlike pial AVMs) which had higher success, because the coils could be deployed to sacrifice the venous drainage very close to point of arteriovenous shunting, resulting in thrombosis of the fistula. It is more difficult to deploy coils across the point of arteriovenous shunting from the arterial side, whereas the liquid embolic agents, particularly Onyx, can be injected at somewhat of a distance and pushed forward across the fistulous point. Whether a transarterial, transvenous, or combined approach is utilized depends on the unique angioarchitecture of the fistula.

Surgery

While endovascular approaches have emerged as the primary treatment for most DAVFs, certain fistula types are still best dealt with via open surgery as the first line strategy.98 Furthermore, surgery has been used to successfully treat DAVFs after previous partial, incomplete, or failed endovascular treatment. Finally, surgery can be used adjunctively in a combined approach to provide direct access for embolization of DAVFs that are inaccessible by a purely endovascular route.

Preoperative embolization may facilitate surgical treatment99 by lessening the risk of catastrophic hemorrhage, which may occur simply during the performance of the craniotomy.91 The use of the crainiotome is discouraged, as a sinus or venous laceration could produce a fatal hemorrhage. Contingencies for the rapid administration of blood products must be made (large bore central lines). The scalp incision, craniotomy flap, and dural incision should be planned in a strategic manner to control and sequentially eliminate the blood supply to the lesion at each step, while maximizing the exposure as needed. Surgical options for the treatment of DAVFs include the following techniques98:
1. radical fistula excision
2. sinus skeletonization
### Table 82.11 Angiographic classification of dural AVMS\(^{93a}\)

#### Venous drainage: sinus

</tbody>
</table>
3. disconnection of cortical venous drainage
4. ligation of the fistulous point and/or outflow vein
5. sinus packing
6. coagulation of arterial feeders to the lesion

While surgery vs. endovascular treatment can be considered for all DAVF locations, two locations generally remain more favorable for surgery:
1. anterior fossa/ethmoidal
2. tentorial DAVFs

The endovascular approach to these fistulas is difficult whereas the surgical approach is often straightforward. Surgically-assisted embolization, whereby a craniotomy is performed followed by direct puncture for embolization of the target vessel, may be utilized in select cases.

Stereotactic radiosurgery
May be used post-embolization. Pan et al reported a complete obliteration rate of 58% of transverse/sigmoid fistulae treated with only radiosurgery (1650–1900 cGy) or with radiosurgery after surgery/embolization had failed to produce complete obliteration. 71% of the patients were cured of their symptoms.

With the continued improvement of endovascular technology over the past two decades, the role of radiosurgery for DAVF treatment has steadily decreased; however, it remains an option for those difficult lesions in which endovascular/surgical options have been exhausted.

82.8 Vein of Galen malformation
82.8.1 General information
Enlargement of the great cerebral vein of Galen (VOG) may occur in “vein of Galen malformations” (VOGM) (some refer to these as vein of Galen aneurysms). Congenital, develop before the 3-month embryo stage, and probably consists not of the vein of Galen but rather of the medial vein of the prosencephalon) or secondarily to high flow from adjacent deep parenchymatous AVMs or pial fistulae. Parenchymatous AVMs can be distinguished from true VOG malformations by retrograde filling of the of the internal cerebral vein in the former. True VOG malformations are predictably fed from the medial and lateral choroidal, circumferential, mesencephalic, anterior choroidal, pericallosal and meningeal arteries. Agenesis of the straight sinus may be an associated finding.

82.8.2 Presentation
Newborns tend to present with congestive heart failure in first few weeks of life (due to high blood flow) and a cranial bruit. Hydrocephalus may result from obstruction of the sylvian aqueduct by
the enlarged VOG, or it may be caused by the increased venous pressure (which can also produce prominence of the scalp veins\textsuperscript{105}).

Parenchymatous AVMs are usually diagnosed later in life due to neurological manifestations\textsuperscript{106} including focal neurologic deficit and hemorrhage.

82.8.3 Classification

Classified based on the location of the fistula\textsuperscript{107,108};
1. pure internal fistula: single or multiple
2. fistulae between thalamoperforators and the VOG
3. mixed form: the most common
4. plexiform AVMs

82.8.4 Natural history

Untreated VOG malformations have a poor prognosis, with neonates having nearly 100% mortality, and 1–12 month olds having ≈ 60% mortality, 7% major morbidity, and 21% being normal.\textsuperscript{109}

Parenchymatous AVMs behave similar to other AVMs.

82.8.5 Treatment

Hydrocephalus

Hydrocephalus associated with VOGM is obstructive, due to the varix. Although admonitions about shunting were common due to fear of precipitating a hemorrhage, when hydrocephalus is present the patient needs a shunt.

Vein of Galen malformations

Pediatric patients are often in poor medical condition, limiting the efficacy of operative treatment. Treatment options for these include embolization of the main feeding arteries. Prognosis is poor. Those presenting with hydrocephalus from aqueductal obstruction often do so at the end of the first year of life. Neurosurgical excision may be considered here, and the prognosis is better.

Repeated embolization while monitoring the venous drainage is employed.

Parenchymal AVM with enlarged VOG

The AVM is treated by the same methods as other AVMs (embolization, resection or radiosurgery).

82.9 Carotid-cavernous fistula

82.9.1 General information

Key concepts

- direct (high flow, from ICA) or indirect (low flow, from meningeal branches)
- classic triad (more common with direct CCF): chemosis, pulsatile proptosis, ocular bruit
- risk of SAH is low. Major risk is to vision
- natural history of low flow CCF is up to 50% spontaneous thrombosis

See also anatomy and venous inflow and outflow of the cavernous sinus (p. 86).

Carotid-cavernous fistula (CCF): divided into direct (Type A) and indirect (Types B-D)\textsuperscript{110};
1. Type A: direct high-flow shunts between the internal carotid artery and cavernous sinus:
   a) traumatic (including iatrogenic): occur in 0.2% of patients with craniocerebral trauma. Iatrogenic: may follow percutaneous trigeminal rhizotomy,\textsuperscript{111} endovascular procedures...
   b) spontaneous: usually due to ruptured cavernous sinus ICA aneurysm. May also occur in patients with connective tissue disorders
2. indirect (dural): most are shunts: from dural arteries that are branches of the external carotid (not from ICA) (exception: Type B) – low flow
82.9.2 Presentation

1. orbital and/or retro-orbital pain
2. chemosis (arteriolization of conjunctiva)
3. pulsatile proptosis
4. ocular and/or cranial bruit
5. deterioration of visual acuity: may be due to hypoxic retinopathy as a result of reduced arterial pressure and increased venous pressure and increased intraocular pressure
6. diplopia: abduces (VI) palsy is the most common
7. pupillary dilatation
8. ophthalmoplegia (usually unilateral, but may present initially as bilateral or may progress to bilateral)
9. increased intraocular pressure
10. neo-vascularization of the iris or retina
11. rarely: SAH

Indirect CCFs generally have a more gradual onset and milder presentation than direct.

82.9.3 Evaluation

CT or MRI: usually demonstrates proptosis. Serpiginous and engorged intraocular vessels including the superior ophthalmic vein (best seen on T2WI coronals – helps to differentiate from rectus muscles) and convexity of lateral wall of cavernous sinus.

Angiography: shunting of blood from ICA into cavernous sinus. Rapid opacification of petrosal sinus and/or ophthalmic vein may be seen.
1. Huber maneuver: lateral view, inject VA and manually compress affected carotid. Helps identify upper extent of fistula, multiple fistulous openings, and complete transection of ICA
2. Mehringer-Hieshima maneuver: inject contrast at a rate of 2–3 ml/s into affected carotid while compressing the carotid in the neck (below the catheter tip) to control flow to help demonstrate the fistula

82.9.4 Treatment

General information

20–50% of low flow CCF spontaneously thrombose, therefore one may observe these as long as visual acuity is stable and intra-ocular pressure is <≈ 25. Symptomatic (e.g. progressive visual deterioration) high-flow CCFs rarely resolve spontaneously, and urgent treatment is usually indicated. Treatment is usually in the form of embolization by an interventional neuroradiologist or trapping between surgically placed clips.

Even if normal ocular motility cannot be achieved in affected eye, preservation of vision is desirable because:
1. for some ocular motility abnormalities, surgical treatment may reduce diplopia
2. patient may be provided with frosted eyeglass lens which will eliminate diplopia but will maintain peripheral vision
3. in the rare event of injury to contralateral eye (trauma, central retinal artery occlusion…) there would be “reserve” vision in the eye with reduced motility (with loss of the other eye, there would not be diplopia)

Indications for treatment

1. proptosis
2. visual loss
3. cranial nerve VI palsy
4. intractable bruit
5. severely elevated intraocular pressure
6. increased filling of cortical veins on angiography
Endovascular treatment

Options include:
1. Electrolytically detachable coils
2. Amplatzer vascular plug

Routes available include:
1. transarterial through internal carotid. If this fails (e.g. wide aneurysm neck), the carotid artery may be occluded on either side of fistula to trap it (sacrifices carotid artery, therefore test occlusion must be done first to determine if patient can tolerate this; however note: test occlusion with an open fistula may give false positive result because steal through the fistula may reduce CBF and cause neurologic symptoms not related to the occlusion acting alone). The distal occlusion needs to be proximal to the ophthalmic artery
2. transarterial through external carotid: useful only for dural fistulas
3. transvenous:
   a) traversing heart to enter jugular vein, then through petrosal sinus to cavernous sinus. Lower success rate (~20%) than transarterial route
   b) via superior ophthalmic vein: entered where supra-optic vein enters orbit to become superior ophthalmic vein. If possible, it is best to wait for the vein to become arterialized by the high flow pressure. Reports of “disasters” due to injury to the fragile vein performed before arteriolization took place may have been due to more primitive balloon catheters that were standard before current commercially produced versions were available (which are softer than original). Must avoid lacerating the vein inside the orbit, and avoid distal ligation of the vein without proximal occlusion (shunts even more blood into eye)

Choice of technique

With indirect fistulas, it is mandatory to place coils on the venous side (otherwise new feeders will be recruited).

Coils or clips may be used to occlude direct fistulas.

82.10 Sigmoid sinus diverticulum

Sigmoid sinus diverticulum (SSD, see Fig. 82.1) or sigmoid sinus dehiscence is found in 1.2% of asymptomatic patients. However, these abnormalities may be found ipsilaterally in up to 23% of patients with pulsatile tinnitus, presumably due to turbulent flow which may occur in these abnormalities. SSD are more common in women.

Fig. 82.1 Axial contrast head CT (left) and AP venous phase angiogram (right) showing sigmoid sinus diverticulum on the patient’s left side.
When treatments such as masking noise generators fail, surgical intervention can be considered. Surgical treatment options include:

- Endovascular coiling/stenting
- Transmastoid “resurfacing” (see below)
- Cranietomy with clip reconstruction

Transmastoid “resurfacing” consists of partial mastoidectomy, and subtotal obliteration of the area of the diverticulum (so-called sinus wall resurfacing) with e.g. bone chips, fibrin glue, or muscle.

84 Evaluation and Treatment for Stroke 1280

85 Special Conditions 1301

86 Cerebral Arterial Dissections 1322
83 General Information and Stroke Physiology

83.1 Definitions

TIA. (Transient ischemic attack): transient neuronal dysfunction secondary to focal ischemia (of brain, spinal cord, or retina) without (permanent) acute infarction\(^1\) (note: obsolete operational definitions used an arbitrary 24 hour cutoff for duration of symptoms). 10–15% of patients with TIA have a stroke within 3 months, 50% of which occur within 48 hours.

Stroke. Permanent (i.e. irreversible) death of neurons caused by inadequate perfusion of a region of brain or brain stem.

Watershed infarct. Ischemic infarction in a territory located at the periphery of two bordering arterial distributions due to a disturbance in flow in one or both of the arteries.

83.2 Cerebrovascular hemodynamics

83.2.1 Cerebral blood flow (CBF) and oxygen utilization

Table 83.1 shows typical CBF values and the corresponding neurophysiologic state. CBF<20 is generally associated with ischemia and if prolonged will produce cell death.\(^2\) However, this assumes normal metabolic rate and may be more applicable to global cerebral hypoperfusion.\(^3\) There is a higher CBF threshold for loss of electrical excitability than that for cell death – this has led to the concept of the ischemic penumbra – nonfunctioning cells that are still viable.\(^2\)

CBF is related to blood pressure as shown in Eq (83.1).

\[
\text{CBF} = \frac{\text{CPP} \cdot \text{CVR}}{\text{MAP} - \text{ICP}}
\]

where CPP = cerebral perfusion pressure (p.856), CVR = cerebrovascular resistance (see below), and MAP = mean arterial pressure.

83.2.2 Cerebrovascular resistance (CVR)

CVR is affected by the PaCO\(_2\) such that there is a linear increase in CBF with increasing PaCO\(_2\) within the range of 20–80 mm Hg.

CVR is also affected by changes in CPP which produce changes in blood vessel tone via a myogenic mechanism. In the range of CPP=50–150 mm Hg the CVR of normal brain tissue varies linearly to

\(\delta83:1b\)
maintain an almost constant CBF. This phenomenon is called (cerebral) autoregulation, which is altered in pathologic states.

### 83.2.3 Cerebral metabolic rate of oxygen consumption (CMRO₂)

CMRO₂ averages 3.0–3.8 ml/100 gm tissue/min. The ratio of CBF to CMRO₂ (the coupling ratio⁴) in the quiescent brain is 14–18. With focal cortical activity, local CBF increases ≈ 30% while CMRO₂ increases ≈ 5%⁵ CMRO₂ can be manipulated to some degree.

### 83.2.4 Cerebrovascular reserve and reactivity

May be evaluated with xenon-enhanced CT, CTP (p.228), TCD, SPECT, or MRI.⁴ Response of CBF to a vasodilator challenge with 1000 mg of IV acetazolamide (ACZ) (Diamox®) is classified as⁴:

- **Type I**: normal baseline CBF with 30–60% increase following ACZ challenge
- **Type II**: decreased baseline CBF with blunted response of <10% increase or <10 ml/100 gm/min absolute increase after ACZ challenge
- **Type III**: decreased baseline CBF with paradoxical decrease of regional CBF following ACZ challenge, suggesting a steal phenomenon in regions with maximally dilated vasculature at baseline

### 83.3 Collateral circulation

#### 83.3.1 Collateral circulation for ICA stenosis/occlusion

The effects of ICA stenosis/occlusion may be ameliorated by collateral blood flow. Potential alternate routes for blood to reach brain tissue include:

1. flow through the circle of Willis
   - a) from contralateral ICA through anterior communicating a.
   - b) from forward flow through the ipsilateral posterior communicating a.
2. retrograde flow through ophthalmic a. parasitizing blood from both ECAs via:
   - a) facial a. → angular a. → dorsal nasal a. & medial palpebral a.
   - b) maxillary a.
     - • middle meningeal a. → lacrimal a.
     - • vidian a. (a. of the pterygoid canal)
   - c) transverse facial a. → lateral palpebral a.
   - d) superficial temporal a. → supraorbital a.
3. proximal maxillary a. → anterior tympanic a. → caroticotympanic branch of ICA
4. cortical-cortical anastomoses
5. dural-leptomeningeal anastomoses

#### 83.3.2 Collateral circulation for vertebrobasilar stenosis/occlusion

Available collaterals depend on the site of occlusion.

- **Basilar artery occlusion. Collateral flow via:**
  1. posterior communicating aa.
  2. anastomoses between SCA and PICA

Proximal vertebral artery (VA) occlusion. Collateral flow via:

1. ECA → occipital a. → muscular branches of VA → VA
2. thyrocervical trunk → ascending cervical a. → direct connection or spinal radicular aa. → VA
3. contralateral VA and/or ascending cervical a. via spinal radicular branches and anterior spinal artery

### 83.4 “Occlusion” syndromes

#### 83.4.1 Occlusion of major vessels organized by vascular territories

See Fig. 2.1 for the distribution territories of the major cerebral arteries. To indicate lateralization of findings, (CL) = contralateral, (IL) = ipsilateral.
Internal carotid artery and its branches

Risk and extent of stroke is influenced by suddenness of occlusion, location of occlusion, and collateral circulation (see above)

1. statistics:
   a) acute ICA occlusion (all comers): 26–49% risk of stroke (not all of these strokes are severe)
   b) annual stroke risk in 1261 patients with symptomatic ICA occlusion: 7% overall, 5.9% ipsilateral to the occlusion (mean follow-up = 45.5 mos) (even with anticoagulation or antiplatelets drugs) (12 prospective studies)
   c) St. Louis Carotid Occlusion Study: 2-year ipsilateral ischemic stroke rate in patients with symptomatic ICA occlusion = 5% in patients with normal O2 extraction fraction (OEF) by PET scan, and 26% in patients with increased OEF
   d) stroke risk is less when one includes asymptomatic ICA occlusions (i.e. there are people walking around with ICA occlusion and no symptoms)
   e) in patients presenting with ICA territory stroke or TIA, complete ICA occlusion is found in 10–15%

2. worst-case scenario of total ICA occlusion with no a-comm or p-comm flow and no collateral rescue: stroke in ACA and MCA territories (Table 83.2)

3. anterior cerebral artery: \{CL\} weakness of LE>UE

4. posterior cerebral artery
   a) unilateral occipital lobe infarction → homonymous hemianopsia with macular sparing (visual cortex of the macula receives dual blood supply from MCA and PCA)
   b) Balint syndrome
   c) cortical blindness (Anton syndrome)
   d) Weber syndrome
   e) alexia without agraphia
   f) thalamic pain syndrome (Dejerine-Roussy syndrome)

5. artery of Percheron (p. 83): bilateral thalamic and mesencephalic infarctions

Posterior circulation

1. vertebral artery
   a) medial medullary syndrome (Dejerine syndrome)
   b) lateral medullary syndrome (Wallenberg syndrome): see below

2. basilar artery

3. AICA: lateral pontine syndrome (Marie-Foix syndrome)

<table>

Gerstmann syndrome (p. 98): with dominant parietal lobe infarct

a[CL] = contralateral, [IL] = ipsilateral. An “X” indicates that the deficit is present
b with involvement on side of nondominant hemisphere
c plus \{CL\} upper quadrantanopsia
d with involvement on the side of the dominant hemisphere
4. PICA: sometimes lateral medullary (Wallenberg) syndrome: see below
5. SCA: infarction of superior cerebellar vermis and superior cerebellum
6. anterior spinal artery
7. recurrent medial striate artery (of Heubner): expressive aphasia + mild hemiparesis (UE>LE, proximal muscles weaker than distal)
8. anterior choroidal artery (ACHA) syndrome: first described by Foix et al. in 1925. The complete triad consists of CL hemiplegia, hemihypesthesia and homonymous hemianopsia (mnemonic: 3 H’s), however, incomplete forms are more common. Occlusion is usually due to small vessel disease and CT or MRI usually shows infarct in posterior limb of IC (just above temporal horn of lateral vent)\(^{13}\) and white matter posterior and lateral to it. Occlusion is usually tolerated fairly well, and ligation of this artery was actually utilized in treatment of Parkinsonism sometimes without ill effect\(^{16}\) (p 540) – see Surgical treatment of Parkinson’s disease (p.1524) – but internal capsule infarct occurred in \(\approx 15\%\).

Lateral medullary syndrome (LMS)

AKA Wallenberg’s syndrome, AKA PICA syndrome. Classically attributed to PICA occlusion, but in 80–85% of cases the vertebral artery is also involved.\(^ {17}\) No cases have been reported arising from brainstem hemorrhage. Onset is usually acute. The findings are listed in Table 83.3 (NB: absence of pyramidal tract findings, and no change in sensorium). The location of the lesion and medullary structures are shown in Fig. 83.1.

Note. This is essentially the only location where a lesion will produce sensory loss on one side of the face (ipsilateral to the lesion) and contralateral sensory loss in the body. All in the absence of pyramidal tract findings (i.e. overt weakness).

These patients sometimes develop severe cerebellar swelling that responds to neurosurgical decompression (the tissue aspirates easily).

In a patient presenting with LMS, one needs to rule-out vertebral dissection (p.1325) since this would be treated with heparin. MRI including fat-suppressed T1WI and MRA would detect dissection in most cases.

Prognosis: 12% of 43 patients died during the acute phase from respiratory and cardiovascular complications and 2 new posterior-fossa strokes occurred.\(^ {18}\) Recurrent vertebrobasilar territory stroke rate was 1.9%per year.\(^ {18}\)

83.4.2 Lacunar strokes

General information

Small infarcts in deep noncortical cerebrum or brainstem (Table 83.4) resulting from occlusion of penetrating branches of cerebral arteries. Size of infarcts ranges from 3–20 mm (CT detects larger ones; better sensitivity in white matter).

</table>
Small (3–7 mm) lacunes may be due to lipohyalinosis (vasculopathy due to HTN) of arteries <200 microns (may also be cause of many ICHs); this vasculopathy is indicative of small vessel disease, unlikely to be prevented by carotid endarterectomy.

Clinically, diagnosis virtually excluded by: aphasia, apractagnosia, sensorimotor stroke, monoplegia, homonymous hemianopsia (HH), severe isolated memory impairment, stupor, coma, LOC, or seizures.

L’etat lacunaire: multiple lacunes → chronic progressive neuro decline with one or more episodes of hemiparesis; results in invalidism, dysarthria, small-step gait (marche á petits pas), imbalance, incontinence, pseudobulbar signs, dementia. Many signs and symptoms are possibly due to NPH (unrecognized originally).

Lacunar syndromes
Major syndromes (see reference 19 for others):
1. pure sensory stroke or TIA (the most common lacunar manifestation) usually isolated unilateral numbness of face, arm, and leg. Only 10% of TIA go on to stroke. Lacune in sensory (posteroventral) thalamus → CT detection is poor. Dejerine-Roussy = rare thalamic pain syndrome that may develop late

</tbody>
</table>

Fig. 83.1 Typical lesion in lateral medullary syndrome (indicated as shaded area)
2. pure motor hemiparesis (PMH): (2nd most common lacunar manifestation) pure unilateral motor deficit of face, arm and leg without sensory deficit, HH, etc. Lacune in posterior limb of IC, or in lower basis pontis where corticospinal (CS) tracts coalesce, or rarely in mid-cerebral peduncle

3. ataxic hemiparesis: contralateral PMH + cerebellar ataxia of affected limbs (if they can move). Lacune in basis pontis at junction of upper third and lower two-thirds → dysarthria, nystagmus and unidirectional toppling possible. Differential severity in face, arm and leg possible because CS fibers dispersed by nuclei pontis (unlike compact pyramids and peduncle)
   a) variant: dysarthria-clumsy hand syndrome: lesion in same location or genu of IC. May be mimicked by a cortical infarct, but latter will have numb lips

4. PMH sparing the face: lacune in medullary pyramid; at onset, there may be vertigo and nystagmus (approaching lateral medullary syndrome)
   a) variant: thalamic dementia: central region of one thalamus + adjacent subthalamus → abulia, memory impairment + partial Horner’s (miosis + anhydrosis)

5. mesencephalothalamic syndrome: “top o’ the basilar syndrome.” Usually caused by embolus. Infarct typically butterfly shaped & bilateral involving rostral brainstem and cerebral hemisphere regions fed by the distal basilar artery. Clinical: III palsy, Parinaud’s syndrome & abulia, may have amnesia, hallucinations and somnolence, usually without significant motor dysfunction

6. Weber’s syndrome: Cr. N. III palsy with contralateral PMH (no sensory loss). Usually due to occlusion of interpeduncular branches of basilar artery → central midbrain infarction, disrupting cerebral peduncle and issuing fibers of III. May also be due to aneurysm of basilar bifurcation or BA-SCA junction

7. PMH with crossed VI palsy: lacune in paramedian inferior pons

8. cerebellar ataxia with crossed III palsy (Claude syndrome): lacune in dentatorubral tract (superior cerebellar peduncle)

9. hemiballism: classically, infarct or hemorrhage in subthalamic semilunar nucleus of Luys

10. lateral medullary syndrome: see below

11. locked-in syndrome: bilateral PMH from infarct at IC, pons, pyramid or (rarely) cerebral peduncles

83.5 Stroke in young adults

83.5.1 General information

Only 3% of ischemic strokes occur in patients < 40 yrs age. Over 10% of ischemic strokes occur in patients ≤ 55 yrs. Incidence: 10 per 100,000 persons age 35–44 yrs; 73 per 100,000 for age ≤ 55 yrs.

83.5.2 Etiologies

The differential diagnosis is lengthy, with trauma being the most common cause of strokes (22%) in patients under 45 yrs. Most of the rest are covered by the small number of etiologies listed below (excludes: trauma, post-op stroke, SAH, and intracerebral hemorrhage).

1. atherosclerosis: 20%—less common than in older population (all 18 patients in one series had either ID-DM, or were males > 35 yrs with ≥ 1 risk factors (see below), most had TIAs earlier)

2. embolism with recognized source: 20%
   a) cardiac origin is the most common (above), most have previously known cardiac disease:
      - rheumatic heart disease
      - prosthetic valve
      - endocarditis
      - mitral valve prolapse (MVP): present in 5–10% of young adults, in 20–40% of young adults with stroke (although one series found MVP in only 2% of stroke in young adults)
      - A-fib
      - left-atrial myxoma
   b) fat embolism syndrome: neurologic manifestation is usually global neurologic dysfunction; see Fat embolism syndrome (p. 835)
   c) paradoxical embolism: e.g. ASD, pulmonary AVM including Osler-Weber-Rendu syndrome, patent foramen ovale (above)
   d) amniotic fluid embolism: may occur typically in the post-partum period

3. vasculopathy: 10%
   a) inflammatory
      - Takayasu’s
   b) infective: TB, syphilis, ophthalmic zoster
• amphetamine abuse
• herpes zoster ophthalmicus (HZO): usually presents with delayed contralateral hemiplegia with a mean of ≈ 8 weeks following HZO
• mucormycosis: a nasal and orbital fungal infection primarily in diabetics and immunocompromised patients that causes an arteritis which may thrombose the orbital veins and ICA or ACA. Produces proptosis, ocular palsy, and hemiplegia
• associated with systemic disease such as: SLE (lupus), (also see below under Coagulopathy); arteritis (especially periarteritis nodosa (p.199)) when confined to CNS is usually multifocal and progressive, but may mimic stroke early; multiple sclerosis (MS); cancer; rheumatoid arthritis

b) non-inflammatory
• fibromuscular dysplasia (p.200)
• carotid or vertebral artery dissections (including posttraumatic)
• moyamoya disease (p.1313)
• homocystinuria: a genetic defect in methionine metabolism that produces intimal thickening and fibrosis in almost all vessels with associated thromboembolic events (arterial and venous, including dural venous sinuses). Estimated risk of stroke is 10–16% Patients have a Marfan syndrome-like physical appearance, malar blotches, mental retardation, and elevated levels of urinary homocysteine
• pseudoxanthoma elasticum

4. coagulopathy: 10% The following are associated with hypercoagulable states
a) SLE: lupus anticoagulant → prolonged PTT incompletely corrects with 50/50 mix. Collagen vascular disease only rarely presents initially with stroke
b) polycythemia or thrombocytosis
c) sickle cell disease
d) TTP (thrombotic thrombocytopenic purpura)
e) antithrombin III deficiency (controversial – not seen in large series of young adults with stroke)
f) protein C or protein S deficiency (familial): protein C attenuates hemostatic reactions, homozgyous deficiency is fatal in the neonatal period. Heterozygous deficiency is associated with thrombotic strokes. A rare complication during initial therapy with warfarin is a drop in protein C before other coagulation factors resulting in a hypercoagulable state
g) antiphospholipid-antibody syndrome (APLAS): causes venous and/or arterial thrombosis. The two best known antiphospholipid-antibodies are anticardiolipin antibodies (ACLA), and lupus anticoagulant (LAC). Once they become symptomatic, treatment is high-intensity warfarin therapy to an INR ≥3. There is a dramatic increase in thrombotic events after discontinuing warfarin. Aspirin is useless
h) following use of the drug 3,4-methylenedioxymethamphetamine (MDMA, known on the street as ecstasy), possibly independent of the hypercoagulable state that occurs with hyperthermia when insufficient fluids are consumed in conjunction with use of the drug

5. peripartum: 5% (usually within 2 wks of parturition)
6. miscellaneous causes: 35%
a) uncertain etiology
b) oral contraceptives (BCP): associated with ninefold increased risk for stroke, many with prior migraine history
c) venous thrombosis (including dural sinus thrombosis): incidence may be increased with use of BCP
d) migraine: widely accepted, but difficult to assess objectively (incidence of stroke in these patients may be same as general population). Rare. Usually occurs in women, with a benign long-term course; recurs in <3% Possible mechanisms include: vasospasm, platelet dysfunction and arteriopathy. Strokes often occur during a migrainous attack or shortly thereafter
e) cocaine abuse: stroke may result from vasoconstriction, or from HTN in the presence of aneurysms or AVMs (frank vasculitis occurs but is rare with cocaine, unlike amphetamines); strokes with alkaloidal cocaine (“crack”) are equally divided between ischemic and hemorrhagic
f) posterior reversible encephalopathy syndrome (PRES) (p.194)

83.5.3 Risk factors
In a retrospective “neighborhood control” study of 201 Australian patients aged 15–55 (mean =45.5) with first-time strokes, the following risk factors were identified:
1. diabetes: odds ratio = 12
2. HTN: odds ratio = 6.8
3. current cigarette smoking: odds ratio = 2.5  
4. long-term heavy alcohol consumption: odds ratio = 15 (heavy alcohol ingestion within 24 hrs preceding the stroke was not a risk factor)

83.5.4 Evaluation
1. history & physical exam directed at uncovering systemic disease (see above) and modifiable risk factors (see above)  
2. cardiology work-up including EKG and echocardiogram  
3. bloodwork (include as appropriate):  
   a) routine: electrolytes, CBC, platelet count and/or function, ESR (elevation may suggest SLE, arteritis, atrial myxoma… but a normal ESR does not rule-out vasculitis), PT/PTT, VDRL (should be obtained in all young adults with stroke), fasting lipid profile  
   b) for unexplained stroke: ANA, antithrombin III, protein C, protein S, homocysteine, factor V Leiden, PPD, sickle-cell screen, toxicology screen (blood and urine, to R/O drugs such as cocaine), SPEP, lupus anticoagulant, serum amino acid, tissue plasminogen-activator and inhibitor  
4. miscellaneous tests: U/A, CXR, CSF exam when indicated  
5. cerebral angiography: not always necessary for patients with obvious systemic disease or strong evidence for cardiac embolism; may occasionally diagnose cerebral embolism if performed within 48 hrs of ictus

83.6 Atherosclerotic carotid artery disease

83.6.1 General information
Atherosclerotic plaques begin to form in the carotid artery at 20 yrs of age. In the extracranial cerebral circulation, plaques typically start on the back wall of the common carotid artery (CCA). As they enlarge, they encroach on the lumen of the ICA. Calcified hard plaques may not change with time. The risk of stroke correlates with the degree of stenosis and with certain types of plaque morphology, and is also increased in hypercoagulable states and with increased blood viscosity.

Plaque morphology
“Vulnerable” plaques are atherosclerotic plaques likely to cause thrombotic complications, or those that tend to progress rapidly. Criteria for vulnerable plaques include: intimal thickening, plaque fissure, lipid/necrotic core with thin fibrous cap, calcification, thrombus, intraplaque hemorrhage, and outward remodeling. Some of these features can be identified with high-resolution MRI.

83.6.2 Presentation

General information
Carotid artery lesions are considered symptomatic if there is one or more lateralizing ischemic episodes appropriate to the distribution of the lesion. A lesion is considered to be asymptomatic if the patient only has non-specific visual complaints, dizziness, or syncope not associated with TIA or stroke. The majority (80%) of carotid atherothrombotic strokes occur without warning symptoms.

Asymptomatic carotid stenosis
Usually discovered as a carotid bruit. Asymptomatic bruit: prevalence increases with age (2.3% in ages 45–54 yrs, 8.2% at ≥75). Accuracy of a bruit in predicting ICA stenosis: 50–83% (depending on cohort, criteria for stenosis...). Sensitivity is as low as 24%.

Symptomatic carotid disease
May present as a TIA, RIND or stroke with any of the following findings; see also ICA occlusion syndromes (p.1265):
1. retinal insufficiency or infarction (central retinal artery is a branch of the ophthalmic artery): ipsilateral monocular blindness  
   a) may be temporary: amaurosis fugax, AKA transient monocular blindness (TMB). Four types:
Type I: embolic. Described “like a black curtain coming down” in one eye. Complete loss of vision, usually lasts 1–2 minutes
Type II: flow related. Retinal hypoperfusion → desaturation of color, usually described as a graying of vision
Type III: vasospastic. May occur with migraines
Type IV: miscellaneous. May occur with anticardiolipin antibodies
a) blindness may be permanent
1. middle cerebral artery symptoms:
   a) contralateral motor or sensory TIA (arm and face worse than leg) with hyperreflexia and upgoing toe
   b) language deficits if dominant hemisphere involved

83.6.3 Evaluation of the extent of carotid disease

Overview
Symptomatic patients will usually be assessed as part of a stroke/TIA protocol.
Check CBC with platelet count, fibrinogen, PT/PTT/INR (to R/O hypercoagulable state).
Funduscopic exam may show Hollenhorst plaques (cholesterol crystal emboli) in the retina.
Classification of patients based on the hemodynamics and also the embolic propensity of carotid lesions has thus far been too complex to be utilized in large studies. The tests described below place a great deal of emphasis on the greatest degree of stenosis which is probably an oversimplification. Plaque composition and morphology is probably important.

Recommendations for screening for carotid stenosis
1. the U.S. Preventive Services Task Force (USPSTF) currently recommends against screening for carotid stenosis in the adult general population (grade D recommendation: moderate or high certainty that the service has no net benefit or that the harm outweighs the benefit)42
2. the AHA Primary Prevention of Stroke Guidelines does not recommend screening for asymptomatic carotid stenosis43
3. the American Society of Neuroimaging advised that screening should be considered only for age ≥ 65 years with 3 or more cardiovascular risk factors44
4. the Society of Vascular Surgery recommends ultrasonography screening for age ≥ 55 years with cardiovascular risk factors, such as a HTN, diabetes, smoking, hypercholesterolemia, or known cardiovascular disease45

Assessment options
See also recommendations for which tests to use (p.1274).

Angiography
The “gold standard” test is a catheter arteriogram. It cannot be justified as a screening test because it is invasive, and too costly and risky (recent data show <1% risk of transient or permanent deficit (risk is 2–3 times higher in symptomatic patients than in asymptomatic)46,47,48 in good hands). Also, unlike duplex doppler and MRA, it does not provide any information about the thickness of the plaque. Different definitions of the degree of stenosis are employed. Table 83.5 compares the definitions used by the NASCET study49 to that of the ECST.50 For both, N is the linear diameter of the carotid artery at the site of greatest narrowing. The studies differ in the denominator, NASCET uses D (the diameter of the normal artery distal to the carotid bulb – taken at the first point at which the arterial walls become parallel), whereas the ECST uses B (the estimated carotid bulb diameter).

For example, using the NASCET definition, the degree of stenosis is shown in Eq (83.2).

% stenosis NASCET\(\% = \left(1 - \frac{N}{D}\right) \times 100\)

The relationship between the degree of narrowing based on the NASCET definition vs. that of the ECST has also been estimated by equation51 as shown in Eq (83.3).
An angiogram also affords the opportunity to perform endovascular intervention if indicated.

**Duplex doppler ultrasound**

B-mode image evaluates the artery in cross-sectional plane, and spectrum analysis shows blood flow. Performs poorly with a “string sign.” Cannot scan above the angle of the mandible. Lower frequencies give greater depth of penetration, but signal definition is sacrificed (used in transcranial doppler). Sensitivity: 88% specificity: 76%.

**Magnetic resonance angiography (MRA)**

May obviate the need for angiography in some cases of carotid stenosis, specifically in symptomatic patients with a focal “gap” of signal intensity loss with distal reappearance of signal.

Sometimes overestimates the degree of stenosis. Sensitivity: 91% specificity: 88% for extracranial carotid disease.

2D TOF-MRA is adequate (contrast-MRA shows more, but is not necessary for surgical lesions).

Can be performed at the time as MRI with stroke protocol in TIA/stroke patients, and also detects thrombus or dissection. As with Doppler, has difficulties distinguishing very severe stenosis from occlusion. Less operator dependent than Doppler, but is more expensive and time-consuming. MRI is more difficult to perform if the patient is critically ill, unable to lie supine, or has claustrophobia, a pacemaker or ferromagnetic implants. High-resolution MRI may also detect vulnerable plaques.

**Computed tomography angiography (CTA)**

CTA involves ionizing radiation (x-rays) and IV iodinated contrast, limiting its use in patients with dye allergies and renal dysfunction. Results are comparable to MRA and Doppler.
can be performed within a few seconds and yields high-resolution images of all vessels from the aortic arch through the intracranial/extracranial vessels as well as the surrounding soft tissues. In a metaanalysis, sensitivity and specificity for detection of a 70% to 99% stenosis were 85% and 93%, respectively.\textsuperscript{58} CTA is still evolving and may help detect vulnerable plaques (p.1271). Another potential advantage: ability to obtain CT-perfusion (p.228) studies at the same time.

Choice of imaging test/management decisions

Despite a great deal of research on the subject, there are no data to support a particular testing algorithm.\textsuperscript{1} Doppler, CTA, or MRA are acceptable initial screening tests. In patients with an abnormal screening test, a common strategy is to obtain a second confirmatory noninvasive test to evaluate the carotid bifurcation before intervention. The combination of carotid ultrasound and MRA has proved cost effective with good interobserver reliability.\textsuperscript{59} If two noninvasive tests are discordant, catheter angiography should be considered before intervention.

83.6.4 Treatment

Treatment alternatives are primarily between the following.
1. “best medical management”: see below
2. carotid endarterectomy (p.1290)
3. endovascular techniques: combined angioplasty and stenting (± distal embolus protection)

Medical treatment

General information

What constitutes “best medical management” has not been precisely determined, and recommendations are constantly changing. Some or all of the following are utilized:
1. antiplatelet therapy (p.164):
   a) usually aspirin (ASA) (see below)
   b) clopidogrel, either alone or in combination with ASA (see below)
   c) combination of extended release dipyridamole and ASA (Aggrenox®) (no benefit from dipyridamole (Persantine®) alone)
2. antihypertensive therapy as appropriate
3. good control of diabetes if present
4. patients with asymptomatic A-fib should be treated with anticoagulation; see Cardiogenic brain embolism (p.1304)
5. antilipid therapy if needed – Statins
6. intervention to help patients to quit smoking

Antiplatelet therapy

**Drug info: Aspirin**

Irreversibly inhibits cyclooxygenase preventing synthesis of vascular prostacyclin (a vasodilator and platelet inhibitor) and platelet thromboxane A2 (a vasoconstrictor and platelet activator). Platelets, lacking cellular organelles, cannot resynthesize cyclooxygenase whereas the vascular tissues do so rapidly.\textsuperscript{60} NB < 1000 mg ASA per day probably does not help with high grade stenosis where there is perfusion failure or flow failure. Some (but not all) studies show less effectiveness in women.\textsuperscript{61} and no large study has shown that ASA prevents a second stroke in patients that have already had one.

: For angina, a bolus dose of 160–325 mg PO is followed by maintenance doses of 80–160 mg/d (lower doses appear to be as effective as higher doses).\textsuperscript{62} Optimal dose for cerebrovascular ischemia continues to be debated. 325 mg PO qd reduces risk of stroke following TIA by 25–30%. Daily doses of 81 or 325 mg when compared to higher doses were associated with a lower rate of stroke, MI and death (6.2% vs. 8.4%) following carotid endarterectomy.\textsuperscript{63}
**Drug info: Aspirin/ER-Dipyridamole (Aggrenox®)**

Combination of extended release dipyridamole and ASA (Aggrenox) is more effective than ASA alone for prevention of TIA, stroke, and myocardial infarction.\(^{64,65,66}\) Aggrenox was not superior to clopidogrel, with increased hemorrhage with Aggrenox.\(^{67}\) Side effects: H/A with initial therapy.

- : 1 capsule PO BID. Supplied: fixed dose capsules of aspirin 25 mg/extended-release with dipyridamole 200 mg.

**Drug info: Clopidogrel (Plavix®)**

A thienopyridine. Incidence of severe neutropenia (0.04%) is close to that of ASA (≈ 0.02%).\(^{68}\) Interferes with platelet membrane function by inhibiting ADP-induced platelet fibrinogen binding and release of platelet granule contents, as well as subsequent platelet-platelet interactions. Produces a time and dose dependent irreversible inhibition of platelet aggregation and prolongation of bleeding time. May replace ASA if intolerance or resistance. Used in combination with ASA for some endovascular procedures. Although clopidogrel plus aspirin is recommended over aspirin for acute coronary syndromes, the MATCH\(^{69}\) results do not suggest a similar benefit for stroke and TIA. Combination therapy significantly increased risk of hemorrhage.\(^{69}\)

Pharmacokinetics: Dosed once daily. Requires several days to reach maximal effect (a loading dose may be used, e.g. after an acute event such as an MI, or before stenting). Takes ≈ 5 days off the drug for platelet inhibition to reverse.

- : 75 mg PO qd. Loading dose: 225 mg (3 pills) the first day of therapy. Supplied: 75 mg film-coated tablet.

**Choice of antiplatelet agents**

Individualization is recommend for antiplatelet agents for secondary stroke prevention. ASA is effective, and its low cost may help compliance. A small reduction of vascular events with Aggrenox may justify its expense from a broader healthcare perspective. Clopidogrel is appropriate for those intolerant or resistant to ASA. Clopidogrel plus ASA may be indicated in patients with recent cardiac ischemia or vascular stenting.\(^{70}\)

**Asymptomatic carotid artery stenosis**

**Key concepts**

- natural history: reveals low stroke rate (2%/yr) half of which are not disabling
- large randomized trials have revealed moderate surgical benefit versus medical management for: asymptomatic stenosis >60%
- treatment selection criteria depend on patient’s age, gender and comorbidities (and therefore life expectancy), and on perioperative complication rate

**Practice guideline: Asymptomatic carotid stenosis**

- Level I\(^1\): CEA is reasonable in asymptomatic patients with >70%ICA stenosis if risk of perioperative stroke, MI and death is low
- Level II\(^1\): It is reasonable to choose CEA over CAS when revascularization is indicated in older patients especially when the anatomy is unfavorable for endovascular intervention
- Level II\(^1\): It is reasonable to choose CAS over CEA when revascularization is indicated in patients with anatomy unfavorable for surgery
- Level II\(^1\): prophylactic CAS may be considered in highly selected patients with asymptomatic ICA stenosis (≥60%by angiography, >70%by validated Doppler ultrasound), but the effectiveness compared to medical therapy alone is not well established
• Level II: In patients with high risk of complications by either CEA or CAS (includes: age > 80 years, NYHA heart failure class II or IV, LVEF < 30%, class III or O V angina pectoris, left main or multivessel CAD, need for cardiac surgery within 30 days, MI within 4 weeks, and severe chronic lung disease), the effectiveness of revascularization over medical therapy alone is not well established.

Abbreviations: CEA = carotid endarterectomy, CAS = carotid artery stenting

Natural history
Prevalence of carotid stenosis > 50% in men and women > 65 years of age is 5–10% with 1% having stenosis > 80%.72,73,74

Natural history studies reflect an annual stroke risk of 1–3.4% with asymptomatic carotid artery stenosis of 50–99% at 2–3 years.75,76,77,78,79,80 A cohort study found similar cumulative rates of ipsilateral stroke over 10 years (9.3% or 0.9%/year) and 15 years (16.6% or 1.1%/year).81

Attempts to identify subgroups of patients with asymptomatic carotid stenosis at elevated stroke risk suggest that the rate of unheralded stroke ipsilateral to a hemodynamically significant extracranial carotid artery stenosis is 1–2% annually, with some data suggesting that the stroke rate may be higher with progressing stenosis or with more severe stenosis. Asymptomatic carotid stenosis is an important marker of concomitant ischemic cardiac disease.75,76,77,80,81 In the REACH Study,82 patients with asymptomatic carotid stenosis (n = 3164) had statistically significantly higher age- and sex-adjusted 1-year rates of transient ischemic attack, non-fatal stroke, fatal stroke, and cardiovascular death compared with patients without asymptomatic carotid stenosis (n = 30,329).

Surgery vs. medical management: the studies
ACST
See reference.83

The largest multicenter randomized trial to date83 revealed a moderate benefit for immediate CEA vs. medical management in patients age < 75 with asymptomatic stenosis ≥ 60%

Details: 3,120 patients with ≥ 60% stenosis by duplex ultrasound were randomized to immediate CEA (50% had CEA within 1 month, 88% within 1 year) or medical therapy at the discretion of the treating physician. Mean follow-up: 3.4 years. Exclusion criteria included: poor surgical risk, prior ipsilateral CEA, and probable cardiac emboli. Surgeons were required to have a perioperative morbidity and mortality rate of < 6%.

Net five-year risk for all stroke or perioperative stroke or death: 6.4% in the CEA group, vs. 11.8% in the medical group (p < 0.0001). Fatal or disabling stroke: 3.5% vs. 6.1% Fatal stroke alone: 2.1% vs. 4.2%. Although men and women benefited, men benefited more. CEA did not demonstrate a statistically significant benefit for patients over the age of 75. Statistical benefit was not seen in the immediate CEA group until nearly two years after surgery, despite a relatively low perioperative morbidity and mortality rate of 3.1% (in contrast to patients with symptomatic stenosis (NASCET) where benefit was seen much earlier).

ACAS
See reference.85

Large trial that randomized patients in good health with asymptomatic stenosis (calculated in the same manner as the NASCET study) ≥ 60% to CEA plus aspirin, or aspirin alone85 found a reduced 5-year risk of ipsilateral stroke if CEA was performed with < 3% perioperative morbidity and mortality and is added to aggressive management of modifiable risk factors.
Details: CEA reduced 5-year stroke risk 66% in males, 17% in females (not statistically significant), and 53% overall (males & females lumped together). CEA did not significantly protect against major stroke or death (P = 0.16) (half of the strokes were not disabling), and was somewhat protective against any stroke or death (P = 0.08). The study group was 95% Caucasian, and 66% were male. Excluded patients (age > 79 yrs, unstable CAD, uncontrolled HTN) may have been higher risk. Surgeons were carefully selected and the surgical morbidity (1.5%) and mortality (0.1%) was very low. Surprisingly, ~ half of the total morbidity (1.2%) was related to angiography. The implication is that for a generally healthy white male with ACAS > 60% management with CEA (when performed by a surgeon with a low complication rate, as described) reduces his annual risk of all strokes from 0.5% to 0.17% (the reduction of risk for severe stroke is less). The benefit from CEA is realized within less than one year after the CEA. This is in contrast to the ACST trial (see above) and is most likely due to the lower perioperative event rate. The risk from mortality from other causes (including MI) is ≈ 3.9% per year. Combined stroke and death rates in community hospitals while improved over the last 20 yrs, remains higher at ≈ 6.3% than at centers used in this study.

Veteran’s Administration Cooperative Study (VACS)
See reference. CEA reduces ipsilateral neurologic events, but did not reduce the rate of ipsilateral strokes nor death (most deaths were secondary to MI). This trial did not include women and was not powered to detect differences in outcome subgroups.

CASANOVA Study
See reference. No difference in outcome between CEA vs. aspirin (new stroke or death), but an unusual protocol lessened its statistical validity.

Mayo Clinic Asymptomatic Carotid Endarterectomy (MACE) Study
See reference. There were no major strokes or deaths in either the medical or the endarterectomy group. Surgically treated patients were not given aspirin, and 26% had an MI compared to 9% in the aspirin-treated medical arm, reflecting the high incidence of concomitant CAD in patients with an asymptomatic carotid artery stenosis.

84 Evaluation and Treatment for Stroke

84.1 Rationale for acute stroke treatment

84.1.1 General information

In the complete absence of blood flow, neuronal death occurs within 2–3 minutes from exhaustion of energy stores. However, in most strokes, there is a salvageable penumbra (tissue at risk) that retains viability for a period of time through suboptimal perfusion from collaterals. Progression of local cerebral edema from the injury results in compromise of these collaterals and progression of ischemic penumbra to infarction if flow is not restored and maintained. Prevention of this secondary neuronal injury drives the treatment of stroke and has led to the creation of designated Primary Stroke Centers that offer appropriate and timely triage and treatment of all potential stroke patients.

Current standard of care requires the administration of IV tPA to all eligible patients. Documentation is necessary to justify deviation from this standard of care in the current medico-legal environment.

In centers with advanced capabilities (Comprehensive Stroke Centers), other treatment modalities are also offered.

84.2 Evaluation

84.2.1 History – key components

1. time last seen normal (stroke on awakening being increasingly evaluated by perfusion studies to ensure the presence of viable tissue)
2. current deficit and clinical presentation
3. NIH Stroke Scale score (p.1282) should be assessed and recorded
4. reasons for not administering IV tPA (if any) should be documented

84.2.2 CAT scan (emergent)

General information

Upon presentation with symptoms of a potential stroke, a noncontrast brain CT scan should be done immediately to rule-out hemorrhage (intraparenchymal or SAH), hematoma, early signs of ischemia, old infarcts or injuries, and other lesions (e.g. tumor).

CAT scan findings with ischemic stroke (“pale” infarcts)

General information

NB: These principles do not apply to small lacunar infarcts, nor to hemorrhagic strokes. NB: CT is normal in 8–69% of MCA strokes in the first 24 hours.1

Findings at various times after ischemic stroke

Hyperacute (<6 hours after stroke). Early signs of infarction involving large areas of the MCA territory correlate with poor outcome.2 Early findings may include:3
1. hyperdense artery sign (see below): low sensitivity, but helpful if present
2. focal low attenuation within the gray matter*
3. loss of the gray-white interface*
4. attenuation of the lentiform nucleus
5. mass effect*
   a) early: effacement of the cerebral sulci (often subtle)4
   b) late: midline shift in large territory infarction
6. loss of the insular ribbon (hypodensity involving the insular region)
7. enhancement with IV contrast: occurs in only 33% Stroke becomes isodense (called “masking” effect) or hyperdense with normal brain, and, rarely, may be the only indication of infarction4

* These findings are probably due to increased water content resulting from the following: cellular edema arising from altered cell permeability which produces a shift of sodium and water from the extracellular to the intracellular compartment, which also increases the extracellular osmotic pressure causing transudation of water from capillaries into the interstitium.5
24 hrs. Most strokes can be identified as a low density by this time.

1–2 wks. Strokes are sharply demarcated. In 5–10% there may be a short window (at around day 7–10) where the stroke becomes isodense, called “fogging effect.” IV contrast will usually demonstrate these.

3 wks. Stroke approaches CSF density.

Mass effect. Common between day 1 to 25. Then atrophy is usually seen by ≈ 5 wks (2 wks at the earliest). Serial CT scans have shown that midline shift increases after ischemic stroke and reaches a maximum 2–4 days after the insult.

Calcifications. Over a long period of time (months to years) approximately 1–2% of strokes calcify (in adults, it is probably a much smaller fraction than this; and in pediatrics it is a higher percentage than this). Therefore, in an adult, calcifications almost rule-out a stroke (consider AVM, low grade tumor…).

Hyperdense artery sign
First described in the MCA in 1983. The cerebral vessel (usually the MCA) appears as a high density on unenhanced CT, indicating intra-arterial clot (thrombus or embolus). Seen in 12% of 50 patients scanned within 24 hrs of stroke, and in 34% of 23 very early CTs done to rule out hemorrhage. Sensitivity for MCA occlusion is low, but specificity is high (although it may also be seen with carotid dissection, or (usually bilaterally) with calcific atherosclerosis or high hematocrit). Does not have independent prognostic significance.

Enhancement
CT enhancement with IV contrast in stroke:
1. many enhance by day 6, most by day 10, some will enhance up to 5 wks
2. rule of 2’s: 2% enhance at 2 days, 2% enhance at 2 mos
3. gyrain enhancement: AKA called “ribbon” enhancement. Common. Usually seen by 1 week (grey matter enhances > white). DDX includes inflammatory infiltrating lesions such as lymphoma, neurosarcoidosis… (due to breakdown of BBB)
4. rule of thumb: there should not be enhancement at the same time there is mass effect

84.2.3 CT angio (CTA)
CTA (p. 227) is useful for assessing the location and extent of vascular occlusion in acute ischemic stroke, and may identify the bleeding source in subarachnoid hemorrhage. Findings can direct treatment towards endovascular options when a proximal or significant large vessel occlusion is seen.

84.2.4 CT perfusion
Theoretically identifies salvageable penumbra as a region of mismatch between CBF and CBV. Assumption: the infarcted core (with no salvageable tissue) has decreased CBF within a region of decreased CBV (CBF/CBV match). A mismatched area (decreased CBV without a decrease in CBF) represents potentially salvageable penumbra. Implication: thrombolitics and interventional treatment modalities without mismatch will likely increase morbidity and mortality without clinical benefit.

84.2.5 MRI
With newer, faster acquisition times, and with gradient echo sequences that are highly sensitive to hemorrhage, MRI is increasingly being utilized in the hyperacute setting and is at times replacing CT as the initial evaluation. More sensitive than CT (especially DWI-MRI (p. 232) – and particularly in the 1st 24 hrs after stroke), and especially with brainstem or cerebellar infarction. More contraindications (p. 230) than CT.

Contrast MRI: not often used. 4 enhancement patterns:
1. intravascular enhancement: occurs in ≈ 75% of 1–3 day-old cortical infarcts, and is probably due to sluggish flow and vasodilatation (thus, it is not seen with complete occlusion). May indicate areas of brain at risk of infarction
2. meningeal enhancement: especially involving the dura. Seen in 35% of cortical strokes 1–3 days old (not seen in deep cerebral or brainstem strokes). No angiographic nor CT equivalent
3. transitional enhancement: above two types of enhancement coexist with early evidence of BBB breakdown; usually seen on days 3–6

4. parenchymal enhancement: classically appears as a cortical or subcortical gyral ribbon enhancement. May not be apparent for the first 1–2 days, and gradually approaches 100% by 1 week. Enhancement may eliminate “fogging effect” (as on CT) which may obscure some strokes at ≤2 weeks on unenhanced T2WI.

84.2.6 MRI perfusion

Similar to CT perfusion (p. 228), areas of matched DWI and PWI abnormality are thought to represent infarcted tissue. PWI abnormalities that do not have a DWI correlate are thought to represent potentially salvageable penumbra.12

84.2.7 Emergency cerebral catheter angiography

Indications:
1. early stroke in carotid distribution + history of amaurosis fugax or bruit or retinal emboli, etc. suggesting increasing carotid stenosis, thrombogenic ulcerated plaque, or carotid dissection
2. if diagnosis still questionable (e.g. aneurysm, vasculitis)
3. with rapid recovery, suggesting carotid TIA in face of increasing stenosis
4. AVOID angiography if unstable or if severe disabling neuro deficit

Findings:
1. cutoff sign: vessel ends abruptly at the point of obstruction
2. string sign: narrow strand of contrast in a vessel with high grade stenosis
3. “luxury perfusion”: reactive hyperemia is a recognized response of cerebral tissue to injury (trauma, infarction, epileptogenic focus…). Luxury perfusion is blood flow in excess of demand due to abolition of CBF autoregulation due to acidosis.13 The exact nature of the perfusion is not known (i.e. if it is capillary, arteriole…). On angiography it shows up as accelerated circulation adjacent to the infarct with a stain or blush and early venous drainage

84.2.8 NIH stroke scale (NIHSS)

Administer in order shown (Table 84.1). Record initial performance only (do not go back).

84.3 Management of TIA or stroke

84.3.1 Treatment options timeline

See Fig. 84.1.

<td>severe aphasia (great need for inference, questioning and guessing by listener; limited range of information can be exchanged)</td>
</tr>
<tr>
<td>3</td>
<td>mute or global aphasia (no usable speech or auditory comprehension) or patient in coma (item 1a = 3)</td>
</tr>
</tbody>
</table>

10. Dysarthria

Patient may be graded based on information already gleaned during evaluation. If patient is thought to be normal, have them read (or repeat) the standard text shown in this box.

- MAMA
- TIP-TOP
- FIFTY-FIFTY
- THANKS
- HUCKLEBERRY
- BASEBALL PLAYER
- CATERPILLAR

| 0     | normal speech |
| 1     | mild to moderate (slurs some words, can be understood with some difficulty) |
| 2     | severe (unintelligible slurred speech in the absence of, or out of proportion to any dysphasia, or is mute/anarthric) |
| 9     | intubated or other physical barrier |

11. Extinction and inattention (formerly neglect)

Sufficient information to identify neglect may already be gleaned during evaluation. If the patient has severe visual loss preventing visual DSSS, and the cutaneous stimuli are normal, the score is normal. Scored as abnormal only if present.

| 0     | normal, no sensory loss |
| 1     | visual, tactile, auditory, spatial or personal inattention or extinction to DSSS in one of the sensory modalities |
| 2     | profound hemi-inattention or hemi-inattention to more than one modality. Does not recognize own hand or orients to only one side of space. |

A. Distal motor function (not part of NIHSS) (a = left arm, b = right)

Patients hand is held up at the forearm by the examiner, and is asked to extend the fingers as much as possible. If patient cannot do so, the examiner does it for them. Do not repeat the command.

| 0     | normal (no finger flexion after 5 seconds) |
| 1     | at least some extension after 5 seconds (any finger movement is scored) |
| 2     | no voluntary extension after 5 seconds |

Higher NIHSS scores correlate with more proximal vascular lesions (larger vessel occlusion causes more widespread deficit).

*Revised 1/24/91. Based on Cincinnati stroke scale. Contact the Public Health Service, National Institutes of Health, National Institute of Neurologic Disorders and Stroke, Bethesda, Maryland, U.S.A. for copies of a grading form (which has more details on some aspects of grading) and for training information.
84.3.2 Thrombolytic therapy

General information

Plasminogen activators catalyze the conversion of plasminogen to the fibrinolytic compound plasmin. The primary agent used is alteplase (recombinant tissue plasminogen activator (rtPA), or just tPA) (Activase®) which is FDA approved for the IV treatment of acute ischemic stroke (see below).

Tissue plasminogen activator

IV tPA

For intraarterial tPA see endovascular therapy.

A randomized double-blind NINDS study of 624 patients with an ischemic stroke having a clearly defined time of onset and a CT scan prior to drug administration, found improved neurologic outcome at 3 months in patients who received alteplase (these patients were 30% more likely to have minimal or no disability)\(^\text{16}\) which persisted at 6 and 12 mos\(^\text{17}\) in all subgroups of ischemic stroke. The recurrent stroke rate in control and tPA patients was similar (5%). In contrast, statistical benefit at 90 days could not be confirmed in the second European Cooperative Acute Stroke Study (ECASS II).\(^\text{18}\)

Early data indicated tPA had to be given ≤3 hrs after the onset of symptoms, however, this window was extended to 4.5 hours after the ECASS-3\(^\text{19}\) looked at 821 stroke patients randomized between placebo or tPA in the 3- to 4.5-hour time-window. Compared to placebo, tPA-treated patients experienced a 7.2% absolute increase in the rate of excellent recovery at 90-day follow-up (P=0.04). Although tPA therapy was associated with an increased rate of symptomatic intracerebral hemorrhage (7.9% for tPA versus 3.5% for placebo, \(P<0.001\)), it was not associated with an increased rate of death (7.7% for tPA versus 8.4% for placebo, \(P=0.68\)). For every 100 acute ischemic stroke patients given tPA in accordance with the NINDS protocols, 32 will benefit and 3 will be harmed.\(^\text{20}\)

Guidelines for the administration of IV tPA

Eligibility:
1. age ≥18 years (although use in childhood stroke is increasing\(^\text{21}\)
2. time since last seen normal ≤3 hrs prior to administration (ECASS III extends window to 4.5 hours in select patients\(^\text{22}\); ECASS III did not include: patients ≥80 years of age, patients with baseline NIHSS (p.1282) scores >25, and prior stroke in diabetics. These patients are not excluded from treatment with IV tPA in the 0–3-hour window by the regulatory authorities in the United States and Canada.)
3. “wake-up” stroke (seen in 25% of ischemic stroke patients) may also be safe to treat in select circumstances\(^\text{23}\)

Contraindications (see reference\(^\text{16}\)):
1. intracerebral hemorrhage (ICH): on admitting CT, or history of prior ICH
2. clinical presentation of SAH (even with negative CT)
3. known intracranial aneurysm or AVM
4. active internal bleeding
5. known bleeding diathesis, including but not limited to:
   a) patients on anticoagulants, or those who received heparin in past 48 hrs
   b) platelet count <100,000/mm\(^3\)
6. serious head trauma, serious stroke, or intracranial surgery within past 3 months
7. SBP > 185 mm Hg, or DBP > 110 mm Hg that cannot be controlled despite use of nicardipine infusion or IV labetalol

Cautions:
1. seizure witnessed at the time of onset of stroke symptoms
2. major surgery within the last 14 days
3. arterial puncture at non-compressible site within past 7 days
4. recent lumbar puncture
5. rapidly improving or minor symptoms
6. blood glucose > 400 mg/dl or < 50 mg/dl
7. history of GI or urinary tract hemorrhage within past 21 days
8. post myocardial infarction pericarditis

Treatment protocol: Also, see Contraindications (p. 1286).
alteplase (Activase®): initiate < 4.5 hrs from onset of deficit. NINDS protocol: 0.09 mg/kg IV bolus over 1 min, followed by 0.81 mg/kg constant infusion over 60 minutes (up to a maximum of 90 mg total, including the bolus). HTN is aggressively controlled.
Anticoagulants and antiplatelet drugs are held for 24 hrs after treatment. If there is an indication for anticoagulation, obtain a non-contrast CT 24 hours prior to starting anticoagulation since there is a risk of subclinical intracerebral hemorrhage.

ICH following IV tPA
There is an increased risk of symptomatic intracerebral hemorrhage (ICH) with the use of tPA (NINDS study: 6.4% vs. 0.6% with placebo; ECASS II: 8.8% vs. 3.4%). In spite of this, the NINDS study found that mortality in the tPA group was similar to controls at 3 mos (17% vs. 21%). The following factors were associated with an increased risk of symptomatic ICH (with only a 57% efficiency rate of predicting ICH): severity of NIHSS score, or pre-treatment CT showing brain edema or mass effect. In one study, ICH did not influence outcome except in the rare instance when a massive hematoma occurred. Outcomes were still better in the treated group, and the conclusion is that these patients are still reasonable candidates for tPA. Since then, multicenter analyses have demonstrated that size of infarction and elevated blood sugar are independent risk factors for symptomatic ICH.

Management of post-tPA ICH:
1. discontinue tPA infusion of and obtain STAT head CT
2. send labs: PT, aPTT, platelet count, fibrinogen, and type & cross
3. prepare to administer 6–8 units cryoprecipitate containing Factor VIII
4. prepare to administer 6–8 units of platelets
5. if emergent EVD placement or other interventional procedure is needed, consider the use of recombinant Factor VIIa (40–80 mg/kg) immediately beforehand (NB: this is only a temporizing measure and cryoprecipitate needs to still be given)

84.3.3 Endovascular therapy for stroke
Recent trials favor rapid endovascular intervention in acute ischemic stroke with proximal vessel occlusion, small infarct core and moderate to good collateral circulation. Techniques include intraarterial tPA, mechanical clot retrieval. See Endovascular neurosurgery section (p.1595) for details.

84.3.4 Management of patients not undergoing therapy directed at thrombus

Admitting orders
These guidelines are for TIA or stroke, but not SAH (p.1163) nor intracerebral hemorrhage (ICH) (p.1339). See reference for rationale for these recommendations. The following guidelines for initial management should be maintained 48 hrs after last neuro deterioration.
1. frequent VS with crani checks (q 1 hr × 12 hrs; then q 2 hrs)
2. activity: bed rest
3. labs:
   a) routine: CBC+platelet count, electrolytes, PT/TT, U/A, EKG, CXR, ABG
   b) “special” (when appropriate): RPR (to rule-out neurosyphilis), ESR (to rule-out giant cell arteritis), hepatic profile, cardiac profile
   c) at 24 hrs: CBC, platelet count, cardiac profile, lipid profile, EKG
4. O₂ at 2 L per NC; repeat ABG on 2 L O₂
5. monitor cardiac rhythm ×24 hrs (literature quotes 5–10% prevalence of EKG changes, and 2–3% acute MIs in patients with stroke)
6. diet: NPO
7. nursing care
   a) indwelling Foley (urinary) catheter if consciousness impaired or if unable to use urinal or bedpan; intermittent catheterization q 4–6 hrs PRN no void if Foley not used
   b) accurate I’s & O’s; notify M.D. for urine output <20 cc/hr × 2 hrs by Foley, or <160 cc in 8 hrs if no Foley
8. IV fluids: NS or 1/2 NS at 75–125 cc/hr for most patients (to eliminate dehydration if present)
   a) avoid glucose: hyperglycemia may extend ischemic zone (penumbra). Although hyperglycemia may be a stress response and may not be neurotoxic, recommendations are to strive for normoglycemia.
   b) avoid overhydration in cases of ICH, CHF, or SBP>180. It had been suggested that an optimal Hct for compromise between O₂ delivery and decreased viscosity was ≈33% and that fluid management should strive for this, however the early promise of this theory has not been borne out
9. treat CHF and arrhythmias (check CXR & EKG). MI or myocardial ischemia may present with neuro deficit, these patients should be admitted to CCU
10. avoid diuretics unless volume overloaded
11. blood pressure (BP) management:
   a) for patients presenting with HTN: management must take baseline BP into account: see Hypertension in stroke patients below for management
   b) for patients presenting with hypotension (SBP <110 or DBP <70):
      • unless contraindicated (viz.: ICH, cerebellar infarct, or decreased cardiac output) give 250 cc NS over 1 hr, then 500 cc over 4 hrs, then 500 cc over 8 hrs
      • if fluid ineffective or contraindicated: consider pressors
12. medications
   a) ASA 325 mg PO q d (unless hemorrhagic stroke proven or suspected)
   b) stool softener
13. see following sections for discussion of anticoagulation (p.1289), steroids (p.1289), and mannitol (p.1290)

**Hypertension in stroke patients**

**General information**

HTN may actually be needed to maintain CBF in the face of elevated ICP, and it usually resolves spontaneously. Therefore treat HTN cautiously and slowly to avoid rapid reduction and overshooting the target. Avoid treating mild HTN. Indications to treat HTN emergently include:

1. acute LV failure (rare)
2. acute aortic dissection (rare)
3. acute hypertensive renal failure (rare)
4. neurologic complications of HTN
   a) hypertensive encephalopathy
   b) converting a massive pale (ischemic) infarct into a hemorrhagic infarct
   c) patients with ICH; some HTN is needed to maintain CBF, see Initial management of ICH (p.1339)

**Hypertension treatment algorithm (modified)**

See reference. Recommended lower limits for treatment endpoints are shown in Table 84.2.

1. If DBP >140 (malignant hypertension): ≈20–30% reduction is desirable. Cardene infusion or IV labetalol are agents of choice; arterial-line monitor recommended; sympatholytics (e.g. trimethaphan) contraindicated (they reduce CBF)
2. SBP >230 or DBP 120–140 × 20 mins: labetalol (p.126) (unless contraindicated): start at 10 mg slow IVP over 2 mins, then double q 10 min (20, 40, 80, then 160 mg slow IVP) until controlled or

Anticoagulants

Heparin
A prospective trial\(^3\) administering continuous IV infusion of unfractionated heparin titrated to keep APTT 1.5–2.5 × control found no significant improvement in outcome.\(^3\)\(^6\) The recurrent stroke rate in the 7 days following a stroke was only 0.6–2.2% per week.\(^3\)\(^5\)\(^3\)\(^7\) Effectiveness is unproven in strokes and TIs except with cardiogenic brain embolism (p.1304). Anticoagulation may also be hazardous,\(^3\) however the complication rate has not been assessed prospectively (small, nonrandomized studies have found symptomatic ICH in 1–8% and other bleeding complications in 3–12%).\(^3\) Conversion rate of pale → hemorrhagic stroke is 2–5% (dog studies suggest the risk is increased only when HTN not well controlled). Conclusion: the risk of heparin therapy for acute focal cerebral ischemia exceeds any proven benefit,\(^3\) and is not justified in most cases (especially when used just to placate the frustrated clinician).\(^3\)\(^9\)\(^4\)\(^0\) The American Heart Association has recommended: “Until more data are available, the use of heparin remains a matter of preference of the treating physician”.\(^3\)\(^5\) A small but significant reduction in recurrent stroke has been shown with ASA.

Warfarin
High-intensity warfarin therapy has proven helpful for the antiphospholipid antibody syndrome (APLAS) (p.1270).

For the rare indication for anticoagulation therapy:
1. first, R/O hemorrhage by CT before beginning therapy
2. ASA 325 mg PO q d in all patients with non-hemorrhagic stroke where anticoagulants or surgery not indicated (NB: angiography may be slightly more difficult in patients on ASA)
3. anticoagulants (heparin/warfarin):
   a) indications (rare)
      • probably effective for cardiogenic emboli (below)
      • shown ineffective for stroke in evolution (neuro deficit that begins, recurs, fluctuates, or worsens while patient in hospital), crescendo TIA or completed stroke. Note: in 74 patients with recent TIs, elevating PTT 1.5–2.5 x normal with heparin did not reduce recurrent TIs nor strokes. Bleeding occurred in 9 (12.2%). Additional risk: hemorrhage from heparin induced thrombocytopenia.\(^4\)\(^1\)
      • unproven, but generally used for carotid dissection
   b) contraindicated with large cardiac embolism, large stroke (risk of hemorrhagic conversion), peptic-ulcer disease that has bled in past 6 mos, uncontrolled severe HTN
   c) start IV heparin and simultaneous warfarin (Coumadin®). Maintain heparin during first ≈ 3 days of warfarin because of initial hypercoagulability, see Anticoagulation (p.156) for target APTT and INR
   d) stop warfarin after 6 months (benefits decline, risks rise)

Steroids (including Dexamethasone (Decadron®))

Indications:
1. steroid responsive vasculitis, e.g. giant cell arteritis (temporal arteritis)
2. cerebellar infarct/bleed with mass effect
Mannitol
1. indicated for cerebellar infarct/bleed, prior to surgery, or if mass effect
2. contraindicated in hypotension
3. initial dose: 50 to 100 gm IV over 20 minutes

Emergency surgery
Possible indications:
1. herniation from subdural hematoma
2. suboccipital craniectomy for progressive neurologic deterioration due to brainstem compression from cerebellar hemorrhage/infarction (see below)
3. decompressive craniectomy for malignant MCA territory stroke (see below)
4. carotid endarterectomy for high grade carotid stenosis ipsilateral to fluctuating neuro deficit; see Emergency carotid endarterectomy (p. 1295)

84.4 Carotid endarterectomy
84.4.1 Indications

Trials and results
Table 84.3 shows the status of current studies for the surgical treatment of carotid stenosis (NB: some of the results may be contradictory).

The North American Symptomatic Carotid Endarterectomy Trial\(^3\) (NASCET) found that for patients with a hemispheric or retinal TIA or a mild (non-disabling) stroke within 120 days and ipsilateral high-grade stenosis (>70%), that carotid endarterectomy (CEA) reduced the rate of fatal and non-fatal strokes (by 17% at 18 months) and death from any cause (by 7% at 18 months) when compared to best medical management (when surgery was performed with perioperative risk of stroke

\(^a\)abbreviations: NASCET=North American Symptomatic Carotid Endarterectomy Trial; ECST=European Carotid Surgery Trial; CASANOVA=Carotid Artery Stenosis with Asymptomatic Narrowing Operation Versus Aspirin; ACAS=Asymptomatic Carotid Atherosclerosis Study; ACST=Asymptomatic Carotid Atherosclerosis Study; VACS=Veteran's Administration Cooperative Study; CEA=carotid endarterectomy; BMM=best medical management
\(^b\)reduction in risk of all nonfatal strokes and death from any cause with CEA vs. BMM (e.g. with an absolute risk reduction of 16.5 at 2 yrs, for every 100 patients treated, 16.5 nonfatal strokes or deaths were prevented over a 2 year period)
\(^c\)surgery moderately beneficial (requires low complication rate)
\(^d\)the overall health of the patient is critical
\(^e\)results equivocal
or death of 5.8%. Results were twice as good for patients with stenosis from 90–99% than for those with 70–79%. Furthermore, with CEA the frequency of major functional impairment was reduced at 2 years. NB: see differences in techniques for measuring stenosis between NASCET and ECST Table 83.5.

See also asymptomatic patients (p. 1275).

Unresolved controversies

Include:
1. progressive STROKE (“stroke in evolution”): see Emergency carotid endarterectomy (p. 1295)
2. abrupt occlusion: see Emergency endarterectomy (p. 1295)
3. tandem lesions (e.g. carotid siphon and bifurcation stenosis): although this topic remains controversial, CEA in patients with tandem lesions has not been associated with increased postoperative stroke rates. Recent case series also report success with endovascular treatment
4. progressive retinal ischemia

84.4.2 Timing with respect to acute stroke

For patients with small fixed deficits or small infarcts on CT or MRI, the risk of early CEA is not increased. In the pooled analysis of the three symptomatic CEA studies, patients randomized in the trials within 2 weeks of the last symptomatic event had greater benefit from CEA. Data from Sundt (see below) indicates that a stroke is a risk factor for a complication only if it occurred within 7 days pre-op.

Since the introduction of tPA for the treatment of acute ischemic stroke, there have been reports on the successful treatment of residual critical ICA stenosis following tPA recanalization as early as 24 hours after administration of tPA in patients with small fixed deficit or small ischemic areas on MRI.

84.4.3 Pre-op risk factors for CEA

Identifying patients at high risk for complications after CEA has proven challenging. Typically, the exclusion criteria from studies is cited, but in most cases these are simply patients that were not included in the study because it was the investigators perception these patients might be “high risk.” Therefore these risk factors are not validated. They are included here for completeness.

NASCET and ACAS: age > 80 years, prior ipsilateral CEA, prior contralateral CEA within 4 months, prior neck XRT, tandem lesion larger than target lesion, other conditions that could cause symptoms (atrial fibrillation, prior stroke with persistent major deficit, valvular heart disease), major organ failure, uncontrolled hypertension or diabetes mellitus, and significant coronary artery disease.

The SAPPHIRE Trial (Stenting and Angioplasty with Protection in Patients at High-Risk for Endarterectomy): patients with clinically significant cardiac disease (CHF, abnormal stress test, or need for open-heart surgery), severe pulmonary disease, contralateral carotid occlusion, contralateral laryngeal-nerve palsy, previous radical neck surgery or neck XRT, recurrent stenosis after endarterectomy, and age > 80 years. The ARCHER Trial (ACCULINK for Revascularization of Carotids in High-Risk patients) also included patients with tracheostomy, spinal immobility, and dialysis-dependant renal failure.

84.4.4 Carotid endarterectomy – surgical considerations

Perioperative management

Pre-op management (carotid endarterectomy)
1. ASA 325 mg TID for at least 2 days, preferably 5 days pre-op (NB: patients should be kept on their ASA for surgery, and if not on ASA they should be started, in order to reduce risks of MI and TIA)
Post-op management (carotid endarterectomy)

1. patient monitored in ICU with A-line
2. keep patient well hydrated (run IVF ≥ 100 cc/hr for most adults)
3. SBP ideally 110 – 150 mm Hg (higher pressures are permitted in patients with chronic severe HTN)
   a) BP frequently labile in 1st 24 hrs post-op, may be due to “new” pressure in carotid bulb; to prevent rebound hyper- or hypo-tension, avoid long acting agents

   b) hypotension
      • check EKG – R/O cardiogenic shock
      • if mild, start with fluids (crystalloid or colloid)
      • phenylephrine (Neo-Synephrine®) for resistant hypotension
   c) hypertension: nicardipine (Cardene®) (p.126) is the agent of choice. Avoid rebound hypotension

4. avoid antiplatelet drugs for 24–48 hrs post-op (causes oozing); may start these 24–72 hrs post-op (note: ASA 325 mg + dipyridamole 75 mg TID have been shown not to reduce the rate of restenosis after endarterectomy\(^{61}\))
5. optional: reverse half of heparin with protamine 10 minutes after closing arteriotomy

Post-op check (carotid endarterectomy)
In addition to routine, the following should be checked:
1. change in neurologic status due to cerebral dysfunction, including:
   a) pronator drift (R/O new hemiparesis)
   b) signs of dysphasia (especially for left sided surgery)
   c) mimetic muscle symmetry (assesses facial nerve function)
2. pupil diameter and reaction (R/O stroke, Horner’s syndrome)
3. severe H/A (especially unilateral) > may indicate hyperperfusion syndrome
4. STA pulses (R/O external carotid occlusion)
5. tongue deviation (R/O hypoglossal nerve injury)
6. symmetry of lips (R/O weakness of lower lip depressors due to retraction of marginal mandibular branch of facial nerve against mandible, usually resolves in 6–12 wks, must differentiate from central VII palsy due to stroke)
7. check for hoarseness (R/O recurrent laryngeal nerve injury)
8. assess for hematoma in operative site: note any tracheal deviation, dysphagia

Post-op complications (carotid endarterectomy)
To justify CEA, the absolute upper limit of (significant) complication rate should be ≤ 3%.
1. overall in-hospital mortality: 1%\(^{62}\)
2. disruption of arteriotomy closure: rare, but emergent (see below)
   a) evidenced by:
      • swelling of neck: rupture may produce a pseudoaneurysm
      • tracheal deviation (visible, palpable, or on CXR)
      • symptoms: dysphagia, air hunger or worsening hoarseness, difficulty swallowing
   b) dangers:
      • asphyxiation: most immediate danger
      • stroke
      • exsanguination (unlikely, unless skin closure is also disrupted)
   c) late (often delayed weeks to months): false aneurysm\(^{63}\). Risk = 0.33% Presents as neck mass. Risk is increased with wound infection and possibly with patch graft as compared to endarterectomy alone\(^{63,64,65}\)
3. stroke (cerebral infarction) intra-op or post-op rate\(^{66}\): 5%
   a) embolic (the most common cause of minor post-op neurologic deficit): source may be denuded media of endarterectomy
   b) intracerebral hemorrhagic (ICH) (breakthrough bleeding): occurs in < 0.6%\(^{67}\). Related to cerebral hyperperfusion in most\(^{68,69}\) (see below). Usually occurs within first 2 weeks, often in basal ganglion 3–4 days post-op with hypertensive episode. Patients at greatest risk are those with severe stenosis and limited hemispheric collateral flow
   c) post-op ICA occlusion
      • most common cause of major post-op stroke, but may be asymptomatic
      • risk is reduced by attention to technical details at surgery\(^{70}\) (p 249)
      • some may be due to hypercoagulable state induced by heparin (predictable in patients whose platelet count drops while on heparin. No known therapy for this condition\(^{70}\) (p 249–50))
the endarterectomized surface is highly thrombogenic for 4 hrs following endarterectomy (Sundt recommends not reversing heparin)

in Sundt’s series using patch graft: 0.8% incidence, associated with major stroke in 33% and minor stroke in 20%

occlusion rate with primary closure: 4% in Sundt’s experience, 2–5% in literature.

post-op TIAs: most due to ICA occlusion. Some may be due to microemboli. Hyperperfusion syndrome produces a 1% incidence of post-op TIAs.

seizures: usually focal in onset with possible generalization, most occur late (post-op day 5–13) with an incidence of up to 4%.

late restenosis: identifiable restenosis occurs in 1% of patients. Restenosis is usually due to fibrous hyperplasia, after 2 yrs it is typically due to atherosclerosis.

4. post-op TIAs: most due to ICA occlusion. Some may be due to microemboli. Hyperperfusion syndrome produces a 1% incidence of post-op TIAs.

5. seizures: usually focal in onset with possible generalization, most occur late (post-op day 5–13) with an incidence of up to 4%.

6. late restenosis: identifiable restenosis occurs in 1% of patients. Restenosis is usually due to fibrous hyperplasia, after 2 yrs it is typically due to atherosclerosis.

7. cerebral hyperperfusion syndrome (AKA normal pressure hyperperfusion breakthrough): classically thought to result from return of blood flow to an area that has lost autoregulation due to chronic cerebral ischemia typically from high-grade stenosis. Usually presents as ipsilateral vascular headache or eye pain that subsides within several days or with seizures.

8. hoarseness: the most common cause is laryngeal edema and not superior nor recurrent laryngeal nerve injury.

9. cranial nerve injury: the most common complication after CEA with an incidence of up to 8–10%.
   a) hypoglossal nerve: tongue deviation towards the side of injury: incidence ≈ 1% (with mobilizing XII to allow displacement). Unilateral injury may cause speaking, chewing and swallowing difficulties. Bilateral injuries can cause upper airway obstruction.
   b) vagus or recurrent laryngeal nerve: unilateral vocal cord paralysis: 1% risk.
   c) mandibular branch of facial nerve: loss of ipsilateral lip depressor.

10. headache:

11. hypertension: may develop 5–7 days post-op. Longstanding HTN may occur as a result of the loss of the carotid sinus baroreceptor reflex.
angiogram: identifies whether ICA is occluded, or if deficit is from another cause (e.g. emboli from endarterectomy site) that would not benefit from re-exploration or possibly endovascular treatment

3. disruption of arteriotomy closure, management
   a) OPEN WOUND – if there is any stridor, it is critical to do this before trying to intubate (although ideally performed in O.R., the delay may be decisive). Evacuate clot (start with a sterile gloved finger) and stop bleeding, preferably without traumatizing the artery, a DeBakey clamp is optimal
   b) INTUBATION – high priority, may be difficult or impossible if trachea is deviated (open wound immediately). Preferably done by anesthesiologist in controlled setting (i.e. O.R.) unless there is acute airway obstruction
   c) call O.R. and have them prepare set-up for endarterectomy, and take patient to O.R.

84.4.5 Operative technique

Anesthesia and monitoring

Most (but not all) surgeons monitor some parameter of neurologic function during carotid endarterectomy, and will alter technique (e.g. insert a vascular shunt) if there is evidence of hemodynamic intolerance of carotid clamping (only occurs in $\approx 1-4\%$).

1. local/regional anesthesia: permits “clinical” monitoring of patient’s neurologic function $^{83,84}\text{Disadvantages: patient movement during procedure (often exacerbated by sedation and alterations in CBF), lack of cerebral protection from anesthetic and adjunctive agents. The only prospective randomized study found no difference between local and general anesthesia.}^{85}$ The multicenter, randomized controlled General Anesthesia versus Local Anesthesia (GALA) Trial$^{86}$ found no significant differences in the prevention of stroke, MI, or death for either anesthetic technique. Subgroup analysis showed trends (not statistically significant) favoring local anesthesia for perioperative death, event-free survival at 1 year, and patients with contralateral occlusion. Local anesthesia was associated with a significant reduction of shunt insertion. $\text{A Cochrane Database Review found no evidence from randomized trials to favor either anesthetic technique}^{87}$

2. general anesthesia, possibly including barbiturates (thiopental boluses of 125–250 mg until 15–30 second burst suppression on EEG, followed by small bolus injections or constant infusion to maintain burst suppression$^{59}\text{a) EEG monitoring}^{\text{b) SSEP monitoring}}$
   a) EEG monitoring
   b) SSEP monitoring
   c) measurement of distal stump pressure after CCA occlusion (unreliable), e.g. using a shunt if stump pressure <25 mm Hg
   d) transcranial Doppler
   e) near-infrared spectroscopy

Position and incision

1. supine, neck slightly extended and rotated slightly ($\approx 30^\circ$) away from the operative side
2. the incision curves gently and follows the anterior border of the sternocleidomastoid muscle, and curves posteriorly at the rostral end
3. keep the horizontal portion of the incision $\approx 1$ cm away from the mandible to avoid injury to marginal mandibular branch of facial nerve (which lies in the inferior parotid gland and supplies lip depressor) due to retraction against mandible
4. retractors should not be placed deeper than the platysma to avoid injury to recurrent laryngeal nerve which runs between the esophagus and trachea. Blunt retractors are used to avoid internal jugular vein injury

Dissection

1. the common facial vein (CFV) usually crosses the field over the carotid bifurcation, it is doubly ligated and divided. It leads to the internal jugular vein (IJV)
2. identifying the IJV is key, dissection is carried down between the carotid artery and the IJV
3. the ansa hypoglossi runs superficial to the ICA and serves as a useful guide to the hypoglossal nerve (XII) which should be identified since it is at greater risk when it is not seen. XII can arise anywhere from the carotid bifurcation to the angle of the mandible, although it is usually in the vicinity of the CFV. Mobilization can be facilitated by dividing the small artery (sternocleidomastoid branch of the ECA) and vein that cross over it$^{79}$
4. the ansa hypoglossi can usually be spared, and if mobilized, allows medial retraction of the hypoglossal nerve out of harm’s way. If it is necessary to divide the ansa it is done close to the hypoglossal nerve to be certain it is not a branch of the vagus and to minimize neurologic deficit (the ansa has an anterior cervical limb from the cervical plexus)

5. the superior thyroid artery is the first branch of the ECA, and helps differentiate ECA from the ICA (the ICA is located posterior to the ECA)

6. the carotid bulb may be anesthetized with ≈2–3 ml of 1% plain lidocaine using a 27 Ga needle. This may be done routinely, or, as some prefer only if hypotension and/or bradycardia occur during dissection (indicating IX nerve stimulation)

7. the ICA must be exposed beyond the extent of the plaque which can be determined by gentle palpation with a moistened finger and by visualization as the area where the artery turns from yellowish to its normal pinker color

**Occlusion and arteriotomy**

1. a vessel loop is placed around the ECA at least 2 cm above the bifurcation
2. a vessel loop is also placed around the ICA but is looped only once
3. umbilical tape with a choke is placed around the CCA 2–3 cm below the bifurcation
4. IV heparin (usually 5,000 IU) is given 1 minute prior to cross clamping
5. a temporary aneurysm clip is placed on the superior thyroid artery
6. the order of occlusion of the vessels is as follows (mnemonic: “ICE”):
   a) ICA (e.g. with temporary aneurysm clip)
   b) CCA (e.g. with a small DeBakey clamp)
   c) ECA (e.g. with temporary aneurysm clip)
7. during ICA clamping, mild hypertension is maintained by the anesthesiologist
8. shunt: some surgeons use some form of monitoring (EEG, BSAER, etc.) to determine if a shunt is needed – see Anesthesia and monitoring (p.1294) – yet others routinely use a shunt whenever possible without assessing the need
9. the arteriotomy is begun in the CCA with a #11 scalpel, and once the lumen is entered, a Potts’ scissors carries the incision through to the ICA beyond the plaque. Stay in the midline to facilitate arteriotomy closure

**Plaque removal**

1. the plaque usually cannot be completely removed from the CCA, and thus it is usually transected with a Potts’ scissors taking care not to inadvertently incise the artery wall and to leave as smooth an edge as possible
2. in the ICA, great care must be made to avoid leaving an intimal flap which could become a nidus for an arterial dissection. If necessary the intima may be tacked down by suturing from the lumen out on both ends (using double armed suture) and tying the knot outside the vessel

**Arteriotomy closure and vessel release**

1. arteriotomy may be performed with a running Prolene suture using either
   a) primary closure
   b) or with a patch graft to increase the caliber of the vessel and reduce the risk of re-stenosis
   c) limited evidence suggests that carotid patch angioplasty may reduce the risk of perioperative arterial occlusion and re-stenosis. Synthetic patches (Dacron, PTFE) are preferred to autologous vein (risk of aneurysmal dilatation, thrombogenic surface) [88,89]
2. the order of releasing the vessels (reverse that of the clamping order):
   a) ECA
   b) CCA (allows air and debris to be washed into the ECA)
   c) ICA

**84.4.6 Emergency carotid endarterectomy**

**General information**

Emergency CEA indications include crescendo TIAs and stroke in evolution. The treatment paradigm of these conditions has shifted towards the use of interventional methods, such as thrombolysis and stenting, although there are no randomized controlled trial data to support that approach. A recent meta-analysis of emergent CEA has shown that the pooled stroke and stroke/death rates after CEA
for crescendo TIA in 176 patients were 6.5% and 9.0% respectively. For those with stroke in evolution, the overall stroke and stroke/death rates in 114 patients were 16.9% and 20.0% respectively.90

After retrospective analysis of 64 emergency endarterectomies91 the guidelines given below were suggested. However, the efficacy of immediate surgical removal of obstruction is controversial and unproven. In one early study, over 50% of patients suffered fatal intracranial hemorrhage within 72 hours of emergency carotid endarterectomy.

Initial management of patient presenting with acute neuro deficit

1. obtain history directed at determining presence of previous stroke and other serious medical illness, and to try to differentiate from seizure
2. baseline neurological assessment including evaluation of STA pulses and carotid bruits
3. during evaluation: close control of BP. O2 per NC. Labs + EKG; see Management of TIA or stroke (p. 1282). Consider hemodilution with LMD
4. CT to R/O ICH or infarction (early stroke will not be visible)
5. when carotid disease is suspected, and CT is negative for ICH or acute infarct, emergency angiography, MRI/MRA or CTA is performed

Indications for emergency carotid endarterectomy

General information
In patients with acute neurological deficits, the need for rapid decision making often does not allow differentiating between TIA, stroke in evolution and acute stroke, nor in assessing the stability or fluctuating nature of the deficit.

Indications
1. stroke in evolution
2. crescendo TIA: TIA that abruptly increase in frequency to ≥ several per day
3. following intra-arterial thrombolysis, emergent/urgent CEA is indicated for residual critical carotid stenosis54,92

Contraindications
See also more details (p. 1286). Patients with depressed levels of consciousness or acute fixed deficits.

Surgical management
Again, most cases would now be managed initially with endovascular thrombolysis and stenting. Surgery would considered if this is not an option.
1. for emergency surgery, it is essential that blood pressure be stable
2. in patients with complete occlusion, ICA is not occluded intra-op (to avoid breaking up thrombus, if present)
3. if thrombus present
   a) attempt spontaneous extrusion using back pressure
   b) if this fails, attempt to remove with smoothened suction catheter
   c) if this fails, pass balloon embolectomy catheter as far as base of skull (caution: avoid injury to distal ICA that could cause CCF)
   d) obtain intra-op angiogram unless thrombus emerges and backflow is excellent
   e) plicate ICA (avoid creating a blind pouch at origin) if there is good backflow or if satisfactory angiography cannot be obtained

Surgical results
Highest correlation was with presenting neurologic status (Table 84.4).

84.5 Carotid angioplasty/stenting

84.5.1 General information

There are no well-designed studies that convincingly show superiority of angioplasty/stenting over CEA in average risk symptomatic patients, and the recommendation in these patients is to continue with the time-tested technique of CEA.

There is a paucity of randomized control trials comparing carotid angioplasty/stenting with CEA, and many nonrandomized registries. However, data from multicenter randomized trials showing that carotid angioplasty/stenting is as safe over the short term or as efficacious over the long term as CEA in average-risk symptomatic patients are lacking. Published trials are heterogeneous (clinically and methodologically), too small to provide robust and convincing data, and limited in long-term follow-up. Only the SAPHIRE study comparing CEA with stenting (using a distal embolic protection device) for moderate to severe carotid stenosis with comorbidities that might increase the risk of CEA (high-risk patients), found that angioplasty/stenting was not inferior (risk within 3% P=0.004) to CEA (based on a composite primary end point of stroke, death, or MI within 30 days, or death from neurologic causes or ipsilateral stroke between 31 days and 1 year). However, the study methodology has been criticized.

A 2007 Cochrane review concluded that available data on carotid angioplasty/stenting are difficult to interpret and does not support a change in clinical practice away from recommending CEA as the treatment of choice for suitable carotid artery stenosis.

84.5.2 Indications for angioplasty/stenting

Carotid stenting performed with adequate procedural quality levels, should be considered instead of CEA in the presence of:

1. severe vascular and cardiac comorbidities:
   a) congestive heart failure (New York Heart Association class III/IV) and/or known severe left ventricular dysfunction
   b) open heart surgery needed within 6 weeks
   c) recent myocardial infarction (< 24 hours and > 4 weeks)
   d) unstable angina (Canadian Cardiovascular Society class III/IV)
   e) contralateral carotid occlusion

2. specific conditions:
   a) contralateral laryngeal nerve palsy
   b) radiation therapy to the neck
   c) previous CEA with recurrent restenosis
   d) high cervical internal carotid/below the clavicle common carotid lesions
   e) severe tandem lesions
   f) age > 80 years
   g) severe pulmonary disease

The 2009 European Society for Vascular Surgery (ESVS) Guidelines state that carotid angioplasty/stenting is indicated in cases of: contralateral laryngeal nerve palsy; previous radical neck dissection or cervical XRT; prior CEA (re-stenosis); high bifurcation or intracranial extension of a carotid lesion, provided that the peri-interventional stroke or death rate is not higher than that accepted for CEA (Class C recommendation).

AHA Guidelines state that angioplasty/stenting might be a reasonable alternative to CEA in asymptomatic high risk patients. However, they stress that it remains uncertain whether this group of patients should have either procedure.

[94] Alberts MJ. Results of a multicenter prospective randomized trial of carotid artery stenting vs. carotid endarterectomy. Stroke. 2001; 32

85 Special Conditions

85.1 Totally occluded internal carotid artery

85.1.1 General information

10–15% of patients presenting with carotid territory stroke or transient ischemic attacks (TIA) are found to have carotid occlusion. This amounts to an estimated 61,000 first ever strokes and 19,000 TIA's per year in the United States. Prevention of subsequent stroke in symptomatic patients with carotid artery occlusion remains a difficult challenge. The overall rate of subsequent stroke is 7% per year for all stroke and 5.9% per year for ischemic stroke ipsilateral to the occluded carotid artery. These risks persist even despite treatment with antiaggregants and anticoagulants. The prevalence of asymptomatic carotid occlusion is not known, and the incidence of ipsilateral stroke in never-symptomatic carotid occlusion is negligible.

85.1.2 Presentation

3 patterns of stroke with acute carotid artery occlusion:
1. stump emboli: produces cortical infarcts. Emboli usually go up the external carotid (higher flow, and reverse flow that may occur through ICA initially prevents embol from ICA). Later, ICA emboli may occur.
2. whole hemisphere stroke
3. watershed infarct

In symptomatic patients: hemiparetic TIA 53%, dysphasic TIA 34%, fixed neuro deficit 21%, crescendo TIAs 21%, amaurosis fugax 17%, acute hemiplegia 6%. One series had 27% asymptomatic. Patients may have the so-called "slow carotid stroke" of carotid occlusion which is a stuttering progressive stroke.

85.1.3 Natural history

See reference.

Patients with mild deficit and angiographically proven ICA occlusion have a stroke rate (in two series) of 3 or 5% per year (2 or 3.3% related to occluded side). In patients with acute ICA occlusion and profound neurological deficit, 2–12% make good recovery, 40–69% will have profound deficit, and 16–55% will have died by the time of follow-up.

85.1.4 Endovascular thrombolysis and stenting for acute carotid occlusion

Case reports and series of endovascular treatment of internal carotid artery occlusion have confirmed the feasibility of this technique. Intra-arterial thrombolysis within 6 hours of stroke onset may increase recanalization rates to 37%–100% and clinical improvement to 53%–94% without significant increase in hemorrhagic transformation when compared with intravenous thrombolytic therapy alone. Although results appear promising, randomized controlled trials on cervical carotid thrombolysis and/or stenting are lacking.

85.1.5 Surgery

Options include: endarterectomy, Fogarty balloon catheter embolectomy (utilizing a No. 2 French catheter with 0.2 ml balloon gently passed 10–12 cm up ICA from small arteriotomy made distal to atheromatous plaque), extracranial-intracranial bypass. Restored patency rate is inversely related to suspected duration of occlusion. Chronically occluded ICA has poor patency rate and little gain from re-opening.

Determining the exact time of occlusion is frequently impossible. One must often rely on clinical grounds, therefore an occasional chronic occlusion will be included.

Retrograde filling of ICA to petrous or cavernous segment from ECA (e.g. via ophthalmic) or from contralateral ICA is a good sign of operability.

Surgical results
32% (15/47 cases) immediate surgical failures (no or minimal back bleeding), at least 3 deaths. Among immediate successes no strokes and no TIAs. If operated <2 days reported patency rate 70–100% from 3–7 days 50–100% 8–14 days 27–58% 15–30 days 4–61% over 1 month (2 series) 20–50%.

85.1.6 Guidelines
Emergency operations for acute neuro deficit associated with total occlusion should not be performed after about 2 hrs. Extremely poor neuro status (lethargy/coma) is a contraindication to surgery. Patients without persistent neuro deficit: operate ASAP. If the patient has recurrent TIAs (despite maximal medical therapy) following recent carotid occlusion, and no definite infarct on MRI, consider by-pass surgery.

85.2 Cerebellar infarction
85.2.1 General information
Relatively rare (seen on only 0.6% of all CTs obtained for any reason). Cerebellar infarcts may be classified as involving the PICA distribution (cerebellar tonsil and/or inferior vermis), superior cerebellar artery distribution (superior hemisphere or superior vermis), or other indeterminate patterns. 80% of patients developing signs of brainstem compression will die, usually within hours to days.

85.2.2 Early clinical findings
In most cases the onset is sudden, without premonitory symptoms. The first 12 hrs after onset were characterized by lack of progression. Early findings are due to the intrinsic cerebellar lesion (ischemic infarction or hemorrhage):
1. symptoms
   a) dizziness or vertigo
   b) nausea/vomiting
   c) loss of balance, often with a fall and inability to get up
   d) headache (infrequent in one series)
2. signs
   a) truncal and appendicular ataxia
   b) nystagmus
   c) dysarthria

85.2.3 Later clinical findings
Patients with cerebellar infarction may subsequently develop increased pressure within the posterior fossa (due to cerebellar edema or mass effect from clot), with brainstem compression (particularly posterior pons). Clinical findings generally increase between 12–96 hrs following onset. Compression the sylvian aqueduct can cause acute hydrocephalus with attendant increased ICP.

85.2.4 Imaging studies
CT scan: may be normal very early in these patients. There may be subtle findings of a tight posterior fossa: compression or obliteration of basal cisterns or 4th ventricle or hydrocephalus.
   MRI: (including DWI) more sensitive for ischemia, especially in the posterior fossa.

85.2.5 Surgical indications
Surgical decompression (see below) should probably be done as soon as any of the following signs develop if there is no response to medical therapy. It is important to recognize a lateral medullary syndrome (LMS) which may often accompany a cerebellar infarct. With LMS, the signs are usually present from the onset (dysphagia, dysarthria, Horner’s syndrome, ipsilateral facial numbness, crossed sensory loss...), and are not accompanied by a change in sensorium. There is no place for surgical decompression in LMS since it represents primary brainstem ischemia and not compression.
Findings proceed in the approximate following sequence if there is no intervention:
1. abducens (VI) nerve palsy
2. loss of ipsilateral gaze (compression of VI nucleus and lateral gaze center)
3. peripheral facial nerve paresis (compression of facial colliculus)
4. confusion and somnolence (may be partly due to developing hydrocephalus)
5. Babinski sign
6. hemiparesis
7. lethargy
8. small but reactive pupils
9. coma
10. posturing → flaccidity
11. ataxic respirations

85.2.6 Suboccipital craniectomy for cerebellar infarction

Unlike the situation with supratentorial masses causing herniation, there are several reports of patients in deep coma from direct brainstem compression who were operated upon quickly who made useful recovery.17,18,19 See also Guidelines for patients with cerebellar hemorrhage (p. 1344).

The operation of choice is a suboccipital decompression to include enlargement of the foramen magnum. The dura is then opened and the infarcted cerebellar tissue usually exudes “like toothpaste” and is easily aspirated. Avoid using ventricular drainage alone as this may cause upward cerebellar herniation (p. 303) and does not relieve the direct brainstem compression.

85.3 Malignant middle cerebral artery territory infarction

85.3.1 General information

A distinct syndrome that occurs in up to 10% of stroke patients,20,21 which carries a mortality of up to 80% (mostly due to severe postischemic cerebral edema → increased ICP → herniation).21 Patients usually present with findings of severe hemispheric stroke (hemiplegia, forced eye and head deviation) often with CT findings of major infarct within the first 12 hours. Most develop drowsiness shortly after admission. There is progressive deterioration during the first 2 days, and subsequent transtentorial herniation usually within 2–4 days of stroke. Fatalities are often associated with: severe drowsiness, dense hemiplegia, age >45–50 yrs,22 early parenchymal hypodensity involving >50% of the MCA distribution on CT scan,23 midline shift >8–10 mm, early sulcal effacement and hyperdense artery sign (p. 1281) in MCA.

Neurosurgeons may become involved in caring for these patients because aggressive therapies in these patients may reduce morbidity and mortality. Options include:
1. conventional measures to control ICP (with or without ICP monitor): mortality is still high in this group, and elevated ICP is not a common cause of initial neurologic deterioration in large hemispheric stroke
2. hemicraniectomy (decompressive craniectomy): see below
3. to date, the following treatments have not improved outcome: agents to lyse clot, hyperventilation, mannitol, or barbiturate coma

85.3.2 Hemicraniectomy for malignant MCA territory infarction

May reduce mortality to as low as 32% in nondominant hemisphere strokes24 (37% in all comers25) with surprising reduction of hemiplegia, and in dominant hemisphere strokes, with only mild-moderate aphasia (better results occur with early surgery, especially if surgery is performed before any changes associated with herniation occur). Meta-analysis26 of 3 randomized controlled trials found that hemicraniectomy within 48 hours after stroke onset resulted in decreased mortality and increased the number of patients with a favorable functional outcome. Indications: No firm indications. Guidelines:
1. age <70 years
2. more strongly considered in nondominant hemisphere (usually right)
3. clinical & CT evidence of acute, complete ICA or MCA infarcts and direct signs of impending or complete severe hemispheric brain swelling (severe post-admission neurologic deterioration is the usual event that triggers surgical intervention)

See also Technique (p. 1467).
85.4 Cardiogenic brain embolism

85.4.1 General information

About one stroke in six is cardioembolic. Emboli may be composed of fibrin-rich thrombi (e.g. mural thrombi due to segmental myocardial hypokinesis following MI or ventricular aneurysm), platelets (e.g. nonbacterial thrombotic endocarditis), calcified material (e.g. in aortic stenosis), or tumor particles (e.g. atrial myxoma).

85.4.2 Following acute myocardial infarction (AMI)

2.5% of patients will have a stroke within 1–2 weeks of an AMI (the period when most emboli occur). The risk is higher with anterior wall MI (≈ 6% vs. inferior wall MI (≈ 1%).

85.4.3 Atrial fibrillation (A-fib)

Nonrheumatic patients with a-fib have a 3–5 fold increased risk of stroke,\(^{27}\) with a 4.5% rate of stroke per year without treatment.\(^{28}\) The incidence of a-fib in the U.S. is 2.2 million. About 75% of strokes in patients with A-fib are due to left atrial thrombi.\(^ {29}\) Independent risk factors for stroke in patients with A-fib are: advanced age, prior embolism (stroke or TIA), HTN, DM, and echocardiographic evidence of left atrial enlargement or left ventricular dysfunction.\(^ {27}\)

The CHADS2 scoring system for patients with a-fib has been widely validated\(^ {30}\) and is shown in Table 85.1. The points are totaled and risk assessment is shown in Table 85.2. For patients with a CHADS2 score ≥ 2, warfarin therapy was significantly protective for out-of-hospital death or hospitalization for stroke, MI or hemorrhage (CI=0.61–0.91).\(^ {31}\)

85.4.4 Prosthetic heart valves

Patients with mechanical prosthetic heart valves on long-term anticoagulation have an embolism rate of 3%/year for mitral and 1.5%/year for aortic valves. With bioprosthetic heart valves and no anticoagulation the risk is 2–4%/year.

85.4.5 Paradoxical embolism
Paradoxical embolism can occur with a patent foramen ovale which is present in 10–18% of the general population, but in up to 56% of young adults with unexplained stroke.\textsuperscript{32}

85.4.6 Endocarditis

**Diagnosis**

Blood cultures and TEE help evaluate.

No specific neurologic features can distinguish these patients. The diagnosis is suggested in imaging studies showing multiple intracranial ischemic strokes in different arterial distributions, the differential diagnosis includes: vasculitis, intracranial atherosclerosis (focal plaques, more common in Asian populations that consume Western diets), and intravascular lymphomatosis.

The diagnosis of cardiogenic brain embolism (CBE) as a cause of a stroke relies on demonstrating a potential cardiac source, the absence of cerebrovascular disease, and non-lacunar stroke.

Large areas of hemorrhagic transformation within an ischemic infarct may be more indicative of CBE due to thrombolysis of the clot and reperfusion of infarcted brain with subsequent hemorrhagic conversion. Hemorrhagic transformation most often occurs within 48 hrs of a CBE stroke, and is more common with larger strokes.

**Detection of cardiac source**

Most centers rely on echocardiography (without transesophageal ability). Using restricted criteria (i.e. excluding mitral valve prolapse), about 10% of patients with ischemic stroke will have potential cardiac source detected by echo, and most of these patients have other manifestations of cardiac disease. In stroke patients without clinical heart disease, only 1.5% will have a positive echo; the yield is higher in younger patients without cerebrovascular disease.\textsuperscript{33}

EKG may detect atrial fibrillation which may be seen in 6–24% of ischemic strokes, and may be associated with a 5-fold increased risk of stroke (see below).

**Treatment**

CBE is essentially the only condition for which anticoagulation has been shown to significantly reduce the rate of further strokes.

One must balance the risk of recurrent emboli (12% of patients with a cardioembolic stroke will have a second embolic stroke within 2 weeks) against that of converting a pale infarct into a hemorrhagic one. No study has shown a clear benefit of early anticoagulation.

Recommendations for anticoagulation:

1. if anticoagulation is to be used, it should not be instituted within the first 48 hrs of a probable CBE stroke
2. CT should be obtained after 48 hrs following a CBE stroke and before starting anticoagulation (to R/O hemorrhage)
3. anticoagulation should not be used in the face of large infarcts
4. start heparin and warfarin simultaneously. Continue heparin for 3 days into warfarin therapy, see Anticoagulation (p. 156)
5. optimal range of oral anticoagulation to minimize subsequent embolism and/or hemorrhage has not been determined, but pending further data, an INR of 2–3 appears satisfactory
6. patients with asymptomatic A-fib have 66–86% reduction in stroke risk with warfarin (Coumadin®).\textsuperscript{27,34} ASA is only about half as effective, but may be sufficient for those without associated risk factors (p. 1304)\textsuperscript{27}

85.5 Vertebrobasilar insufficiency

85.5.1 General information

Signs and symptoms resulting from inadequate blood flow through the posterior cerebral circulation (vertebral arteries, basilar artery and their branches).
85.5.2 Symptoms

Table 85.3 shows a mnemonic of the symptoms of vertebrobasilar insufficiency (VBI). Predicting the site of the lesion based only on clinical evaluation is very unreliable.

Diagnostic criteria for VBI are shown in Table 85.3.

VBI may also be suspected in a patient with transient episodes of “dizziness” (vertigo that is otherwise unexplained, e.g. absence of orthostatic hypotension or benign positional vertigo) that is initiated by positional changes. VBI may sometimes be due to compression of the VA at the C1-C2 level with:

1. head turning (below)
2. odontoid process (p.981)
3. anterior atlantoaxial subluxation: e.g. in rheumatoid arthritis (p.1134)
4. with rotary atlantoaxial subluxation (p.968)

85.5.3 Pathophysiology

Atheromatous and stenotic lesions of the posterior circulation occur most frequently at the VA origin.

VBI symptoms may be due to:

1. hemodynamic insufficiency (may be the most common etiology), including:
   a) subclavian steal: reversed flow in VA due to proximal stenosis of subclavian artery
   b) stenosis of both VAs or of one VA where the other is hypofunctional (e.g. hypoplastic, occluded, or terminates in PICA) causing reduced distal flow in face of inadequate collaterals (below)
2. embolism from ulcerations
3. atherosclerotic occlusion of brainstem perforators
4. Vertebrobasilar hypoplasia: reported as a possible etiology for cerebellar stroke.

85.5.4 Natural history

No clinical study accurately defines the natural history. The estimated stroke rate is 22–35% over 5 years, or 4.5–7% per year (one study estimating 35% stroke rate in 5 years did not use angiography).

Risk of stroke after first VBI-TIA has been estimated as 22% for first year.

85.5.5 Evaluation

Adequate investigation usually requires selective four-vessel angiography, sometimes with provocative maneuvers (see e.g. Bow Hunter’s Syndrome below). CTA may also be useful.

85.5.6 Treatment

Anticoagulation is the mainstay of medical management. Alternatives include anti-platelet drugs such as ASA (efficacy of either remains unproven).

---

Table 85.3 Mnemonic: “The 5 D’s of VBI”

- “drop attack”
- diplopia
- dysarthria
- defect (visual field)
- dizziness

Table 85.4 Criteria for clinical diagnosis of VBI

Clinical diagnosis requires 2 or more of the following

- motor or sensory symptoms or both, occurring bilaterally in the same event
- diplopia: ischemia of upper brainstem (midbrain) near ocular nuclei
- dysarthria: ischemia of lower brainstem
- homonymous hemianopsia: ischemia of occipital cortex (NB: this is binocular, in contrast to amaurosis fugax which is monocular)
Surgical treatment includes:
1. vertebral endarterectomy
2. transposition of VA to ICA (with or without carotid endarterectomy, with or without saphenous vein patch graft) or to thyrocervical trunk or to subclavian artery
3. bypass grafting (e.g. occipital artery to PICA)
4. C1–2 posterior arthrodesis (p.1479) may prevent potentially life-threatening stroke in cases of os odontoideum (p.982)

85.6 Bow hunter’s stroke

85.6.1 General information
A special subset of VBI. The term was coined in 1978 by Sorensen. Bow hunter’s stroke (BHS): hemodynamic VBI induced by intermittent VA occlusion resulting from head rotation (ischemic sequelae range from TIA (bow hunter’s sign) to completed stroke). May occur with forced (e.g. with chiropractic neck manipulation) or voluntary head rotation.

Occlusion usually involves the VA contralateral to the direction of rotation, and usually occurs at the Cl–C2 junction (due to the immobility of the VA at this location). However, other sites have also been reported. VA occlusion does not produce symptoms in most individuals due to collateral flow through the contralateral VA and/or the circle of Willis. Symptomatic occlusion usually involves the dominant VA, however, may also occur with non-dominant VA. Most cases of BHS occur in patients with an isolated posterior circulation (incompetent posterior communicating arteries).

BHS has also been postulated as one possible cause of SIDS.

85.6.2 Contributing factors
1. external VA compression
   a) spondylotic bone spurs: particularly in the foramen transversarium
   b) tumors
   c) fibrous bands (e.g. proximal to entrance of VA into C6 foramen transversarium)
   d) infectious processes
   e) trauma
2. tethering of the VA
   a) at the transverse foramina of Cl & C2
   b) along the sulcus arteriosus proximal to where the VA enters the dura
3. defect in odontoid process
4. atherosclerotic vascular disease

85.6.3 Diagnosis

General information
BHS should be suspected in patient with symptoms of VBI precipitated by head movement. This may be very difficult to differentiate from vertigo and nausea due to vestibular dysfunction (which can also be induced by head movement) – (rotation of the body keeping the head motionless should not cause symptoms from vestibular symptoms and might help distinguish these conditions).

Dynamic cerebral angiography (DCA)
NB: significant consequences can be precipitated during DCA in patients with BHS. The involved VA shows loss of flow as the head is rotated from the neutral position to the contralateral side. Carotid injections demonstrate patency of P-comms and the presence of any persistent fetal anastomoses.

CT angiogram (CTA)
Same precautions as with DCA (see above). Probably not the initial diagnostic study of choice. If the DCA is negative, CTA is not needed. If DCA is positive, CTA may be helpful to demonstrate the arterial relationship to the bony anatomy.
85.6.4 Treatment

Options include:
1. anticoagulation
2. cervical collar: to remind patient not to turn their head
3. for VA compression at C1–2 (see Table 85.5 for a comparison):
   a) C1–2 fusion (p.1481)
   b) VA decompression: CI “hemilaminectomy” via a posterior approach
4. for compression at other sites: elimination of the source of compression where possible (e.g. sectioning of offending fibrous band, removal of osteophytic spurs…)

Management recommendations: For compression at C1–2, it is suggested that VA decompression be performed as the initial treatment. This should be followed by DCA to verify maintenance of patency with head turning. Patients who fail clinically or on DCA should undergo C1–2 fusion. Patients need to know pros and cons of each option.

85.7 Cerebrovascular venous thrombosis

85.7.1 General information

There are 3 types of cerebrovascular venous thrombosis (CVVT) (any of which may produce venous infarctions):
1. dural sinus thrombosis (DST)
2. cortical venous thrombosis
3. deep venous thrombosis

85.7.2 Etiologies

Partial list of etiologies

Many conditions have been incriminated with CVVT. Some common ones are listed here:

1. infection
   a) usually local, e.g. otitis media (leading to the now obsolete term otitic hydrocephalus), sinusitis, peritonsillar abscess, paranasal sinusitis: in the pre-antibiotic era, CVVT was most commonly associated with chronic suppurative infection
   b) meningitis
2. pregnancy & puerperium: see below
3. birth control pills (BCP) (oral contraceptives)
4. dehydration and cachexia (marantic thrombosis): includes burns and cachexia of neoplastic disease
5. cardiac disease (including CHF)
6. ulcerative colitis (UC): 1% of UC patients have some thrombotic complication (not necessarily all intracranial), and this is the cause of ≥ 33% of deaths (usually pulmonary embolism, PE)
7. periarteritis nodosa
8. sickle cell trait
9. trauma: including closed head injury (see below)
10. iatrogenic: e.g. S/P radical neck surgery, transvenous pacemaker placement, post-craniotomy
11. malignancy: including myeloproliferative disorders
12. hypercoagulable state (AKA thrombophilia)
   a) protein C deficiency or resistance to activated protein C: hereditary factor V Leiden mutation may produce resistance to activated protein C. Apparent protein C deficiency may be an artifact of dehydration in some cases
   b) antithrombin III deficiency
   c) protein S deficiency

d) antiphospholipid antibodies: associated with a variety of clinical syndromes including ischemic stroke, DVTs, thrombocytopenia, systemic lupus erythematosus SLE. The best known antibodies include
  - anticardiolipin antibodies
  - lupus anticoagulant
e) paroxysmal nocturnal hemoglobinuria (PNH)
f) plasminogen deficiency
g) systemic lupus erythematosus

h) factor VIII elevation: may explain some cases of CVVT in pregnancy (see below)

13. diabetes mellitus: especially with ketoacidosis
14. homocystinuria (p.200)
15. Behçet’s syndrome (p.200)
16. rarely associated with lumbar puncture, associated with hereditary activated protein C resistance due to the factor V R506Q mutation (FV Leiden) in one report

In the absence of factors such as BCP use, CVVT is highly suggestive of myeloproliferative disorder.

Pregnancy/puerperium

Highest risk is in first 2 wks post-partum. One series found no case of CVVT occurred later than 16 days post-partum. Incidence ≈ 1/10,000 births. Etiology may be related to elevation of clotting factors (VII, X and especially factor VIII).

Trauma

A rare sequela of closed head injury. CVVT occurs in ≈ 10% of combat injuries involving the brain. May occur in absence of skull fracture. CVVT should be suspected in patients with fractures or missiles crossing sinus.

85.7.3 Relative frequency of involvement

The relative frequency of involvement of dural sinuses and other veins with thrombotic issues

1. sinuses
   a) superior sagittal sinus (SSS) and left transverse sinus (TS) (70% each)
   b) multiple sinuses in 71%
   c) isolated inferior sagittal sinus: rare, first case report in 1997
   d) straight sinus

2. superficial cortical veins

3. deep venous system (e.g. internal cerebral vein)

4. cavernous sinus; rare. Thrombophlebitis of the cavernous sinus may be caused by sphenoid sinusitis. MRI may show enlargement and abnormal enhancement of the cavernous sinus, increased signal of the petrous apex and clivus on T2WI, and narrowing of the cavernous portion of the ICA.

85.7.4 Pathophysiology

Venous thrombosis reduces venous outflow from the brain and diminishes effective blood flow to the involved area. This venous engorgement causes white matter edema. The increased venous pressure may also lead to infarction and/or hemorrhage. These processes may all elevate ICP. Thus, clinical findings may be due to elevated ICP, and focal findings may be due to edema and/or hemorrhage. Cerebral infarction due to venous stasis is called venous infarction.

85.7.5 Clinical

Clinical presentations of DST are shown in Table 85.6. There are no pathognomonic findings. Many signs and symptoms are due to elevated ICP. May present as a syndrome clinically indistinguishable from idiopathic intracranial hypertension; see pseudotumor cerebri (p.768).

There is a high association of concurrent thromboembolic disease in other organs.

The anterior 1/3 of the SSS may occlude often without sequelae. Posterior to this, venous infarction is more likely to develop. Midportion SSS occlusion usually → increased muscle tone ranging from spastic hemi- or quadri-pareis to decerebration. Posterior SSS thrombosis → field cuts or cortical blindness, or massive stroke with cerebral edema and death. Occlusion of the TS may occur...
without deficit unless the contralateral TS is hypoplastic, in which cases presentation is similar to posterior SSS occlusion.

SSS occlusion alone will not cause cranial nerve findings except perhaps for visual obscuration and abducens (VI) nerve palsy from elevated ICP. Thrombosis in the jugular bulb may compress the nerves in the jugular foramen pars nervosa causing hoarseness, aphonia, difficulty swallowing and breathlessness; see Vernet’s syndrome (p.100).

### 85.7.6 Diagnosis of DST

#### General information

Catheter angioigraphy is better at demonstrating the presence of residual flow, and can identify areas of reversal of flow, and can sometimes demonstrate clot as a filling defect. However, CT (especially CTA) & MRI are better for identifying areas of clot. Angiography is often used as a complementary test when the diagnosis is suggested by CT or MRI.

#### CT scan

**Non-contrast CT**

May be normal in 10–20% of cases of DST. Findings include:

1. hyperdense sinuses and veins (high density clots in cortical veins has been dubbed the cord sign which is pathognomonic for cerebral venous thrombosis; seen in only 2/30 patients)
2. petechial “flame” hemorrhages (intraparenchymal): seen in 20% (suspect sinus thrombosis with intracerebral hemorrhages in unusual locations for aneurysm or “hypertensive” hemorrhage)
3. small ventricles: seen in 50%
4. thrombosis of superior sagittal sinus may produce a triangular-shaped high density within the sinus posteriorly near the Torcular herophili on axial CT images (some refer to this as the delta sign, but this causes confusion with the “empty delta sign”, see below) (there is also confusion when an apparent “empty delta sign” is seen without contrast, this may occur when there is blood surrounding the SSS, e.g. following subarachnoid hemorrhage, this has been called a “false delta sign” or pseudodelta sign.74). Recommendation: avoid the confusion of the variations on “delta signs” and describe the findings
5. white matter edema
6. above changes occurring bilaterally

#### IV contrast CT

Findings of DST include:

1. with contrast, the dura around the sinus may enhance and become denser than clot in 35% of cases.75 Near the Torcular herophili this produces what has been called the empty delta sign,76 but sometimes this, too, is called the delta sign
2. gyral enhancement occurs in 32%
3. dense deep (white matter) veins (collateral flow)
4. intense tentorial enhancement (common)

---

*series A: 20 young females64; series B: 38 cases from France72
MRI
MRI excels for diagnosis and follow-up. Shows absence of flow and clot burden, also demonstrates parenchymal changes. Can differentiate occluded sinus from congenital absence. Shows cerebral edema and non-acute hemorrhagic changes to better advantage than CT. Also may help estimate age of clots (Table 85.7). MR-angiography may increase the utility. MR-venography (MRV) tends to overestimate the degree of occlusion.

Angiography for DST
Accuracy is close to MRI, and some still consider it to be the standard of diagnosis. MRI has some advantages over angiography (e.g. on angiography a hypoplastic transverse sinus may not visualize, or non-opacified blood entering a sinus may mimic a filling defect).

Findings include:
1. non-filling of segments of sinuses, or filling defects in segments that are visualized
2. prolonged circulation time: present in 50% of cases (may need delayed films to see veins)
3. stumps and abnormal collateral pathways

LP
OP usually increased. CSF may be bloody or xanthochromic.

Bloodwork
To detect predisposing conditions when the etiology is unknown. Some tests that may be useful include evaluation for thrombophilia (protein C and S levels, antiphospholipid antibodies = anticardiolipin antibodies and lupus anticoagulant) as well as tests for specific predisposing conditions (CBC, Factor II level, serum homocysteine level, paroxysmal nocturnal hemoglobinuria (PNH) panel, leukocyte alkaline phosphatase).

Ultrasound for DST
May be used in diagnosis of superior sagittal sinus thrombosis in the neonate.

Evaluation for underlying disorder
At the time of presentation, work-up is difficult because the acute process will cause numerous abnormalities in the clotting system. The best time to work these patients up is ≈ 3 months after they recover from the acute phase.

85.7.7 Treatment

General information
Driving principle: treat the underlying abnormality (if possible).

Should be aggressive because recoverability of brain is probably greater than with arterial occlusive stroke. Management is complicated because measures that counteract thrombosis (e.g. anticoagulation) tend to increase the risk of hemorrhagic infarct (the risk of which is already increased), and measures that lower ICP tend to increase blood viscosity → increased coagulability.

<td>black (flow void)</td>
</tr>
</tbody>
</table>
Specific measures

1. correct underlying abnormality when possible (e.g. antibiotics for infection)
2. heparin (systemic); see dosing information (p.164) especially if patient is in DIC. Several studies show a lower mortality rate with heparin than without. It remains the best treatment even when there is evidence of intracerebral hemorrhage (ICH) with the attendant risk of increasing the size of the hemorrhage. There is no consensus on duration of treatment or if warfarin should be used afterwards. Success rate may be higher if administered before patient becomes moribund
3. avoid steroids (reduces fibrinolysis, increases coagulation)
4. control HTN
5. anticonvulsants to control seizures
6. monitor ICP if patient continues to deteriorate: ventriculostomy preferred, but caution must be used if patient is on heparin
   a) hydrate aggressively as ICP tolerates
   b) measures to lower ICP: in general, order is almost reverse of that for traumatic intracranial hypertension because diuretics → hypertonicity → ↑ viscosity → ↑ coagulation:
       • elevate HOB
       • hyperventilate
       • drain CSF
       • pentobarbital coma
       • reserve hyperosmotic and/or loop diuretics for last (replace fluid loss with isotonic IV fluids to prevent dehydration; i.e. goal is hypertonic euvolemia)
7. thrombolytic therapy: either systemically or infused directly into clotted sinus, may be followed with heparin. Many reports, but no controlled trials have been published
   a) urokinase or streptokinase
   b) intravenous tissue plasminogen activator (tPA): promising animal evidence, not yet reported in humans
8. when above measures fail, either
   a) decompressive craniectomy (± decompressive lobectomy): this decreases ICP, but may not improve outcome
   b) OR direct “attack” on clotted sinus: direct surgical treatment when deficit progresses in spite of above measures, or ICP not manageable (i.e. failure of medical therapy) (see below)
9. interventional neuroradiology: effectiveness is much reduced with chronic clot
   a) Penumbra® system: sucks out clot, only takes out a small amount of clot
   b) AngioJet®: not FDA approved for this. Not used for arterial clots because of injury to cerebral tissue, but may have some efficacy with venous clot
10. visual loss with papilledema may be treated with optic nerve sheath fenestration/decompression
11. long-term treatment after resolution of acute phase with heparin and/or warfarin × 3–6 months

Direct surgical treatment for DST

Rarely indicated. Thrombectomy and sinus reconstruction are technically possible, but rethrombosis is common. Surgery may be indicated for abscess requiring excision.

Surgical technique for direct treatment of SSS thrombosis

Have available: blood for massive transfusion, large bore IV access, sinus shunt (pre-fabricated, or improvise with high-vacuum silicone grease inside & outside pediatric anode endotracheal tube with cuff on both ends, gas sterilize, prepared pre-op), tissue for sinus reconstruction (e.g. 20 cm of saphenous vein (arteries have a high rate of fibrosis, and there is no published experience with synthetics grafts). Vein grafts are dilated with heparinized saline and should be oriented correctly in case of valves).

Expose a wide portion of the sinus.

Consider ligation when lesion in non-critical location (SSS anterior to rolandic vein, non-dominant transverse or sigmoid, minor sinuses on skull base).

Hemorrhage is controlled by digital pressure, Fogarty catheter (insert directly, or insert a no. 7 Fogarty thru tiny sinotomy proximal to bleeding which allows repair of bleeding site), and/or insertion of shunt.

85.7.8 Prognosis

Mortality: approximately 30% (range: 5–70% (10% in French series).
Poor prognosticators:
1. clinical status:
   a) coma
   b) rapid neurologic deterioration, focal signs.
2. demographics
   a) age: extremes of age (infancy or elderly) and age >37 years
   b) male gender
3. radiographic findings:
   a) hemorrhages, especially larger hemorrhages
   b) venous infarcts
4. deep venous involvement

85.8 Moyamoya disease

85.8.1 General information

Key concepts

- progressive bilateral spontaneous occlusion of ICAs with compensatory capillary collaterals that look like a “puff of smoke” (Japanese: moyamoya) on angiography
- typical presentation: juvenile form → ischemic infarcts/TIAs (suspect diagnosis in any child presenting with TIAs). Adult form → hemorrhage
- pathology: intimal thickening w/o inflammation, may also involve heart, kidneys. Associated aneurysms may be source of bleeding
- evaluation: cerebral angiography is necessary to delineate degree of stenosis as well as to evaluate potential extracranial donor vessels for revascularization. Also identifies aneurysms
- treatment:
  a) medical treatment (antiplatelet drugs, anticoagulation, vasodilators...): not shown to be effective although antiplatelet/anticoagulation is often used
  b) surgical revascularization: reduces the incidence of strokes and TIAs, but benefit on reducing the rate of hemorrhage is unproven

Progressive spontaneous occlusion of one or usually both ICAs (usually at the level of the carotid siphon) and their major branches, with secondary formation of an anastomotic collateral capillary network at the base of the brain which has been termed “moyamoya”, the Japanese word for something hazy like a “puff of cigarette smoke” (which it fancifully resembles on angiography) (first described in 1957 and named in 1969). With progression, involvement includes the proximal MCAs and ACAs and on rare occasion the vertebrobasilar system. Associated aneurysms (see below) and rarely AVMs may be observed.

Eventually the dilated capillary (moyamoya) vessels disappear with the development of collaterals from the ECA (meningeal collaterals are called “rete mirabile”).

85.8.2 Pathophysiology

Primary moyamoya disease

The most common pathology is stenosis of the proximal anterior and middle cerebral arteries that is neither atherosclerotic nor inflammatory in origin. Exact etiology is unknown but some studies show elevated basic fibroblast growth factor in the dura and scalp arteries in patients with moyamoya. The internal elastic lamina of affected vessels may be thinned or duplicated. Similar vascular changes may also occur in the heart, kidney and other organs, suggesting it may be a systemic vascular disease.

Secondary moyamoya disease

AKA “quasi-moyamoya disease” or “moyamoya syndrome”. Angiographic findings of moyamoya associated with e.g.:
1. Graves’ disease/thyrotoxicosis
2. history of cerebral inflammatory disease, including meningitis (especially tubercular (TB) meningitis and leptospirosis)
3. retinitis pigmentosa
4. vascular disorders: atherosclerosis, fibromuscular dysplasia, pseudoxanthoma elasticum
5. congenital disorders: Down syndrome, Marfan syndrome, Turner syndrome, neurofibromatosis type 1, tuberous sclerosis, Apert syndrome
6. hematologic disorders: Fanconi anemia, sickle cell anemia (in the U.S. one of the more common associations) and sickle cell trait
7. following radiation therapy for skull base glioma in children
8. head trauma
9. systemic lupus erythematosus (SLE)

Associated aneurysms
Intracranial aneurysms are frequently associated with moyamoya disease (MMD). This may be a result of the increased flow through dilated collaterals, or it may be that patients with moyamoya may also have a congenital defect in the arterial wall that predisposes them to aneurysms. 3 types: 1) usual sites of aneurysms in the Circle of Willis, 2) in peripheral portions of cerebral arteries, e.g. posterior/anterior choroidal, Heubner’s, and 3) within moyamoya vessels. The frequency of aneurysms in the vertebrobasilar system is \( \approx 62\% \) which is much higher than in the general population.

Aneurysmal SAH may be the actual cause of some hemorrhages that were erroneously attributed to moyamoya vessels.

85.8.3 Epidemiology
Risk factors
A history of inflammation in the head & neck region has been implicated.

Demographics
Incidence in Japan is higher (0.35/100,000/yr) than in North America. Two peaks (may not be same disease): juvenile (highest peak), age <10 yrs (mean 3); adult, 3rd & 4th decade. Slight female predominance (1.8:1). Some evidence for familial tendency (some Asian families have an incidence as high as 7%), genetics appears autosomal dominant with low penetrance. Associated with some HLA antigens (B40 in juvenile form; B54(20) in adult) and anti-double-stranded DNA antibody.

85.8.4 Presentation
Juvenile form
Moyamoya is associated with 6% of childhood strokes. Ischemic presentation more common (81%); includes TIA (41%) which may alternate sides (alternating hemiplegia is a suggestive clinical finding), RINDs, or infarct (40%). Neurologic events are often provoked by straining or by hyperventilation (e.g. during crying or blowing a wind instrument) which is thought to produce hypocapnea with reactive vasoconstriction.

Headache is the most common presenting symptom, but seizures, focal neurologic deficits, choreothetotic movements and hemorrhages can also be presenting symptoms. The risk of hemorrhage is increased in stages 5 & 6 of MMD.

Adult form
Hemorrhage has been described as being more common (60%), but in a Stanford series 89% presented with ischemia. Rupture of the fragile moyamoya vessels produces bleeding in the basal ganglia (BG), thalamus or ventricles (from the ventricular wall) in 70–80% of hemorrhages. SAH may occur, usually due to rupture of associated aneurysms (see above). In the pre-CT era, the most common form of hemorrhage was thought to be SAH from the rupture of moyamoya vessels, but most cases were probably intraventricular blood or SAH from associated aneurysms.

85.8.5 Natural history
Incidence of disease progression in one study was 20% in adult patients with MMD. Female patients had a higher risk of disease progression than males.

Prognosis of untreated MMD is poor, with 73% rate of major deficit or death within 2 years of diagnosis in children, and similarly poor outlook in adults.
85.8.6 Evaluation and diagnosis

Diagnostic criteria

Diagnosis of moyamoya requires bilateral symmetrical stenosis or occlusion of the terminal portion of the ICA as well as the presence of dilated collateral vessels at the base of the brain.\(^9\) (If unilateral, the diagnosis is considered questionable,\(^96\) and these cases may progress to bilateral involvement).

Other characteristic findings include:
1. stenosis/occlusion starting at termination of ICA and at origins of ACA and MCA
2. abnormal vascular network in region of BG (intraparenchymal anastamosis)
3. transdural anastomosis (rete mirabile), AKA “vault moyamoya.” Contributing arteries: anterior falcial, middle meningeal, ethmoidal, occipital, tentorial, STA
4. moyamoya collaterals may also form from internal maxillary artery via ethmoid sinus to fore-brain in frontobasal region

CT

Work-up in suspected cases typically begins with a non-enhanced head CT. Up to 40% of ischemic cases have normal CT. Low density areas (LDAs) may be seen, usually confined to cortical and subcortical areas (unlike atherosclerotic disease or acute infantile hemiplegia which tend to have LDAs in basal ganglia as well). LDAs tend to be multiple and bilateral, especially in the PCA distribution (poor collaterals), and are more common in children.

MRI and MRA

MRA usually discloses the stenosis or occlusion of the ICA. Moyamoya vessels appear as flow voids on MRI (especially in basal ganglia) and a fine network of vessels on MRA, and are demonstrated better in children than adults. Parenchymal ischemic changes are commonly shown, usually in watershed areas.

Angiography

In addition to helping to establish the diagnosis, angiography also identifies suitable vessels for revascularization procedures and unearths associated aneurysms. The angiography-related complication rate is higher than with atherosclerotic occlusive disease. Avoid dehydration prior to and hypotension during the procedure. Six angiographic stages of MMD are described in Table 85.8\(^85\) that tend to progress up until adolescence and stabilize by age 20.

EEG

Non-specific in the adult. Juvenile cases: high-voltage slow waves may be seen at rest, predominantly in the occipital and frontal lobes. Hyperventilation produces a normal buildup of monophasic slow waves (delta-bursts) that return to normal 20–60 seconds after hyperventilation. In >50% of cases, after or sometimes continuous with buildup is a second phase of slow waves (this characteristic finding is called “rebuildup”) which are more irregular and slower than the earlier waves, and usually normalize in ≤10 minutes.\(^97\)

Table 85.8 Six angiographic stages of MMD\(^85\)
Cerebrovascular Disease

85.8.7 Treatment

General information

No medical or surgical treatment has been proven effective in reducing the rate of hemorrhage in the adult with MMD. However, multiple large case series have supported the efficacy of cerebral revascularization for reducing the incidence of ischemic strokes and TIA's.90

Asymptomatic moyamoya disease

Guidelines for management of asymptomatic moyamoya disease have not yet been established. A multi-center, nation-wide survey in Japan focusing on asymptomatic moyamoya disease provided the following findings100: subtle findings of cerebral infarction and disturbed cerebral hemodynamics were detected in 20% and 40% of the involved hemispheres, respectively. Angiographic stage was more advanced in elderly patients. Of 34 medically-treated patients, 7 experienced TIA, ischemic stroke or hemorrhage during a mean follow-up period of 43.7 months. Cerebral infarction or hemorrhage did not occur in the 6 patients who underwent surgical revascularization.

Medical treatment

Medical treatment with platelet inhibitors, anticoagulants, calcium channel blockers,93 steroids, mannitol, low-molecular-weight dextran and antibiotics have not proven to be of benefit. Steroids may be considered for involuntary movements and acutely during recurrent TIAs.

Surgical treatment

General information

Patients with mass effect from clot may be candidates for urgent decompression. Revascularization procedures, however, should be performed when the patient is stable under nonemergent conditions.

Perioperative management

During any surgical procedure:
1. avoid hyperventilation: due to increased sensitivity of collaterals, keep PaCO₂ 40–50 mm Hg to avoid ischemic infarction
2. avoid hypotension: maintain BP at normotensive levels
3. avoid alpha-adrenergic agents because of vasoconstrictive effects
4. cerebral protection: mild hypothermia (32–43°C) and barbiturates are routinely used
5. papaverine helps prevent vascular spasm

Postoperatively following STA-MAC bypass procedures:
1. avoid hypertension: may cause bleeding at anastomotic site and in areas of increased perfusion within the brain
2. avoid hypotension: may result in graft occlusion
3. aspirin is started on the post-op day #1
4. watch for evidence of CSF leak
5. monitor coag studies and correct abnormalities
6. cerebral arteriogram is recommended 2–6 months post-op

Suggested criteria for revascularization procedures

See reference.90
1. patients presenting with infarction or hemorrhage but are in good neurologic condition
2. infarction <2 cm maximal diameter on CT, and all previous hemorrhages have completely resolved
3. angiographic stage is II-IV (see Table 85.8)
4. timing of operation: ≥ 2 months after most recent attack

Surgical revascularization options
Various methods to revascularize the ischemic brain, used primarily in children, include:

1. direct revascularization procedures:
   a) results are superior to indirect revascularization procedures if a donor and recipient vessel of sufficient caliber (≥ 1 mm outer dia) can be identified (may be difficult in the pediatric age group who are the most likely to benefit). Otherwise, indirect revascularization procedures (see below) are options.
   b) Among direct revascularization procedures, STA-MCA bypass is the procedure of choice.
2. indirect revascularization procedures: usually reserved for younger patients (suggested cutoff age ≈ 15 years). May be combined with STA-MCA bypass. Includes:
   a) encephalomyosynangiosis (EMS): laying the temporalis muscle on the surface of the brain (may cause problems with muscle contractions during talking and chewing, and neural impulses on surface of brain)
   b) encephaloduroarteriosynangiosis (EDAS): suturing the STA to a galeal cut to a linear defect created in the dura. Variations on this technique include splitting the dura, either as a pedicle graft or as a vascularized free flap. Felt to have higher potential to revascularize ischemic tissue than above procedures, but there is greater risk of mass effect from the thickness of the omentum.
3. the above indirect revascularization procedures improve blood flow in the MCA distribution, but not ACA circulation. This may be rectified by:
   a) simple placement of frontal burr holes with opening of the underlying dura and arachnoid
   b) “ribbon EDAS” where a pedicle of galea is inserted into the interhemispheric fissure on both sides
4. stellate ganglionectomy and perivascular sympathectomy: unproven that this increases CBF permanently

Outcome with surgical treatment
Neurologic status at time of treatment generally predicts long-term outcome. The mortality rate in adults (≈ 10%) is higher than for juveniles (≈ 4.3%). The cause of death was bleeding in 56% of 9 children and 63% of 30 adults. With treatment the prognosis is good in 58%.

85.9 Extracranial-intracranial (EC/IC) bypass

85.9.1 EC/IC bypass for atherosclerotic occlusive disease

The EC/IC bypass study
The EC/IC bypass, pioneered by Donaghy and Yasargil in 1967, plummeted in popularity after publication of the international cooperative EC/IC bypass study in 1985. The EC/IC trial randomized 1377 patients with symptomatic ICA or MCA stenosis to either STA-MCA bypass or medical therapy with ASA. Despite a graft patency rate of 96% surgical patients suffered more and earlier fatal and nonfatal strokes. Patients with severe MCA stenosis and those with persistent symptoms following ICA occlusion fared especially worse with bypass. During the 55.8 months mean follow-up, the percentage of patients experiencing 1 or more strokes in the medical group compared to the surgical group was 29% vs. 31%

Critics highlight the failure of the study’s inclusion criteria to distinguish between hemodynamic vs. thromboembolic causes of stroke (ischemia secondary to thromboembolic events would not be expected to improve with flow augmentation, and inclusion of such patients in the surgical arm could therefore artificially lower the apparent efficacy of the procedure).

Current state of affairs
Imaging technologies introduced since the EC/IC trial can identify flow-dependent ischemia. Xenon-CT, TCD, SPECT, and MRI may be used in combination with acetazolamide challenge to evaluate cerebrovascular reserve and reactivity (p. 1265).
As cerebral perfusion pressure decreases in severe atherosclerotic occlusive disease, cerebral autoregulation is unable to maintain adequate CBF to meet metabolic demands. In this state of "miserly perfusion", oxygen extraction fraction (OEF) of available blood flow will increase. Abnormal OEF, as quantified by PET, is an independent predictor of subsequent stroke. Patients with abnormal response to acetazolamide challenge (p.228) and/or with elevated OEF are therefore potential candidates for cerebral revascularization.

Indications for EC/IC bypass

1. Patients with misery perfusion (see above)
2. Aneurysms: certain aneurysms are not amendable to either direct microsurgical clipping or endovascular coiling due to extreme size, location, calcification or atherosclerosis, dissection, or the incorporation of perforators or major arteries. EC/IC bypass remains a highly viable adjunctive measure in patients requiring Hunterian occlusion of parent vessel or prolonged temporary occlusion for definite treatment.
3. Tumors encasing or invading major arteries
4. moyamoya disease (p.1313)

Bypass types

The type of graft used depends on preoperative determination of amount of flow augmentation necessary, the size of the recipient graft and the availability of donor vessel:

1. Pedicled arterial grafts: STA, occipital artery
   a) low-flow (15 – 25 ml/min)
   b) only one anastomosis required
   c) 95% graft patency in superficial temporal artery-middle cerebral artery (STA-MCA) bypasses
2. Radial artery graft
   a) moderate to high flow (40 – 70 ml/min)
   b) advantages: physiological conduit for arterial blood; constant location makes it easy to harvest; lumen size closely approximates that of M2 or P1 and reduces flow mismatch with subsequent flow turbulence and graft thrombosis
   c) disadvantages: risk of vasospasm (reduced with pressure distension technique)
   d) >90% graft patency at 5 years
3. Saphenous vein graft
   a) high flow (70 – 140 ml/min)
   b) advantages: easy accessibility; longer length
   c) disadvantages: risk of thrombosis at distal anastomosis due to flow mismatch and turbulence; lower graft patency rates
   d) 82% graft patency at 5 years

86 Cerebral Arterial Dissections

86.1 General information

Key concepts

- hemorrhage into the tunica media of an artery
- may be spontaneous, post-traumatic, or iatrogenic [e.g. angiography-related], may be intracranial or extracranial
- may present with pain (usually ipsilateral H/A or carotidynia), Homer’s syndrome
- (in carotid dissections), TIA/stroke, or SAH
- extracranial dissections are usually treated medically (anticoagulation), intracranial dissections with SAH are treated surgically

This section primarily discusses “spontaneous” dissections. ICA dissection following blunt cervical trauma is much more common (p.851).

86.2 Nomenclature

Some confusion has arisen because of inconsistent terminology in the literature. Although by no means standard, Yamaura¹ has suggested the following:

Dissection. Extravasation of blood between the intima and media, creating luminal narrowing or occlusion.

Dissecting aneurysm. Dissection of blood between the media and adventitia, or at the media, causing aneurysmal dilatation, which may rupture into the subarachnoid space.

Pseudoaneurysm. Rupture of artery with subsequent encapsulation of the extravascular hematoma, may or may not produce luminal narrowing.

86.3 Pathophysiology

The lesion common to all dissections is hemorrhage outside of the vascular lumen due to pathological trans-intimal extravasation of blood from the true lumen into the vessel wall. The hematoma may either dissect the internal elastic membrane from the intima² causing narrowing of the true lumen, or it may dissect into the subadventitial plane producing an adventitial outpouching from the vessel wall (pseudoaneurysm). Rupture through the vessel wall producing SAH occurs occasionally.

Subintimal dissection is more common with intracranial dissections, whereas extracranial vessels (including the aorta) usually dissect at the media or between media and adventitia.

“Spontaneous” dissections have been associated with a large number of conditions, oftentimes the association is unproven. These conditions include:
- fibromuscular dysplasia (FMD): found in ≈ 15% of cases³
- cystic medial necrosis (or degeneration): originally thought to be a common finding, now thought to perhaps be linked to a higher likelihood of fatal dissection
- saccular aneurysm
- Marfan syndrome: autosomal dominant inherited disorder of connective tissue. Phenotypic manifestations are due to production of abnormal fibrillin, the main component of extracellular microfibrils, a component in the media of certain blood vessels, encoded by the FBN1 gene on chromosome 15q21
- Ehlers-Danlos syndrome
- atherosclerosis: only rarely implicated as an etiology. More likely to be a factor with subintimal dissection of extracranial arteries
- Takayasu’s disease
- medial degeneration
- syphilitic arteritis (more common in the past, associated with 60% of dissections before 1950)
• autosomal dominant polycystic kidney disease (p.1193): associated with a higher incidence of cerebral aneurysms
• variant periarteritis nodosa
• allergic arteritis
• homocystinuria
• moyamoya disease (p.1313)  

86.4 Epidemiology

Occurs primarily in middle aged patients, with a mean age of ≈45 yrs (average age of traumatic dissections is slightly younger). More frequent in men. Incidence is unknown, since often times the condition produces mild, transient symptoms. Increased awareness of the condition has resulted in an increased rate of diagnosis. ICA dissection accounts for 1-2.5% of first strokes. However, in middle aged and young adults it comprises 10-25% of strokes.

86.5 Sites of dissection

A review of 260 cases (literature review + new cases) found the incidence by location shown in Table 86.1. The vertebral artery was the most common intracranial site. Previously, it was believed that the ICA was the most common site. This change may be due to the recent increased recognition of arterial dissections as a source of SAH (and vertebral dissections most often present as SAH). Multiple dissections occur in ≈10% (the most common: bilateral vertebrobasilar lesions).

86.6 Clinical

Cerebral arterial dissections may cause symptoms by:
1. embolization secondary to:
   a) platelet aggregation stimulated by the exposed surfaces
   b) dislodged thrombus (formation of which is enhanced by reduced flow)
2. reduced distal flow secondary to:
   a) thrombosis due to reduced flow
   b) occlusion of the true lumen by the expansion of the mural hematoma
3. subarachnoid hemorrhage (atypical presentation, may be more common with posterior circulation dissection than with anterior circulation)

The most common presentation in patients <30 yrs of age was due to internal carotid dissection without SAH. In patients >30 yrs, vertebrobasilar artery (VBA) dissection with SAH was the most common. Headache, usually severe, often predates neurologic deficit by days or weeks (p.1228). See sections ICA (p.1324) and vertebrobasilar (p.1325) for specifics.

86.7 Evaluation

CT. More useful for evaluating brain for infarction. Dissection can sometimes be visualized directly.\(^5\)

CT angiogram (CTA). Often obviates the need for cerebral angiography since CTA scanners with ≥ 16 detectors are equal in predictive value and have an accuracy near 99%\(^9\)

Angiography. The definitive diagnostic study. However, diagnosis may be delayed if the dissection is misinterpreted as:
1. an unusual saccular aneurysm (the most common error)
2. atherosclerotic lesions: with dissections, the location is unusual, the lesion may be isolated, the age is usually younger, and the stenosis is smooth. Cervical ICA dissection typically spares the carotid bulb whereas cervical ICA atherosclerosis tends to involve the bulb.
3. vasospasm following SAH: however, the narrowing with vasospasm is delayed in onset vs. the changes with dissection which are present from the beginning

Angiographic findings may include:
1. luminal stenosis: irregular stenosis over long segments of the artery often with focal areas of near total stenosis (“string sign”)
2. fusiform dilation with proximal or distal narrowing (string and pearl sign)
3. occlusion: artery usually tapers to a point
4. intimal flap: when seen, usually found at proximal end of dissection
5. may see proximal beading (“string of beads” configuration, indicative of FMD)
6. “double lumen sign”: true vessel lumen and an intramural false lumen with an intimal flap. Usually with retention of contrast within the false lumen well into the venous phase. The only pathognomonic sign
7. wavy “ripple” appearance
8. severe kinking (frequently bilateral). With VBA lesions: dolichoectasia

A characteristic of arterial dissections is that they often change configuration on repeat angiography\(^10\) (some resolve, and some worsen). NB: forceful intra-arterial contrast injection during the performance of angiography carries a potential for worsening the dissection.

MRI. Probably not as accurate as CTA or angiography. Optimal MRI study is source T1WI axial images with fat suppression (“fat sat”), look for loss of visualization over several slices, with good visualization above and below. May visualize intimal flap and distinguish a dissection from a fusiform aneurysm.

Crescent sign: bright signal in wall of ICA on T2WI axial images (hematoma in vessel wall).

86.8 Overall outcome

An early review of the literature found an 83% mortality within a few weeks of presentation with vertebrobasilar artery (VBA) dissection.\(^11\) A later report tempered that grim prognosis.\(^12\)

Based on a review of 260 cases,\(^1\) an overall mortality of 26% was found. 70% had a favorable outcome (assessed using Glasgow Outcome scale), 5% poor. Mortality was higher in ICA lesions (49%) than VBA lesions (22%). Mortality was 24% in the SAH group, and 29% in non-SAH cases.

86.9 Vessel specific information

86.9.1 Internal carotid dissection

See above for general information. Posttraumatic ICA dissection (p.1323) is much more common than spontaneous.

Some cases considered “spontaneous” may actually be due to trivial trauma, including violent coughing, nose blowing, and simple neck turning. Usually seen in young women.

In spontaneous dissection, the most common initial symptom is ipsilateral headache. Most of these (60%) are orbital or periorbital, but they may also be auricular or mastoid (39%), frontal (36%), temporal (27%). May also produce sudden onset of severe pain over carotid artery (carotidynia).\(^13\)

Incomplete Horner’s syndrome (oculosympathetic palsy): ptosis and miosis without anhidrosis (due to involvement of plexus around the ICA, sparing the ECA plexus which innervates facial sweat
glands) may occur. Bruits may be heard by the examiner or by the patient. These and other clinical features are shown in Table 86.2.

May be a cause of some cases of infantile and childhood hemiplegia and hemiparesis.14

86.9.2 Vertebrobasilar system artery dissection

Vertebral artery dissections

General information

See general information on cerebral arterial dissections (p. 1322). See also posttraumatic vertebrobasilar dissection (p. 852).

Less common than carotid. Extracranial lesions outnumber intracranial.

Traumatic dissections tend to occur where the VA crosses bony prominences, e.g. at the Cl–2 junction or where it enters the foramen transversarium (usually at C6). Spontaneous dissections tend to be intracranial and commonly occur on the dominant VA. Unlike cervical ICA dissections, which tend not to propagate intracranially through the carotid canal, high cervical VA dissections can readily propagate intracranially through the foramen magnum.

Spontaneous VA dissections have been associated with FMD, migraine, and oral contraceptives.15 Unrecognized or forgotten trauma or sudden head motion may have occurred in some cases reported as spontaneous. Commonly occurs in young adults (mean age: 48 yrs). With spontaneous dissections, 36% of patients have dissections at other sites, 21% of cases have bilateral VA dissections.16

Dissecting aneurysms of the VA (possibly a distinct entity) are also described.17,18,19 They tend to be fusiform, and may be amenable to clipping, and were associated with vertebral dissections in 5 of 7 cases reported in one series.20 As of 1984, only ± 50 cases of dissecting aneurysms were published.20

Presentation

In spontaneous extradural dissections, neck pain is a prominent early finding in most patients, and is commonly located over the occiput and posterior cervical region. Generalized severe headache is also common. TIAs or stroke (usually lateral medullary syndrome (p.1267) 21 or cerebellar infarction, especially in patients with occlusion of the third or fourth portion of the VA22). None of 5 patients developed new neurologic symptoms after the original stroke in an average of 21 months follow-up.22 In 3 of these 5, VA dissection was bilateral.

Dissecting aneurysms may present with altered consciousness, and may cause SAH (seen in 6 of 30 cases of vertebrobasilar complex dissections).20 Rebleeding occurs in 24–30% of those cases presenting with SAH,16 making these lesions treacherous, with a very high mortality.23,24

Traumatic extradural dissections or pseudoaneurysms may have a similar presentation, but can also produce massive external hemorrhage or neck hematomas.16

Evaluation

See section under Cerebral arterial dissections, Evaluation (p.1324).

| Table 86.2 Clinical features of spontaneous ICA dissection |
|-----------------|----------------|
| Feature         | %              |
| focal cerebral ischemia | 76%            |
| headache        | 59%            |
| oculosympathetic palsy | 30%            |
| bruit           | 25%            |
| amaurosis fugax  | 10%            |
| neck pain       | 9%             |
| syncope         | 4%             |
| scalp tenderness | 2%             |
| neck swelling   | 2%             |
Angiography. Diagnosis by angiography may be difficult in many cases (the most common misdiagnosis is ruptured saccular aneurysm of unusual shape\(^25\)).

In post-traumatic dissections, the most common finding is irregular stenosis of horizontal loops of distal extracranial VA as they pass behind C1, often bilateral.

In 14 of 15 post-traumatic VA dissections, the lesion was located posterior to the atlas (distal extracranial 3rd segment), the single exception being a patient with direct trauma causing proximal VA involvement. This predilection is possibly explained by the fact that the first and third portions of the VA are movable, whereas the second and fourth are relatively immobilized by bone.

**Treatment**

Except for cases presenting with hemorrhage or large ischemic stroke, medical therapy should be started emergently. Classically consists of anticoagulation, with heparin acutely, followed by oral agents (e.g. Coumadin) probably for a total of 6 months. Recent preliminary study showed antiplatelet therapy was equally as effective.\(^26\)

As with traumatic dissections, endovascular techniques are now assuming more prominent role in management.

Indications for intervention. Surgery or endovascular techniques (mostly stents, but also occlusion, angioplasty\(^16\)) are required for dissections presenting with SAH (due to their propensity to rebleed) and is recommended for most intradural dissections. For extradural lesions it is indicated for dissections that progress (angiographically) or for persistent symptoms in spite of adequate medical therapy. Some less malignant lesions may be amenable to endovascular stenting.

Endovascular treatment. Balloon-mounted, self-expandable, or covered stents have been used relatively infrequently to treat dissections of the internal carotid or vertebral arteries, with good technical results and low procedure-related complication rates\(^27\) [2011]. Given the small number of patients treated and the fact that medical therapy is generally effective, the role of stenting for dissection remains to be defined. It should be reserved for patients in whom medical therapy is ineffective or contra-indicated or when the dissection causes symptomatic flow-limiting stenosis.

Surgical treatment. At the time of surgery, the site of dissection may be recognized by fusiform or tubular enlargement of the artery with discoloration due to blood within the arterial wall (the discoloration has been described as black, bluish, purple, purple red, or brown\(^25\)).

Surgical treatment of intradural dissection when endovascular techniques are not an option includes the following alternatives:

1. non-clippable aneurysms may be candidates for Hunterian occlusion of the VA proximal to the BA (either by microsurgical technique, or by endovascular techniques which may not be as precise). Some may not tolerate clipping the dominant VA, especially if the contralateral VA is hypoplastic. Conversely, some may tolerate bilateral VA occlusion.\(^28\) Balloon test occlusion\(^16\) is recommended
   a) if the dissection involves the PICA origin, then clip proximal to dissection. PICA then fills from retrograde flow, and the reversal of flow across the site of dissection should push the intima back against the wall
   b) if the dissection is proximal to PICA and doesn’t involve PICA, then trap the aneurysm between clips. PICA fills by retrograde flow
   c) if the aneurysm begins distal to the PICA origin, occlude the VA\(^7\) distal to the PICA takeoff\(^29\)

2. combining VA clipping (non-clippable aneurysms may be candidates for Hunterian occlusion of the VA proximal to the aneurysm) with vascular bypass, options:
   a) side-to-side PICA-PICA anastomosis
   b) transplantation of the PICA origin to the VA outside the aneurysm
   c) occipital artery-to-PICA bypass

3. resection accompanied by autogenous interposition vein graft

4. non occlusive surgical techniques
   a) clipping with specially designed clips for fusiform aneurysms (e.g. Sundt-Kees clip)
   b) wrapping: of dubious benefit

86.9.3 Vertebrobasilar system dissections excluding the VA

Basilar artery dissections tend to present with brain stem infarction and more rarely with SAH.\(^24\)

The prognosis is generally regarded as poor. Endovascular techniques may be able to treat some.

Part XX
Intracerebral Hemorrhage

87 Intracerebral Hemorrhage 1330
87 Intracerebral Hemorrhage

87.1 General Information

Intracerebral hemorrhage (ICH) is a hemorrhage within the brain parenchyma. Formerly commonly referred to as “hypertensive hemorrhage”, but hypertension is a debatable etiology in many cases; see Hypertension as a cause? (p.1334).

87.2 Intracerebral hemorrhage in adults

Key concepts

- the second most common form of stroke (15–30% of strokes), but the most deadly
- unlike ischemic infarct: smooth progressive onset over minutes to hours, often with severe headache, vomiting and alterations in level of consciousness
- unenhanced CT scan of the brain is the initial diagnostic study of choice
- the volume of the hematoma correlates highly with morbidity and mortality
- the clot enlarges in at least 33% of cases within the first 3 hours of onset
- angiography is recommended (as long as it doesn’t delay emergent treatment) except for patients >45 yrs of age with preexisting hypertension and ICH in thalamus, putamen or posterior fossa
- treatment
  a) still controversial. The initial promise of rFVIIa has not been actualized
  b) the usefulness of surgery is still controversial, but seems limited to some cerebellar hemorrhages and select supratentorial hemorrhages that come within 1 cm of the cortical surface

87.3 Epidemiology

87.3.1 Incidence

The second most common form of stroke (~15–30% of all strokes) (earlier estimates: 10%), and the most deadly. Approximately 12–15 cases per 100,000/yr. Early studies estimated an incidence equal to SAH, but more recent studies in the CT era show approximately twice the incidence as SAH (pre-CT studies may have misclassified some ICH as ischemic stroke, and some cases of ICH that rupture into the subarachnoid space (occurs in ~7%) may have been misclassified as SAH). After a decline in the 1970’s, the incidence increased in the 1980s for those age ≥65 years. Onset is usually during activity (rarely during sleep), which may be related to elevation of BP or increased CBF; see Etiologies (p.1332).

87.3.2 Risk factors

The following are epidemiologic risk factors; see also others (p.1332).

1. age: the incidence increases significantly after age 55 years and doubles with each decade of age until age >80 yrs where incidence is 25 times that during previous decade. Relative risk for age >70 yrs is 7
2. gender: more common in men
3. race: in the U.S., ICH affects blacks more than whites. May be related to higher prevalence of HTN in blacks. Incidence may also be higher in Asians
4. previous stroke (any type) increases risk to 23:1
5. alcohol consumption:
   a) recent use: moderate or heavy alcohol consumption both within the 24 hours and the week preceding the ICH were independent risk factors for ICH as shown in Table 87.1
   b) chronic use: one study suggests that consuming >3 drinks a day increases the risk of ICH by ~7 times (p.15)
   c) ICH in patients with high ethanol consumption were more commonly lobar than the typical “hypertensive hemorrhages” in the basal ganglia

87 Intracerebral Hemorrhage
6. cigarette smoking: increases the risk of SAH and ischemic infarction but probably does not increase the risk of ICH.\textsuperscript{9,10} further clarification is needed
7. street drugs: cocaine, amphetamines, phencyclidine\textsuperscript{11}
8. liver dysfunction: hemostasis may be impaired on the basis of thrombocytopenia, reduced coagulation factors, and hyperfibrinolysis\textsuperscript{12} (may be responsible for the increased risk of ICH with chronic EtOH consumption)

### 87.4 Locations of hemorrhage within the brain

#### 87.4.1 General information

Common sites of ICH are shown in Table 87.2. Common arterial feeders of ICHs:

1. lenticulostriates: the source of putaminal hemorrhages (possibly secondary to microaneurysms of Charcot-Bouchard, see below)
2. thalamoperforators
3. paramedian branches of BA

#### 87.4.2 Lobar hemorrhage

This term was popularized in 1980 after a report delineating 4 clinical syndromes associated with hemorrhage in each of the cerebral lobes.\textsuperscript{14} It incorporates primary hemorrhages into the occipital, temporal, frontal and parietal lobes (including ICH arising from cortex and subcortical white matter), as opposed to hemorrhage of deep structures (e.g. basal ganglion, thalamus, and infratentorial structures).\textsuperscript{14} Accounts for 10–32\% of nontraumatic ICHs.\textsuperscript{14} With large hemorrhages, it may be difficult to make a distinction between lobar and deep ICH.

Lobar hemorrhages are more likely to be associated with structural abnormalities than deep hemorrhages (see below). They may also be more common in patients with high alcohol consumption (see above). Lobar hemorrhages may also have a more benign outcome than ganglionic-thalamic hemorrhages.\textsuperscript{14}
Etiologies of lobar hemorrhage: Although many causes of ICH can produce lobar hemorrhages (see below for a detailed list), those that are more likely to produce lobar hemorrhages include:

1. extension of a deep hemorrhage
2. cerebral amyloid angiopathy (p. 1334): the most common cause of lobar ICH in elderly normotensive patients
3. trauma
4. hemorrhagic transformation of an ischemic infarct: see below
5. hemorrhagic tumor (p. 1335). Multiple lobar hemorrhages may occur with metastases
6. cerebrovascular malformation (especially AVM) (p. 1246)
7. rupture of an aneurysm: see below for circumstances likely to produce this
8. idiopathic

87.4.3 Internal capsule hemorrhages

There may be prognostic significance with regard to contralateral motor function if the hemorrhage is medial to and/or extending through the internal capsule (IC), or lateral to the IC and merely compressing it, making the clot more accessible to surgical treatment without damaging the IC.

87.5 Etiologies

87.5.1 History check list

Based on information in this chapter, the following check-list is presented to assist in the gathering of historical information important in evaluating the adult with ICH:

1. hypertension
2. drugs:
   a) sympathomimetics:
      ● amphetamines, cocaine
      ● appetite suppressants or nasal decongestants (phenylpropanolamine, pseudoephedrine)
   b) dietary supplements: especially ephedra alkaloids (ma huang)
   c) anticoagulants: warfarin in particular
   d) antiplatelet drugs: aspirin (patients often forget taking low dose 81 mg), Plavix, NSAIDS
   e) oral contraceptive (birth control pills): questionable association
3. history of alcohol abuse
4. coagulopathies
5. leukemia
6. previous stroke
7. history of known vascular abnormalities (AVM, venous angioma…)
8. tumor: known history of cancer, especially those that tend to go to brain (lung, breast, GI, renal, melanoma…)
9. recent surgery: especially carotid endarterectomy, procedures requiring heparin…
10. recent childbirth and/or eclampsia or preeclampsia
11. history of recent trauma

87.5.2 Etiology list

1. “hypertension” (debatable as a cause or effect, see below) but is a risk factor
   a) acute hypertension (HTN): as may occur in eclampsia (see below) or with use of certain drugs, e.g. cocaine, phenylpropanolamine… (p. 1334)
   b) chronic HTN: possibly causes degenerative changes within blood vessels
2. possibly associated with acutely increased CBF (globally or focally), especially to areas previously rendered ischemic:
   a) following carotid endarterectomy
   b) following repair of congenital heart defects in children
   c) previous stroke (embolic or otherwise): hemorrhagic transformation may occur in up to 43% of strokes during the first month. May follow dislodgment or recanalization of an arterial occlusion, although it has been demonstrated with persistent occlusion. May occur as early as ≤ 24 hrs after a stroke in patients with a negative CT done within 6 hours. Two types:
      ● type 1: diffuse or multifocal. Heterogeneous or mottled appearance within the boundaries of the stroke. Less hyperdense than primary ICH
• type 2: extensive hematoma. Probably unifocal source. As hyperdense as primary ICH and may extend outside the original stroke boundaries. Unlike type 1, classically associated with anticoagulation therapy, and tends to occur in initial few days after stroke and is often associated with clinical worsening. May be difficult to distinguish from primary ICH, and may be frequently misdiagnosed as such.

• migraine: during or following a migraine attack (probably an exceedingly rare event)
  a) following surgery to remove an AVM: “normal perfusion pressure breakthrough.” Some cases may be due to incomplete AVM excision
  b) physical factors: following strenuous physical exertion, exposure to cold...

3. vascular anomalies
   a) AVM: rupture; see Arteriovenous malformation (p.1239)
   b) aneurysm rupture
      • saccular (“berry”) aneurysms: (i) aneurysms of the circle of Willis (COW): aneurysms that have become adherent to brain surface by fibrosis as a result of inflammation or previous hemorrhage may produce ICH when they rupture instead of the usual SAH; (ii) aneurysms distal to the COW (e.g. MCA aneurysms)
      • microaneurysms of Charcot-Bouchard (p.1334)

4. venous angioma rupture: significant ICH from these common lesions is a very rare event
   a) “arteriopathies”
      • amyloid angiopathy: usually → repeated lobar hemorrhages (see below)
      • fibrinoid necrosis (sometimes seen in cases of amyloid angiopathy)
      • lipohyalinosis: subintimal lipid-rich hyaline material
      • cerebral arteritis (including necrotizing angiitis)

5. brain tumor (primary or met): below

6. coagulation or clotting disorders
   a) leukemia
   b) thrombocytopenia:
      • thrombotic thrombocytopenic purpura
      • aplastic anemia
   c) patients receiving anticoagulation therapy (p.1336)
   d) patients receiving thrombolytic therapy:
      • for acute ischemic stroke: incidence of symptomatic ICH within 36 hrs of treatment with rtPA is 6.4% in the placebo treated group
      • for acute MI or other thrombosis: incidence is ≈ 0.36–2% in older patients, in those with anterior MI or higher Killip class, and with bolus administration (vs. infusion). When heparin was used adjunctively, higher doses were associated with higher risk of ICH. ICH is thought to occur in those patients with some preexisting underlying vascular abnormality. Immediate coronary angioplasty is safer than rt-PA when available.
   e) aspirin therapy:
      • one ASA qod was associated with increased risk of ICH, with a rate of 0.2–0.8% per year
      • ASA 100 mg/d did not increase the risk of significant ICH in patients >60 yrs with mild to moderate head injury (GCS ≥ 9)
      • Vitamin E supplements: associated with reduction of 1 ischemic stroke in 476 individuals, and increase of 1 ICH in 1250 patients taking vitamin E

7. CNS infection
   a) especially fungal, which attack blood vessels
   b) granulomas
   c) herpes simplex encephalitis: may initially produce low density lesions that progress to hemorrhagic ones

8. venous or dural sinus thrombosis (p.1308)

9. drug related
   a) substance abuse
      • alcohol: consumption of ≥ 3 drinks/day increases the risk of ICH ≈ 7-fold (p.1330)
      • drug abuse: especially sympathomimetics (cocaine, amphetamine)
   b) drugs that raise BP
      • alpha-adrenergic agonists (sympathomimetics): phenylpropanolamine (may also cause ischemic stroke) which was removed on the order of the FDA from OTC nasal decongestants and appetite suppressants, but other OTC alpha agonists (including phenylephrine, ephedrine and pseudoephedrine) are also problematic
      • ephedra alkaloids: sold as a dietary supplement (ma huang) to suppress appetite and increase energy. Associated in case reports with HTN, SAH, ICH, seizures and death
10. post-traumatic: often in a delayed fashion\textsuperscript{51,52}; see Hemorrhagic contusion (p. 891)

11. pregnancy related: the risk of ICH in pregnancy and puerperium (up to 6 weeks post partum) is \(\approx 1\) in 9,500 births\textsuperscript{53}
   a) most commonly associated with eclampsia or preeclampsia: the mortality of eclampsia is \(\approx 6\%\) with ICH being the most frequent direct cause\textsuperscript{54}; also see Pregnancy & intracranial hemorrhage (p. 1169)
   b) postpartum ICH (median 8 days, range 3–35 days) in the absence of eclampsia has been reported\textsuperscript{55}; when associated with vasculopathy the term postpartum cerebral angiopathy has been used
   c) vascular findings:
      - some cases associated with isolated cerebral vasculopathy in the absence of systemic vasculitis\textsuperscript{56}
      - some cases demonstrate vasospasm
      - some cases show findings (e.g. patchy enhancement in occipital lobes) suggestive of cerebrovascular dysautoregulation (p. 1264)
      - some cases show no vascular-related abnormalities

12. post-operative:
   a) following carotid endarterectomy (see above)
   b) following craniotomy:
      - at site of craniotomy\textsuperscript{57}: risk factors identified: within residual astrocytoma after subtotal resection, following craniotomy for AVM (see above)
      - at site remote from craniotomy. In a series of 37 patients, unlike hematomas at craniotomy site, the following were identified as not being related to risk of hemorrhage: HTN, coagulopathy, CSF drainage, underlying occult lesion, following drainage of chronic SDH (p. 899)
      cerebellar hemorrhage following pterional craniotomy\textsuperscript{58} (this author incriminated possibly rapid overdrainage of CSF), or following temporal lobectomy\textsuperscript{59}

13. idiopathic\textsuperscript{14}

87.5.3 Cerebellar hemorrhage etiologies
Etiologies are similar to ICH of any location, however, some nuances:
1. HTN is a factor in up to two-thirds of cerebellar hemorrhages
2. AVM is a consideration, aneurysm is very rare (possibly AlCA aneurysm, but usually only in association with other high-flow lesion, e.g. AVM\textsuperscript{60})
3. may be related to recent previous spinal or supratentorial surgery

87.5.4 Hypertension as a cause?
Hypertension (HTN) is controversial as cause of ICH since the incidence of both ICH and HTN increases with age (66\% of patients > 65 yrs have HTN). The relative risk for ICH with HTN is 3.9–5.4, depending on the definition of HTN used.\textsuperscript{61} Many patients with ICH are dramatically hypertensive on presentation, however, acute elevations of ICP from the hemorrhage may actually precipitate HTN (part of Cushing’s triad, see Table 56.2). HTN is probably a risk factor primarily for pontine/cerebellar ICH and is probably not a factor in at least 35\% of basal ganglion hemorrhages.

87.5.5 Microaneurysms of Charcot-Bouchard
AKA miliary aneurysms.\textsuperscript{62} Occur primarily at bifurcation of small (<300 mcm) perforating branches of lateral lenticulostriate arteries in basal ganglia (found in 46\% of hypertensive patients over age 66, but only in 7\% of controls\textsuperscript{63}). Possibly the origin of some “hypertensive” ganglionic (putaminal) hemorrhages,\textsuperscript{64} but this is controversial.

87.5.6 (Cerebral) amyloid angiopathy
Cerebral amyloid angiopathy (CAA) AKA congophilic angiopathy. Pathologic deposition of beta amyloid protein (appears as birefringent “apple-green” under polarized light when stained with Congo red) within the media of small meningeal and cortical vessels (especially those in white matter) without evidence of systemic amyloidosis.\textsuperscript{65} Some vessels may show fibrinoid necrosis of vessel wall\textsuperscript{66,67} CAA should be suspected in patients with recurrent hemorrhages (uncommon with “hypertensive hemorrhages” (p. 1330)\textsuperscript{68} that are lobar in location. Gradient-echo MRI may identify petechial hemorrhages or hemosiderin deposits from small cortical hemorrhages which may be associated with CAA.\textsuperscript{69} Less likely in the case of basal ganglion or brain stem hemorrhages.\textsuperscript{14}
Incidence increases with age: CAA is present in \( \approx 50\% \) of those over 70 years of age,\(^70\) however, most do not hemorrhage. CAA is probably responsible for \( \approx 10\% \) of cases of ICH. May be associated with genetic factors (including the apolipoprotein E \( \varepsilon4 \) allele\(^71\)), and may be more prevalent in patients with Down syndrome. Although they are distinct diseases, there is some overlap between CAA and Alzheimer’s disease; the amyloid in CAA is identical to that found in senile plaques of Alzheimer’s disease. CAA may increase the risk of ICH by potentiating plasminogen\(^72\) (may be of special relevance to patients receiving tissue plasminogen activator (t-PA) to treat MI or stroke).

Patients with CAA may present with a TIA-like prodrome (see below). Among patients with lobar hemorrhage, those with the apoE \( \varepsilon4 \) allele typically have their first hemorrhage >5 yrs earlier than noncarriers (73 ± 8 yrs vs. 79 ± 7 yrs).\(^71\)

Diagnostic tests are useful mainly to rule-out other conditions. The definitive diagnosis of CAA requires pathologic evaluation of brain tissue. Criteria for the diagnosis of CAA are shown in Table 87.3.\(^73\)

### 87.5.7 Hemorrhagic brain tumors

Although any brain tumor can hemorrhage, tumoral ICH is usually associated with malignancies. Tumors on occasion can also produce SAH or subdural hematomas.

Malignant tumors most commonly associated with ICH:
1. glioblastoma
2. lymphoma
3. metastatic tumors
   a) melanoma\(^74,75\) \( \approx 40\% \) hemorrhage
   b) choriocarcinoma\(^74,76,77\) \( \approx 60\% \) hemorrhage
   c) renal cell carcinoma
   d) bronchogenic carcinoma: although only \( \approx 9\% \) hemorrhage, this tumor is such a frequent source of cerebral mets that it therefore is a more common source of tumoral ICH

Malignant tumors that hemorrhage less commonly include:
1. medulloblastoma\(^78,79,80,81\) (most commonly in children)
2. gliomas\(^82,83\)

Some benign brain tumors that have been associated with ICH include:
1. meningiomas have been associated with intratumoral, subdural, and nearby parenchymal hemorrhage.\(^84,85,86,87\) Tendency to bleed is similar for angioblastic variety as for other highly vascular meningiomas

\(^a\) e.g. excessive anticoagulation (INR > 3.0), head trauma, ischemic stroke, CNS tumor, cerebrovascular malformation, vasculitis or blood dyscrasia
2. pituitary adenoma, see Pituitary apoplexy (p. 720)
3. oligodendroglioma (relatively benign): rarely presents with hemorrhage,\textsuperscript{88} classically after years of causing seizures
4. hemangioblastoma\textsuperscript{89}
5. vestibular schwannoma\textsuperscript{90,91,92}
6. cerebellar astrocytoma\textsuperscript{93}

87.5.8 Anticoagulation preceding ICH

10\% of patients on warfarin (Coumadin\textsuperscript{®}) develop a significant bleeding complication per year (not all are intracranial), including ICH (65\% mortality in this group). The risk of ICH in patients treated with warfarin for A-fib varies between 0–0.3\% per year\textsuperscript{39} (historically, this was as high as \approx 1.8\% in older studies\textsuperscript{94} from the 1960s and 1970s), but when an elderly subgroup (mean age 80 yrs) was analyzed, this rate was 1.8\% per year.\textsuperscript{39} ICH was the only cause of fatal bleeding complications of warfarin therapy in one series where the cumulative risk of a fatal hemorrhage was 1\% at 1 year and 2\% at 3 yrs.\textsuperscript{95}

The risk of hemorrhagic complications was increased with the length and also the variability of the PT, and during the first three months of anticoagulation.\textsuperscript{95} Patients with cerebral amyloid angiopathy (CAA) (see above) are also at increased risk of ICH following administration of antiplatelet drugs or anticoagulants.\textsuperscript{73}

87.6 Clinical

87.6.1 General information

In general, the neurologic deficit with ICH is characterized by a smooth progressive onset over minutes to hours, unlike embolic/ischemic stroke where deficit is maximal at onset. With ICH, severe headache, vomiting and alterations in level of consciousness may be more common (H/A may not be more prevalent than in embolic stroke, but it is often a first and prominent symptom\textsuperscript{14}).

87.6.2 Prodrome

TIA-like symptoms may precede lobar hemorrhages\textsuperscript{96,97} in patients with CAA, and may occur in up to \approx 50\% of patients for whom a complete history is obtainable. Unlike typical TIs, these usually consist of numbness, tingling or weakness (corresponding to the area where the hemorrhage will subsequently occur) that gradually spreads in a manner reminiscent of a Jacksonian-march and may spill-over vascular territories (probably an electrical phenomenon rather than an ischemic event). This is suggestive of but not pathognomonic for the subsequent development of lobar ICH.

87.6.3 Concomitants of specific lesions in ICH

Putaminal hemorrhage

The most common site for ICH. Smooth gradual deterioration in 62\%(maximal deficit at onset in 30\%); never fluctuating. Contralateral hemiparesis, may progress to hemiplegia or even coma or death. H/A in 14\% at onset. No H/A at any time in 72\% Papilledema and subhyaloid preretinal hemorrhage are rare.

Thalamic hemorrhage

Classically, contralateral hemisensory loss. Also hemiparesis when the internal capsule is involved. Extension into upper brain stem \rightarrow vertical gaze palsy, retraction nystagmus, skew deviation, loss of convergence, ptosis, miosis, anisocoria, \pm unreactive pupils. H/A in 20–40\% Motor deficit similar to putaminal hemorrhage, but contralateral sensory deficit widespread and striking. Hydrocephalus may occur from compression of CSF pathways.

In 41 patients, when hemorrhage \textgreater 3.3 cm on CT, all died. Smaller hematomas usually caused permanent disability.
Cerebellar hemorrhage

May include any combination of the following:
1. symptoms of increased ICP (lethargy, N/V, HTN with bradycardia...) due to hydrocephalus which may occur as a result of:
   a) compression of the 4th ventricle → obstruction of CSF
   b) extension of the hemorrhage into the ventricular system
2. direct compression of brain stem may produce:
   a) facial palsy: due to pressure on the facial colliculus
   b) these patients classically become comatose without first having hemiparesis, unlike many supratentorial etiologies

Lobar hemorrhage

Syndromes associated with hemorrhage in the 4 cerebral lobes\(^1^4\) (≈ 50% have H/A as a first and prominent symptom):
1. frontal lobe (the most distinctive of the syndromes): frontal H/A with contralateral hemiparesis, usually in the arm with mild leg and facial weakness
2. parietal lobe: contralateral hemisensory deficit and mild hemiparesis
3. occipital lobe: ipsilateral eye pain and contralateral homonymous hemianopsia, some may spare superior quadrant
4. temporal lobe: on dominant side, produces fluent dysphasia with poor auditory comprehension but relatively good repetition

87.6.4 Delayed deterioration

General information

Deterioration after the initial hemorrhage is usually due to any combination of the following:
1. rebleeding: see below
2. edema: see below
3. hydrocephalus: higher risk with intraventricular extension or posterior fossa ICH
4. seizures

Rebleeding or extension of bleed

Early rebleeding: Rebleeding (more so in basal ganglion hemorrhages than in lobar hemorrhages) has been documented during the first hour by “ultra-early” scanning and repeating CT scans. Rebleeding is usually accompanied by clinical deterioration.\(^9^8\) The incidence of hematoma enlargement decreases with time, 33–38%in 1–3 hours,\(^9^9\) 16%in 3–6 hrs, and 14% between 24 hrs of onset and a second CT within 24 hrs of the first.\(^1^0^0\) Patients with enlarging hematomas were more likely to have larger hematomas and/or coagulopathy, and had a worse outcome.\(^1^0^0\) Rebleeding may still occur following surgical evacuation of clot even with satisfactory intraoperative hemostasis. Hemo-static agents (e.g. NovoSeven®) may reduce this risk (p.1339). The “spot sign”\(^1^0^1\) on CTA (small enhancing foci within acute ICH) correlated with increased risk of hematoma expansion.

Late rebleeding: Quoted rates for late rebleeding from ICH range from 1.8–5.3%(depending on length of follow-up).\(^1^0^2\) Diastolic BP was significantly higher in the group with recurrent hemorrhage, with a 10%yr risk for DBP > 90 mm Hg vs. < 1.5%for DBP ≤ 90 (mean F/U of 67 months).\(^1^0^2\) Other risk factors include diabetes and tobacco and alcohol abuse.\(^1^0^3\) Recurrent hemorrhages may indicate underlying vascular malformations or amyloid angiopathy (lobar rebleeding is likely to be due to amyloid angiopathy\(^1^0^3\)).

Edema

Edema and ischemic necrosis around the hemorrhage may cause delayed deterioration.\(^1\) Although necrosis from mass effect of the clot contributes a small part to the edema, experiments indicate that by itself, the mass effect is insufficient to account for the amount of edema that occurs. It is believed that an edemogenic toxin is released from the clot. Experiments with various components of blood clots has disclosed that thrombinin concentrations that could be released from the clot causes increased permeability of the blood-brain-barrier, and is also a potent vasoconstrictor. This is the leading suspect as the major cause of delayed edema and deterioration. Also see Cerebral edema (p.90).
87.7 Evaluation

87.7.1 CT scan

CT scan is rapid, and easily demonstrates blood as high density within the brain parenchyma immediately after hemorrhage. Although mass effect is common, the tendency for the hemorrhage to dissect through brain tissue often results in less mass effect than would be anticipated from the size of the clot.

Clot volume carries prognostic significance (p. 1343). It can be measured volumetrically using computer algorithms available on some CT scanners, or it can very simply be approximated by the ellipsoid method\(^{104}\) (originally developed for AVMs, based on the principal that the volume of an ellipsoid is approximately half of that of a parallelepiped into which it is placed)\(^{105}\) and is simpler than other slightly more accurate estimation methods\(^{106}\) as shown in Eq (87.1), where AP, LAT and HT are the diameters of the clot in each of the 3 dimensions (antero-posterior, lateral, and height). To estimate height of a lesion when only axial images are available (as on most initial CTs), count the number of images on which the lesion is seen, and multiply by the slice thickness of the CT cuts\(^{104,106,107}\) (this information is usually printed on the CT), or, subtract the table position of the highest cut that shows the clot from the table position of the lowest cut showing clot.

$$\text{ellipsoid volume} = \frac{\text{AP} \times \text{LAT} \times \text{HT}}{2}$$

On the average, the size of the clot decreases $\approx 0.75 \text{ mm/day}$, and the density decreases by $\approx 2 \text{ CT units/day}$, with little change for 1st 2 wks.

87.7.2 MRI

Usually not the procedure of choice for initial study. Does not show blood well within the first few hours. Difficult to ventilate or access patient during the study. Slower and more expensive than CT. May be useful later, e.g. to help diagnose cerebral amyloid angiopathy (CAA) (p. 1334).

The appearance of ICH on MRI is very complicated. It is highly dependent on the age of the clot\(^{108}\) with 5 stages identified (Table 87.4).

87.7.3 Cerebral angiography

For making the diagnosis of the ICH itself, angiography cannot reliably differentiate the mass effect from an ICH from that due to an ischemic infarct or tumor.\(^{109}\) May demonstrate AVMs and aneurysms when they are associated with the ICH. The yield may be increased by delaying the study.\(^{14}\)

| Table 87.4 Variation of MRI appearance of ICH with time since hemorrhage\(^{108}\) |
|-----------------------------|-----------------|-----------------|-----------------|
| Stage              | Age            | Condition of hemoglobin | T1WI  | T2WI  |
| hyperacute         | <24 hrs        | oxy-Hgb (intracellular) | iso   | sl. ↑ |
| acute              | 1–3 d          | deoxy-Hgb (intracellular) | sl. ↓ | very ↓ |
| subacute           |                |                    |       |       |
| • early            | >3 d           | met-Hgb (intracellular) | very ↑ | very ↓ |
| • late             | >7 d           | met-Hgb (extracellular\(^b\)) | very ↑ | very ↑ |
| chronic            |                |                    |       |       |
| • center           | >14 d          | hemichromes\(^c\) (extracellular) | iso   | sl. ↑ |
| • rim              |                | hemosiderin (intracellular) | sl. ↓ | very ↓ |

\(^{a}\)Abbreviations: oxy-Hgb = oxyhemoglobin, deoxy-Hgb = deoxyhemoglobin, met-Hgb = methemoglobin, iso = iso-intense to brain, ↓ = hypo-intense, ↑ = hyperintense, sl = slightly

\(^{b}\)when the RBC's lyse, the Hgb becomes extracellular

\(^{c}\)diamagnetic (non-paramagnetic) heme derivatives
May demonstrate vascular blush in some cases of tumor. Normal arteriography cannot eliminate cerebrovascular amyloid angiopathy as the etiology of ICH in the elderly.

For indications for cerebral angiography in ICH, see below.

### 87.7.4 ICH score

The system of Hemphill et al. assigns points based on 5 features as indicated in Table 87.5. The points are then summed for the “ICH score.” The associated 30 day mortality is tabulated in Table 87.6.

### 87.8 Initial management of ICH

#### 87.8.1 Outline

(The following assumes the diagnosis has already been made, usually on CT scan.) There is not uniform agreement on almost all aspects of the management of ICH from the optimal BP to the indications for surgery. The following is offered as a guide.

Most aspects of management are controversial. The following is offered as a guide.

1. patients should be managed in an ICU
2. HTN: controversial. Issues: HTN may contribute to further bleeding, especially within the first hour. However, some HTN may be needed to maintain perfusion. Some say reduce MAP to pre-morbid level if known, or by \( \approx 20\% \) if unknown. Note: A study of 8 ICHs showed autoregulation was maintained, but with an elevated lower limit. However, CBF fell when MAP was lowered pharmacologically below the usual MAP, which averaged 80% of the admission MAP (admission HTN followed the ICH).
3. intubate if stuporous or comatose
4. maintain euglycemia
5. maintain normothermia
6. anticonvulsants
   a) seizures are treated with appropriate AEDs
   b) prophylactic AEDs: optional. May decrease risk of early seizures in patients with lobar hemorrhages
   c) AED options
      - Keppra has a very favorable therapeutic/toxic profile. Dose 500 mg BID
      - OR phenytoin: load with 17 mg/kg slow IV over 1 hour, follow with 100 mg q 8 hrs; see phenytoin (PHT, Dilantin®) (p.446)

\( ^a \) possible bias since treatment decisions in elderly patients may have differed from younger patients.
7. Hemostatic issues:
   a) Check INR (or PT), PTT & platelet count (PC), platelet function assay (PFA)
      - correct coagulopathies, see Correction of coagulopathies or reversal of anticoagulants (p.166)
      - platelets: correct thrombocytopenia or platelet inhibiting drugs as discussed below
   b) Bleeding time: not generally helpful
   c) Hemostatic agents: NovoSeven® (recombinant activated coagulation factor VII (rFVIIa)) given IV within 4 hours of onset, see below

8. Steroids: controversial. No benefit from dexamethasone in ICH, with significantly more complications (primarily infectious, GI bleeding and diabetogenic). Consider use if significant peri-hemorrhage edema on imaging (suggested dosage: 4 mg dexamethasone IV q 6 hrs, tapered over 7–14 days)

9. Treat intracranial hypertension presumptively: mannitol and/or furosemide as tolerated, also helps with HTN; for more, see Treatment measures for elevated ICP (p.866). If significant problems from suspected increased ICP, consider ICP monitor

10. External ventricular drain (EVD): for hydrocephalus, some cases of intraventricular blood, or to manage ICP (see below). R/O coagulopathy before placing

11. Follow electrolytes and osmolarity
   a) Aggressively treat hyperglycemia (insulin drip if problematic)
   b) Watch for SIADH (p.114)

12. Angiography: primarily to R/O underlying vascular malformation, but also to R/O aneurysm (a less common cause of ICH), and tumor (which is usually better diagnosed on contrast CT or MRI)
   a) If urgent surgery is indicated (e.g. for herniation), the delay in obtaining an angiogram may be detrimental and it may be best deferred to post-op
   b) Indications: angiography is recommended except for patients >45 yrs of age with preexisting hypertension and ICH in thalamus, putamen or posterior fossa because there was a 0% yield out of 29 patients in this group and low yield in all patients with isolated deep ICH
      - patients >45 yrs with a history of HTN and a lobar ICH: angiography had a 10% yield, primarily AVM
      - patients with intraventricular hemorrhage (without parenchymal hematoma): the yield of angiography was ≈ 65% primarily AVM
   c) An underlying lesion may be obliterated by ICH, especially acutely. If initial angiography is negative, repeat after CT shows resorption of clot (≈ in 2–3 mos). If still negative, follow CT or MRI q 4–6 mos for ≈ 1 year to R/O tumor. Delaying the initial angiogram for several weeks may increase the yield and is also an option
   d) The literature indicates that MRI/MRA has only ≈ 90% sensitivity for detecting structural abnormalities in this setting, and so a negative study cannot completely exclude this possibility
   e) The yield of angiography in ICH would be expected to be lower in patients at increased risk of ICH: patients on warfarin (Coumadin®), chronic alcoholics, patients with amyloid angiopathy...

---

*from Table 87.5

b) No pt. in the study had a score of 6, but “it is expected this would be associated with high rate of mortality”
87.8.2 Thrombocytopenia or platelet inhibiting drugs

1. thrombocytopenia: although platelet transfusions are generally recommended only for PC<50K, ICH is so serious that a suggestion is ideally to keep PC>100K (if this is difficult to attain, aim for platelet count >75K)
2. patients on platelet inhibiting drugs (e.g. aspirin or Plavix®) should receive platelets when needed: start with 6 units of platelets; see Platelets (p.154)

87.8.3 NovoSeven® (recombinant activated coagulation factor VII (rFVIIa))

At the site of a tissue factor (TF) bearing cell, rFVIIa forms a complex with TF resulting in thrombin production. It also converts factor X to its active form, Xa on the surface of activated platelets resulting in a "thrombin burst" at the site of damage. Half life: 2.6 hrs. Expensive (≈ $10,000 per dose).

FDA approved for various bleeding diatheses (including hemophiliacs with antibodies to factor VIII or IX). Phase II "off label" Factor Seven for Acute Hemorrhagic Stroke (FAST) study for ICH appeared promising, however, preliminary results of the phase 3 trial showed no difference in death or major disability at 90 days.

for ICH. Doses studied: 40, 80 & 160 mcg/kg IV over 1–2 minutes given IV within 4 hours of symptom onset reduces 90 day morbidity & mortality, with a dose-related reduction in mean increase of ICH volume at 24 hrs, and a small increase in thrombotic complications (studied in patients with GCS>5, with no plan for surgical evacuation within 24 hours and no history of thrombotic or vaso-occlusive disease). Side effects: thrombotic events (MI, stroke... primarily with higher doses (≥120 mcg/kg), risk may be increased in presence of DIC, predisposing coagulopathy, advanced atherosclerotic disease, crush injury, septicemia, or concomitant treatment with activated or nonactivated prothrombin complex concentrates (aPCC/PCCs) due to increased levels of circulating TF.

87.8.4 Anticoagulation following ICH

Patients with ICH who subsequently require anticoagulation (e.g. for embolic ischemic stroke or for mechanical heart valve) pose a management dilemma. In the case of embolic disease, the fear of converting an ischemic infarct to a hematoma or increasing the size a small ICH with continued anticoagulation has traditionally outweighed the possible benefit of protection from further embolization. However, an anecdotal (retrospective uncontrolled) report of 12 such patients found no incidence of increased intracranial bleeding with either continued anticoagulation (6 patients) or resumption of anticoagulation after an hiatus (several days in 4 patients, 5 days in 1, and 14 days in 1). In another study none of 35 patients who had resumption of warfarin had recurrent intracranial hemorrhage (ICH, SAH or subdural hematoma). While this does not prove that anticoagulation is safe after ICH, it does demonstrate that if there is a strong indication for anticoagulation, and if there is not an acceptable alternative (e.g. Greenfield filter for DVT (p.170)), that anticoagulation in this setting is not always met with disastrous results.

The probability of having an ischemic stroke at 30 days following cessation of warfarin for a median of 10 days using Kaplan-Meier survival estimates are approximately 2.9% for patients who had originally been treated with warfarin for prosthetic heart valves, 2.6% for those treated for atrial fibrillation, and 4.8% for those treated for cardioembolic stroke. These numbers may be gross underestimates as many patients died within 2 weeks, and follow-up imaging was scant; another study showed a much higher rate of 20% see Cardiogenic brain embolism (p.1304) for more details.

Antiplatelet therapy after ICH is not associated with a substantially increased risk of recurrent ICH (prospective cohort study).
Recommendations

A-fib: long-term anticoagulation should be avoided after ICH.\textsuperscript{125} Mechanical heart valves: 1–2 weeks off anticoagulation (to observe ICH, or to evacuate a SDH or clip an aneurysm).\textsuperscript{121,126} Patients with deep hemispheric ICH at high-risk for thromboembolic stroke may benefit from resumption of long-term anticoagulation.\textsuperscript{125} Patients requiring hemodialysis after ICH: heparin-free dialysis may be used.

87.8.5 Ventriculostomy (IVC) AKA external ventricular drainage (EVD)

Indications:
1. intraventricular extension of blood causing acute obstruction of the third ventricular outlet. In these cases, the IVC is usually placed in the lateral ventricle contralateral to the hemorrhage (to avoid putting the catheter directly in clot, which may obstruct the inlets). The prognosis for patients with a significant volume of intraventricular blood is poor. It may be difficult to maintain the patency of the catheter due to occlusion by clot, tissue plasminogen activator may help (see below)
2. acute hydrocephalus
3. fICP management

87.9 Surgical treatment

87.9.1 General information

The first successful evacuation of an intracerebral hematoma was reported by MacEwan in 1888.\textsuperscript{127} The patient recovered completely from an upper extremity monoplegia.

**Booking the case: Craniotomy for ICH**

- Also see defaults & disclaimers (p. 27).
- 1. position: (depends on location of bleed)
- 2. equipment:
  - a) microscope (not used for all cases)
  - b) image guided navigation (not typically used)
- 3. post-op: ICU
- 4. consent (in lay terms for the patient – not all-inclusive):
  - a) procedure: surgery through the skull to remove blood clot, stop any bleeding identified, possible placement of external (ventricular) drain
  - b) alternatives: nonsurgical management
  - c) complications: usual craniotomy complications (p. 28) plus further bleeding which may cause problems (especially in patients taking blood thinners, antiplatelet drugs including aspirin, or those with coagulation abnormalities or previous bleeds) and may require further surgery, areas of the brain that have already been damaged by the bleeding are not likely to recover, hydrocephalus

87.9.2 Indications for surgery

**General information**

Amazingly, after repeated attempts to resolve this dilemma, considerable controversy persists regarding indications for surgery. Surgery may lower morbidity from rebleeding (especially if an aneurysm or AVM is identified as the cause of the ICH), edema, or necrosis from mass effect of hematoma (unproven), but rarely causes neurologic improvement. Meta-analyses\textsuperscript{128,129} yield inconclusive or conflicting results and could not identify whether there was a favorable effect of surgery, the types of ICH and patients that are likely to benefit, and the relative effectiveness of the various available surgical options.

**Randomized prospective studies (RPS) in the current CT/surgical era**

One RPS\textsuperscript{130} found lower mortality for patients with GCS 7–10 treated surgically (note: only 20% of these patients were operated on <8 hrs from the bleed, and the mean time for all patients to
operation was 14.5 hours (range: 6–48 hrs), which may be long. However, survivors in this group were all severely disabled (none were independent).

Another\textsuperscript{115} found no benefit from surgery for putaminal hemorrhages, also with poor outcomes in all patients.

International STICH\textsuperscript{131}: enrolled 1,033 patient. Study shortcomings: possible selection bias (the responsible neurosurgeon had to be uncertain of the benefits of medical vs. surgical treatment), “early surgery” had a somewhat long median time to treatment of 30 hours, and 26% of medically treated patients crossed over and had surgery at a mean of 60 hours (late). Given these limitations, the conclusion was that for supratentorial ICH there was no benefit of early surgery (although there may have been some benefit in the subgroup with a hematoma within 1 cm of the cortical surface). This trial may be more accurately considered to be a comparison of early vs. delayed surgery in patients subjectively judged to need surgery by the investigator.

**Conclusion**

The decision to operate therefore must be individualized based on patient’s neurologic condition, size and location of hematoma, patient’s age, and the patient’s expressed preferences (e.g. by a “living will”) and the family’s wishes concerning “heroic” measures in the face of catastrophic illness.

**Guidelines for considering surgery vs. medical management**

(for separate indications for surgery for cerebellar hemorrhage, see below)

1. **NON-SURGICAL**: factors that favor medical management
   a) minimally symptomatic lesions: e.g. alert patient with subtle hemiparesis (especially patients with GCS>10\textsuperscript{130})
   b) situations with little chance of good outcome
      - high ICH score (p. 1339), which overlaps with the following
      - massive hemorrhage with significant neuronal destruction (see below)
      - large hemorrhage in dominant hemisphere
      - poor neurologic condition: e.g. comatose with posturing (i.e. GCS ≤ 5), loss of brain stem function (fixed pupils, posturing…)
      - ≈ age >75 yrs: do not do well with surgery for this
   c) severe coagulopathy or other significant underlying medical disorder(s): in the event of herniation, rapid decompression surgery may be considered in spite of the risks
   d) basal ganglion (putaminal) or thalamic hemorrhage: surgery is no better than medical management, and both have little to offer\textsuperscript{115,132} (see below)

2. **SURGICAL**: factors that favor rapid surgical removal of the blood clot
   a) lesions with marked mass effect, edema, or midline shift on imaging (removal is considered due to the potential for herniation)
   b) lesions where the symptoms (e.g. hemiparesis/plegia, aphasia, or sometimes just confusion or agitation…) appear to be due to increased ICP or to mass effect (i.e. compression) from the clot or surrounding edema. Symptoms attributable directly to brain injury from the hemorrhage are unlikely to be reversed by surgical evacuation
   c) volume: surgery for moderate volume hematomas (i.e. ≈ 10–30 cc, Eq (87.1)) may be more appropriate than with:
      - small clot (<10 cc): mass effect from clot +edema is usually not significant enough to require surgery
      - large clot: >30 cc: associated with poor outcome (only 1 of 71 patients could function independently at 30 days\textsuperscript{135})
      - massive hemorrhage >60 cc with GCS≤8: 91% 30-day mortality\textsuperscript{133}
      - massive hemorrhage >85 cc (the volume of a sphere with a diameter of 5.5 cm): no patient survived, regardless of treatment in one series\textsuperscript{134}
   d) persistent elevated ICP in spite of therapy (failure of medical management). Evacuating clot definitely lowers ICP, but the effect on outcome is uncertain
   e) rapid deterioration (especially with signs of brain stem compression) regardless of location in a patient considered to be salvageable
   f) favorable location, for example:
      - lobar (as opposed to deep hemispheric): in spite of optimistic results in a non-randomized study done in 1983 indicating good outcomes in patients with deep hemorrhages treated with early surgery\textsuperscript{64} a later randomized study failed to confirm this benefit\textsuperscript{115}
      - cerebellar: see below
• external capsule
• non-dominant hemisphere
g) young patient (especially age $\leq 50$ yrs): they tolerate surgery better than elderly patients, and, unlike elderly patients with brain atrophy, they also have less room in the head to accommodate the mass effect of clot + edema

h) early intervention following hemorrhage: surgery after 24 hrs from onset of symptoms or deterioration may be of less benefit

Management of cerebellar hemorrhage

Recommendations:
1. patients with a Glasgow Coma Scale (GCS) score $\geq 14$ and hematoma $< 4$ cm diameter: treat conservatively
2. patients with GCS $\leq 13$ or with a hematoma $\geq 4$ cm: surgical evacuation
3. patients with absent brain stem reflexes and flaccid quadriplegia: intensive therapy is not indicated. Note: some authors contend that the loss of brain stem reflexes from direct compression may not be irreversible, and that cerebellar hemorrhage represents a surgical emergency (and that the above criteria would thus deny potentially helpful surgery to some, see discussion of cerebellar infarction and decompression (p. 1302)).
4. patients with hydrocephalus: ventricular catheter (if no coagulopathy). Caution: do not overdrain to avoid upward cerebellar herniation (p. 303). Most cases with hydrocephalus also require evacuation of the clot

87.9.3 Surgical considerations

General recommendations
1. send specimens (hematoma, abnormal looking tangle of blood vessels if present, and possibly biopsy walls of hematoma cavity) to pathology for analysis (to rule-out tumor, AVM, amyloid angiopathy,...)
2. surgical options:
   a) “standard approach”: craniotomy with evacuation of the clot under direct vision (with or without microscope)
   b) stereotactic aspiration with thrombolytic agents has also been used; see Stereotactic surgery (p. 1441), evacuation of intracerebral hemorrhage
   c) endoscopic surgery

Surgical techniques for cerebellar hemorrhage
1. position: lateral oblique (p. 1446) with the involved side up
2. if rapidity is crucial, a midline skin incision is preferred because it can be taken down quickly with little fear of encountering a vertebral artery
3. craniectomy (without bone replacement) is preferred over craniotomy to accommodate post-op swelling
4. a prophylactic Frazier burr hole is recommended to allow rapid treatment if post-op hydrocephalus develops – see placement (p. 1450) and use (p. 1452) -, or a ventricular catheter may be placed to monitor ICP and allow CSF drainage post-op
5. in cases where there has been rupture into the ventricular system, the surgical microscope should be used to follow the clot to the fourth ventricle which is then cleared of clot

Intraventricular tissue plasminogen activator (rt-PA)

Intraventricular rt-PA may help lyse clot and maintain catheter patency or reopen a clotted catheter. No well-designed randomized study has been done; but anecdotal evidence suggests it is relatively safe. In cases of suspected aneurysm, AVM or other vascular malformation, it cannot be used until the source of bleeding has been corrected.

In cases of suspected aneurysm, AVM or other vascular malformation, it cannot be used until the source of bleeding has been corrected.

Intraventricular rt-PA in NS is administered through an intraventricular catheter (IVC). The IVC is closed for 2 hours after injection. In the low dose CLEAR-IVH (Clot Lysis: Evaluating Accelerated Resolution of Intraventricular Hemorrhage) trial (a phase II trial with 52 patients), 1 mg tPA intrathecally via a ventricular catheter every 8 hours up to a maximum of 4 days, was associated with a 30 day morality of 15%(compared to an expected 80–85%). Hemorrhagic complication rate...
was 6%. A phase III trial http://clinicaltrials.gov/ct2/show/NCT00784134?term=clear+III+stroke&rank=1 is underway to confirm this.

87.10 Outcome

Thalamic hemorrhages that tend to destroy the internal capsule (IC) are more likely to produce hemiplegia than hemorrhages lateral to the IC that compress but do not disrupt the IC.

Mortality: The chief cause of death (in a series testing the effects of dexamethasone) is cerebral herniation, occurring mainly during the first week and mostly in patients with initial Glasgow Coma Scale scores ≤7. The in-hospital death rate decreased overall during the 1980s but increased for patients ≥65 years of age. Quoted mortality rates vary widely, and depend on size and location of clot, age and medical condition of the patient, and etiology of the hemorrhage. Overall, the 30-day mortality rate is ≈44% for ICH, which is similar to that for SAH (≈46%). Patients with lobar hemorrhages (p.1336) tend to fare better than deep ICH (basal ganglion, thalamus...) with only ≈11% mortality in 26 patients.14

87.11 ICH in young adults

87.11.1 General information

In a review of 72 patients age 15–45 yrs suffering nontraumatic ICH, a presumed cause was found in 76% (Table 87.7). 3 patients had labor or post-partum hemorrhages (p.1334); see also Pregnancy & intracranial hemorrhage (p.1169).

AVM: lobar hemorrhages in this age group are highly suggestive of AVM. Of 40 lobar hemorrhages, 37.5% were determined to be from AVMs.144

Herpes simplex encephalitis: may produce hemorrhagic changes on CT, especially in the temporal lobes; see Herpes simplex encephalitis (p.364).

Drug abuse: especially with sympathomimetics such as cocaine (p.1333) should also be considered in young adults.

Leukemia: ICH may be the initial presentation of leukemia in a young adult (may be due to metastases (chloroma) or to thrombocytopenia).

87.11.2 Outcome

Overall in-hospital survival (including those treated medically) was 87.5%

a-hemangioma, ependymoma, metastatic choriocarcinoma... see Hemorrhagic brain tumors (p.1335)
87.12 Intracerebral hemorrhage in the newborn

87.12.1 General information

Occurs primarily in premature infants. Alternate terms: subependymal hemorrhage (SEH), germinal matrix hemorrhage (GMH), periventricular-intraventricular hemorrhage (PIVH). Intraventricular hemorrhage (IVH) arises from extension of SEH through ependymal lining of ventricle and occurs in 80% of cases of SEH.\textsuperscript{145}

87.12.2 Etiology

The highly vascular germinal matrix is part of the primordial tissue of the developing brain and is the source of future neurons and glial cells. It is located just beneath the ependymal lining of the lateral ventricles, and undergoes progressive involution until 36 weeks gestational age (GA). Thus, the matrix may persist out of utero in premature infants. A disproportionate amount of the total CBF perfuses the periventricular circulation through these capillaries which are immature and fragile and have impaired autoregulation.\textsuperscript{146,147} The site of hemorrhage is age dependent. Between 24–28 weeks GA they occur over the body of the caudate nucleus and at 29 weeks GA or greater they arise over the head of the caudate nucleus.\textsuperscript{148}

87.12.3 Pathogenesis of PIVH in the pre-term infant

The metabolically active GM is susceptible to hypotension and hypoperfusion which can lead to infarction. The GM is a vulnerable watershed zone supplied by Heubner’s artery (from the anterior cerebral artery), terminal branches of the lateral striate arteries (of the middle cerebral artery) and the anterior choroidal artery (of the internal carotid or middle cerebral artery).

1. postnatal hypoxia due to respiratory distress syndrome related to hyaline membrane disease, pneumothorax and/or anemia can deprive the metabolically active GM of oxygen. This ischemia to the endothelial cells lining the capillaries makes them vulnerable to infarction and then disruption
2. hypercapnia maximally dilates the thin walled vessels of the GM. If this is followed by sudden increases in perfusion the result can be rupture of the vessels
3. increased venous pressure from any cause (labor and delivery, positive pressure ventilation, stimulation, endotracheal suctioning, myocardial failure from ischemia) can result in increased venous pressure in the GM leading to hemorrhage
4. dehydration followed by rapid resuscitation with hyperosmolar solutions increases the intravascular volume by osmotically encouraging the movement of fluid from tissues into the intravascular space. With associated increases in systemic blood pressure the GM capillaries are at increased risk of rupture

87.12.4 Risk factors for PIVH

Increased cerebral perfusion pressure (CPP) with the associated increased cerebral blood flow (CBF) and hypoxia are the common denominators for most risk factors for PIVH. The elevated pressure may cause the hemorrhage by rupturing the fragile vessels of the germinal matrix, possibly already damaged by previous insults of high or fluctuating CBF and hypoxia.

Risk factors for PIVH include\textsuperscript{149}:

1. those associated primarily with increased CBF or CPP:
   a) asphyxia: including hypercapnia (see above)
   b) rapid volume expansion
   c) seizures
   d) pneumothorax
   e) cyanotic heart disease (including PDA)
   f) infants being mechanically ventilated having RDS and fluctuating CBF velocity documented by Doppler flow meter\textsuperscript{150}
   g) anemia
   h) decreased blood glucose
   i) arterial catheterization
   j) blood pressure fluctuations
2. younger gestational age (GA)
3. low birth weight
4. acute amnionitis
5. failure to give antenatal steroids (p.1347) during the 48 hours prior to pre-term delivery\(^{(151)}\) (i.e. to women at risk of delivering low birth-weight infants):

6. APGAR’s <4 at 1 minute and <8 at 5 minutes

7. acidosis

8. coagulopathies

9. general anesthesia for C-section

10. extracorporeal membrane oxygenation (ECMO): due to heparinization in addition to increased CPP

11. maternal cocaine abuse\(^{(152)}\)

12. maternal aspirin use

### 87.12.5 Epidemiology

#### Incidence

Depends on the method used for detection (many PIVHs are asymptomatic) and the population being evaluated. 540,000 pre-term infants are born in the United States annually. 85,000 are very pre-term (<32 weeks GA) and 385,000 are late pre-term (34–36 weeks GA). 63,000 very low birth weight (<1500 grams) infants are born each year. Of the preemies weighing <1500 gm birth weight, 20–25% will suffer from a PIVH.\(^{(153,154)}\)

In a 1978 study, PIVH was found by CT in 43% (20/46) of preemies with birth-weight <1500 gm.\(^{(155)}\) Mortality in infants with PIVH was 55% compared to 23% in those without PIVH.\(^{(155)}\) Ultrasound (U/S) detected PIVH in 90% of 113 preemies <34 weeks gestation\(^{(156)}\) (49% were grade III or IV, see Table 87.8 for grading).

#### Timing

The timing of PIVH has a bimodal distribution. A substantial number occur within 6 hours of birth with 50% occurring within 12 hours of birth.\(^{(157,158)}\) At postnatal days 3–4, a second peak occurs. Only 5% of bleeds will develop after postnatal day 4. Progression of hemorrhage has been documented in 10–20% of infants.\(^{(158)}\) Early onset PIVH is more likely to progress and has a higher mortality.\(^{(159)}\)

### 87.12.6 Prevention

Numerous studies have been conducted to find a method of directly reducing the incidence of PIVH among premature infants. Many are controversial. Optimal resuscitation and neonatal care, with an emphasis on measures which minimize cerebral blood flow fluctuations are key.

1. good prenatal care and avoiding pre-term labor
2. antenatal corticosteroids: administration of one course of antenatal corticosteroids to women at risk of having premature birth infants reduces neonatal mortality, respiratory distress syndrome and PIVH.\(^{(160)}\) Multiple courses of antenatal corticosteroids did not improve outcomes and were associated with decreased head circumference, weight and length at birth.\(^{(161)}\)
3. indomethacin: results in cerebral vasoconstriction and reduces the responsiveness of CBF to changes in CO\(_2\), lowers CBF and increases arterial oxygenation reducing patent ductus arteriosus (PDA). However, use is possibly associated with increased risk of intestinal perforation
4. antenatal vitamin K given IM >4 hrs prior to delivery decreases PIVH from 33% to 5%
5. sluicing umbilical cord blood and delaying umbilical cord clamping by 30–120 seconds in premature babies increased hematocrit and decreased PIVH in 5 of 7 studies\(^{(162)}\)
6. using surfactant to reduce RDS
7. minimizing external stimulation (some centers use fentanyl drips)
8. steroids to stabilize the GM vessels

| Table 87.8 Grading subependymal hemorrhage\(^{(155)}\) |
|-----------------|-----------------|
| Grade | Description |
| I | subependymal |
| II | IVH without ventricular dilatation |
| III | IVH with ventricular dilatation |
| IV | IVH with parenchymal hemorrhage |
87.12.7 Clinical

Grading

The most commonly used grading system of Papile et al. based on CT or U/S findings is shown in Table 87.8. PIVH may present acutely, subacutely. Most commonly, it is discovered incidentally on surveillance U/S.

There is a direct correlation between younger gestational age (GA) and the severity of PIVH. In infants 24–26 weeks GA, 32% will have a Grade III PIVH and 19% will have a Grade IV PIVH compared with infants 31–32 weeks GA, 11% will have a Grade III PIVH and 5% will have a Grade IV PIVH.¹⁶³

Presentation

Asymptomatic PIVH

Most PIVHs will be clinically unsuspected, usually with smaller hemorrhages. Retrospectively, these PIVHs may have been suggested by a fall in Hct or delays in neurologic development. These have a 78% 6-month survival, vs. 20% for PIVH showing signs.

Subacute presentation

Usually smaller or more slowly developing hemorrhages. Clinically may present as irritability, reduced motor activity, or abnormal eye movements.

Acute presentation

1. changes in muscle tone or activity: usually decerebrate or decorticate posturing, sometimes flaccid paralysis
2. seizures: often subclinical
3. tense fontanelle
4. hypotension
5. respiratory and cardiac irregularities: apnea & bradycardia (“A’s and B’s”)
6. unreactive pupils and/or loss of extraocular muscle movements
7. Hct drop >10%

Hydrocephalus

General information

20–50% of infants with PIVH will develop either transient or progressive hydrocephalus (HCP). Grades III and IV are more often associated with progressive ventricular dilatation than are lower grades (however, HCP may develop even after low grade PIVH¹⁶⁴). Younger gestational age infants may be at lower risk.

Post PIVH hydrocephalus usually occurs 1–3 weeks after the hemorrhage. Probably caused by cellular debris and/or the toxic effects of blood breakdown products on the arachnoid granulations (communicating HCP), or by an adhesive arachnoiditis in the posterior fossa or rarely by compression or blockage of critical pathways, e.g. at the sylvian aqueduct (obstructive HCP). In a case of HCP following intra-uterine PIVH, aqueductal gliosis was found at autopsy.¹⁶⁵

Differential diagnosis of ventriculomegaly in PIVH

When ventriculomegaly is detected, it needs to be differentiated from the following:

1. transient ventriculomegaly: occurs in the first few days after PIVH. This may not cause elevated ICP. As implied, it is self limited
2. progressive ventriculomegaly: occurs in 20–50% of cases (true hydrocephalus)
3. “hydrocephalus ex vacuo”: due to loss of brain tissue or maldevelopment. Is not progressive on serial U/S. OFCs may fall below normal due to lack of growing brain as stimulus for head growth

Possible presentations

Abnormally increasing OFC (crossing percentile curves faster than body weight), lethargy, apnea and bradycardia, vomiting. There is progressive dilatation of the ventricular system on serial U/S or CT or MRI evaluations.
87.12.8 Pathophysiologic effects of PIVH

Deleterious effects of PIVH on the brain are due to:
1. destruction of the germinal matrix and glial precursors
2. direct injury to neural tissue from hematoma: once hemorrhage resorbs may leave patient with porencephaly or cystic lesions
3. pressure of hematoma on nearby brain tissue reducing CBF even to parts of the same hemisphere distant from the hemorrhage
4. diffuse decreased CBF following the hemorrhage due to elevated ICP
5. injury from the same hypoxic event that precipitated the PIVH
6. decreased CPP leads to periventricular leukomalacia (PVL) and cerebral infarction
7. periventricular hemorrhagic infarction
8. hydrocephalus (see above): numerous deleterious effects on the CNS
9. seizures: repeated or prolonged seizures may be deleterious to neuronal function

87.12.9 Diagnosis

Ultrasound (U/S)

Performed through the open fontanelles. Accuracy ≈ 88% (91% sensitivity, 85% specificity). U/S is invaluable because:
1. it demonstrates the size of the ventricles, the location and size of the hematoma, and the thickness of the cortical mantle
2. it may be brought to the infant’s bedside (obviating transportation)
3. it is non-invasive
4. it is not adversely affected by occasional infant movements (eliminating the need for sedation)
5. there is no exposure to ionizing radiation (radiation from diagnostic imaging in children has long-term risks for cancer and damage to the lens)
6. it may be followed serially with relative ease

CT scan

Sometimes necessary when U/S is not readily available, or in complicated cases where anatomy is difficult to deduce from U/S images. Many ICUs have portable CT scans available which obviates need for patient transport.

Rapid sequence MRI

Pros: Eliminates the risk of ionizing radiation associated with CT scan.
Cons: Requires moving the infant from the neonatal ICU to the radiology suite.

87.12.10 Treatment

General measures

General measures are directed at optimizing CPP without further excessive elevation of CBF by carefully maintaining normal MAP and normalizing pCO₂ and by treating active hydrocephalus as needed (see above).

While daily LPs can control the deleterious effects of posthemorrhagic HCP, they do not reduce the frequency of long-term HCP (requiring permanent shunting). Ventricular size must be monitored with serial U/S.

Medical treatment

1. not very effective. Treated patients fared worse in several studies
2. osmotic agents: isosorbide, glycerol. Effects are short-lived
3. diuretic therapy: has been used, but a large study showed increased nephrocalcinosis and biochemical abnormalities, resulting in a borderline increase in the risk for motor impairment at one year. The results were so compelling, the data-monitoring committee terminated the study prematurely. Furosemide and acetazolamide therapy was deemed neither safe nor effective in treating post-hemorrhagic ventricular dilatation and cannot therefore be recommended.
Surgical/interventional treatment for the clot

Due to poor operative results, surgical evacuation of an intracerebral hemorrhage in the newborn is not indicated with the possible exception of a posterior fossa hemorrhage causing brain stem compression that does not respond to medical treatment. Supportive measures are usually in order.

Intervention for intraventricular blood

General information

34\% of infants <1500 g require shunt/reservoir drainage after failed medical management. Grade III and IV PIVH: >70\% of cases develop progressive ventricular dilatation, and 32–47\% of this subset will ultimately require shunting.

Indications for intervention

Intervention for intraventricular blood is indicated in the setting of progressive ventriculomegaly with the OFC crossing percentile curves and clinical evidence of increased ICP (split sutures, tense fontanelle...).

Serial lumbar punctures

Used at many facilities for hemorrhages with intraventricular extension and communicating hydrocephalus (the usual type of HCP that occurs with PIVH). This should be undertaken with the knowledge that meta-analysis showed sequential lumbar or ventricular taps of \( \approx 10 \text{ ml/kg/tap} \) for prophylaxis or treatment of progressive hydrocephalus offers no clear benefit over conservative treatment, and had an infection rate of 5–9\%. In rare cases, LPs may succeed in temporizing progressive HCP for a few weeks until the infant is large enough for shunt placement.

Infants <800 gm may not tolerate LPs because of desaturation when lying on their side, or the LP itself may be difficult. In these patients, consider 1–2 ventricular taps to at least obtain fluid for analysis (in some cases nothing further needs to be done).

Serial ventricular taps

May be a viable short-term option for those infants who cannot tolerate LPs or in whom there is obstruction to CSF flow in the lumbar subarachnoid space (e.g. due to spinal subdural hematoma from previous LP). However it is not desirable for long-term use because of repeated trauma to brain (risk of porencephaly) and risk of intracerebral, intraventricular, or subdural hemorrhage.

If continued taps are likely (i.e. large hemorrhage, or rapid recurrence of intracranial hypertension as determined by palpation of fullness of anterior fontanelle (AF) following several taps) the acceptable options include:

1. continuing serial LPs (see below)
2. percutaneous ventricular taps: not recommended for more than a few treatments as it causes porencephaly
3. placement of a temporary ventricular access device (TVAD) – a ventricular catheter connected to a subgaleal reservoir (either a Rickham reservoir, or a low profile McComb reservoir). These can be inserted safely at the bedside, obviating the need for transport to the O.R.

   a) temporary ventricular access: the reservoir can be used for serial percutaneous taps. Usually tapped QD or QOD (see below). Use a 27 Ga butterfly needle, clean with at least 3 betadine stick swabs, withdraw \( \approx 10 \text{ ml} \) and send for culture. Reported infection rate: 8–12\%.

   b) ventricular-subgaleal shunt: the side-port of the reservoir is left uncapped. A subgaleal pocket must be created at the time of surgery. Fluid is reabsorbed from this potential space. First performed in 1893 by Mikulicz-Radecki (1850–1905). Use has been reported up to 35 days. Infection rate: \( \approx 6\% \)

   c) the reservoir may be converted to VP shunt if and when appropriate. Not recommended in infants <1100 gms due to very high infection rate
4. external ventricular drainage (EVD): similar to reservoir placement, but with possibility of inadvertent dislodgment (13\%) and comparable infection rate (6\%)
5. early VP shunting: high infection rate, peritoneal cavity not suitable in many cases, e.g. due to necrotizing enterocolitis (NEC), paucity of subcutaneous tissue through which to pass shunt tube... Not recommended for infants <2000 gms
Temporary ventricular access device (TVAD)

Advantages of TVAD
1. avoids shunt in unhealthy children at risk of infection, skin breakdown or other operative/anaesthetic complications
2. clears protein and cellular debris (more favorable for subsequent shunting)
3. avoids repeated penetration of brain with risk of porencephaly
4. provides port for infusion of medication (e.g., antibiotics) PRN
5. avoids cumbersome, easily dislodged EVD with infection risk 6% on average of 13 days of EVD
6. up to 25% of patients will recover and avoid permanent shunt placement

Disadvantages of TVAD
1. requires services of a neurosurgeon (not always available)
2. increases risk of infection of subsequent permanent shunt from 5% to 13% (183)
3. inherent risks of surgery including hemorrhage, infection, ventriculitis, meningitis, CSF leak
4. risks of overdrainage including subdural hematoma, impaired skull growth

Technical considerations for serial taps (via ventricular reservoir or LP)
8–20 cc of fluid are removed initially, and this is repeated daily (or more often if AF become very tense before 24 hours elapse) for several days, and then usually varies from 5–20 cc qod to 15 cc TID depending on response. The frequency and volume of the taps are modified based on:
1. fullness of AF: attempt to keep AF from becoming tense
2. appearance of ventricles on serial U/S: strive to prevent progressive enlargement, reduction in size can usually be achieved
3. follow OFC: should not cross percentile curves (need to differentiate from the so-called “catch-up phase” of brain growth which may occur once the infant overcomes their overall medical problems and is able to adequately utilize nutrition184,185; serial U/S will show rapid brain growth without progressive ventriculomegaly in cases of catch-up brain growth)
4. CSF protein concentration: controversial. Diminishes with serial taps. Some feel that as long as it is ≥100 mg/dl it is unlikely that significant spontaneous resorption will occur and continued serial taps will probably be needed
5. NB: removal of this volume of fluid may cause electrolyte disturbances, primarily hyponatremia; follow serum electrolytes on regular basis

Follow with serial U/S on day 3–5, and then weekly for several weeks, and then bi-weekly. A baseline CT scan is often obtained prior to placement of a permanent shunt.

Insertion of VP shunt or conversion of sub-Q reservoir to VP shunt
Indications and requirements:
1. symptomatic hydrocephalus (p. 1348) and/or progressive ventriculomegaly
2. infant is extubated (and thus off ventilator)
3. infant weighs ≥2000 grams (some prefer ≥2500 grams)
4. no evidence of NEC (might create problems with peritoneal end of catheter)
5. CSF protein ideally <100 mg/dl (because of concerns about plugging of the shunt, or causing ileus or malabsorption of the fluid – which was not seen with high protein fluid shunted from the subdural space186 – and also to see if patient will start reabsorbing CSF on their own)

Technical recommendations:
1. do not tap reservoir for at least 24 hrs before inserting a new ventricular catheter (allows ventricles to expand to facilitate catheterization)
2. obtain U/S the day prior to conversion
3. use a low or very-low pressure system (if CSF protein is high, consider a valveless system), upgrade later in infancy if necessary
4. avoid placing shunt hardware in areas on which these debilitated infants tend to lay (to prevent skin breakdown with hardware exposure)

87.12.11 Outcome

Short-term
Preemies with PIVH have higher mortality than matched preemies without PIVH.
The incidence of mortality and progression of hemorrhage is higher the earlier the hemorrhage occurs. The more severe the hemorrhage, the higher the mortality and the higher the risk of HCP (Table 87.9).
Long-term

The effect of low grade PIVH on long-term neurodevelopment has not been studied well. Most investigators feel that higher grades of PIVH are associated with greater degrees of handicaps than matched controls.

In one study of 12 infants with Grade II PIVH treated with serial LPs and in the 7 with progressive ventriculomegaly with VP shunt followed for a mean of 4.5 years found all were ambulatory and 75% had IQ within normal range.\(^\text{187}\)

A recent study of very low birth weight infants showed that children 18–22 months of age with severe PIVH and shunts had significantly lower scores on the Bayley Scales of Infant Development II compared with children with no PIVH and children with equal grades of PIVH who did not require a shunt.\(^\text{188}\)

87.13 Other causes of intracerebral hemorrhage in the newborn

1. birth trauma may result in subdural hemorrhage, tentorial hemorrhage, parenchymal hemorrhage and/or subarachnoid blood. This is usually detected by imaging (U/S or CT) when an infant develops seizures, apnea, bradycardia or rarely focal neurological deficits. It rarely requires surgical intervention
2. choroid plexus hemorrhage can result in IVH. In some cases HCP can develop and require shunt placement
3. hemorrhagic stroke has been identified in 6.2 per 100,000 live births.\(^\text{189}\) The usual presentation was with encephalopathy (100%) and seizures (65%). 75% of the strokes were idiopathic. Other identified etiologies were thrombocytopenia and a single case of a cavernous malformation. Risk factors for perinatal hemorrhagic stroke include: male gender, fetal distress, emergent c-section, prematurity and post-maturity
4. tumors in the neonate can present with hemorrhage
5. vascular malformations of any form can present in the neonate with hemorrhage, although this is uncommon. Vein of Galen malformations are diagnosed in the neonate in about 40% of cases.\(^\text{190}\)

Most of these infants present with fulminant congestive heart failure and 50% have ventriculomegaly

88 Outcome Assessment

88.1 Cancer

Karnofsky performance scale (KPS). Table 88.1, (after David A. Karnofsky) often used for grading functional status in patients with cancer. A KPS score < 70 (particularly with brain tumors) often identifies patients with a worse prognosis for any given treatment.

WHO performance score. Table 88.2, the WHO Performance score (AKA The Eastern Cooperative Oncology Group (ECOG) score, AKA Zubrod score (after C. Gordon Zubrod), ranges from 0 to 5, with 0 indicating perfect health and 5 death. The advantage over the Karnofsky scale is its simplicity.

88.2 Head injury

The Ranchos Los Amigos scale (Table 88.3) is often used in rating disability following head injury. The Glasgow outcome scale (Table 88.4) is frequently employed in outcome assessment.

88.3 Cerebrovascular events

88.3.1 General information

Several outcome grading scales have come to be favored for use following strokes or SAH. Each emphasizes different aspects of outcome. The Barthel Index (Table 88.6) places weight on activities of daily living (ADLs), while others, such as the modified Rankin scale (Table 88.5) assess levels of independence and includes a comparison to previous activity levels and shows fairly good interobserver consistency. While it does measure functional status, the modified Rankin is not sensitive to subtle neurologic deficits such as dysphasia or visual field defects.

| Table 88.1 Karnofsky performance status scale (modified) |
|---|---|---|
| Score | Criteria | General category |
| 100 | normal: no complaints, no evidence of disease | Able to carry on normal activity and work. No special care is needed |
| 90 | able to carry on normal activity: minor signs or symptoms | |
| 80 | normal activity with effort: some signs or symptoms | |
| 70 | cares for self unable to carry on normal activity or to do active work | Unable to work. Able to live at home, care for most personal needs. Variable assistance is required |
| 60 | requires occasional assistance: cares for most of needs | |
| 50 | requires considerable assistance and frequent care | |
| 40 | disabled: requires special care and assistance | Unable to care for self. Requires equivalent of institutional or hospital care. Disease may be rapidly progressing |
| 30 | severely disabled: hospitalized; death not imminent | |
| 20 | very sick: hospitalized; active supportive care needed | |
| 10 | moribund: fatal processes are progressing rapidly | |
| 0 | dead | |
### Table 8.8.2 WHO performance scale

<table>
<thead>
<tr>
<th>Grade</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>Fully active, no performance restriction as a result of disease.</td>
</tr>
<tr>
<td>1</td>
<td>Restricted in physically strenuous activity. Ambulatory. Able to do light work, e.g. light house work, desk work.</td>
</tr>
<tr>
<td>2</td>
<td>Unable to perform any work activities. Ambulatory. Up &amp; about &gt;50% of waking hours.</td>
</tr>
<tr>
<td>3</td>
<td>Only able to perform limited self care. Wheelchair confined &gt;50% of waking hours.</td>

</tbody>
</table>
88.3.2 Scales

Modified Rankin scale (Table 88.5) Barthel index (Table 88.6). The original Barthel index assigns one of three scores to 10 ratable ADLs, and then the individual scores are summed. The modified Barthel index (MBI) with a 5-step scoring system appears to have greater sensitivity. The total ranges from 0 to 100 (a score of 100 implies functional independence, not necessarily normality).
Of all the factors, independence in bathing was the most difficult. Abilities on the Barthel index tend to return in a fairly consistent order, and so most patients with the same score will have similar patterns of disability.

88.4 Spinal cord injury

Functional Independence Measure™ (FIM™)\textsuperscript{11,12,13} (FIM™). Developed to provide uniform evaluation of disability for spinal cord injuries. Rates 18 items shown in Table 88.7 (13 motor, 5 cognitive) on the 7 level scale shown in Table 88.8.

The FIM™ has high internal consistency and is a good indicator of burden of care.\textsuperscript{14,15}

89.2  Posterior fossa lesions

89.2.1  Cerebellar lesions

General information

The following addresses intra-axial p-fossa abnormalities (for extra-axial lesions, below).

Adult

Single lesion

Note. Rule of thumb: “the differential diagnosis of a solitary intraparenchymal lesion in an adult p-fossa is metastasis, metastasis, metastasis, until proven otherwise.”

1. Tumors:
   a) metastasis
   b) hemangioblastoma (p. 701): the most common PRIMARY intra-axial p-fossa tumor in adults (7–12% of p-fossa tumors). Very vascular nodule, often has cyst. Almost all p-fossa tumors are relatively avascular on angiography except these (look for serpentine signal voids especially in the periphery of the lesion on MRI, much less common in cavernous hemangioma)
   c) cerebellar (pilocytic) astrocytoma (p. 630): may be solid or cystic, tends to occur in younger adults
   d) brainstem glioma: an isolated glioblastoma in the posterior fossa of an adult is a reportable rarity
   e) choroid plexus tumor: usually infratentorial in adults (p. 1380)
   f) cerebellar liponeurocytoma (p. 646)

2. Infectious: abscess

3. Vascular
   a) cavernous hemangioma
   b) hemorrhage
   c) infarction: cerebellar stroke may be associated with H/A and/or pain in suboccipital region or upper neck
      • embolic
      • thrombotic/plaque related
      • vertebral artery dissection: much less common than carotid dissection (p. 1325)
      • vertebrobasilar hypoplasia (p. 1306)

4. Lhermitte-Duclos (p. 647): Focal or diffuse. Nonenhancing. Characteristic tiger stripes. Widens folia (c.f. most neoplasms which destroy folial pattern)
Multiple lesions
1. metastases
2. hemangioblastoma (possibly as part of von Hippel-Lindau) (p.703)
3. abscesses
4. cavernous hemangiomas

Pediatric
Also see Pediatric brain tumors (p.593).

Early data: 67% of childhood brain tumors occur in p-fossa, and astrocytomas were the most common there. Currently: p-fossa tumors comprise 54–60% of childhood brain tumors (breakdown listed below). 4 types account for ≈ 95% of infratentorial tumors in patients ≤ 18 yrs age. The 3 most common are equal in incidence (expressed as percent of p-fossa tumors pooled from 1350 pediatric brain tumors)

1. PNET, including medulloblastoma (p.663): 27%
   a) most start in roof of 4th ventricle (fastigium), and most are solid
   b) differentiating medulloblastoma (MB) from ependymoma:
      • 4th ventricle drapes around medulloblastoma (“banana sign”) from the anterior aspect, c.f. ependymoma which tends to grow into 4th ventricle from floor. Ependymoma may grow through foramen of Luschka and/or Magendie
      • ependymomas tend to be inhomogeneous on T1WI MRI (unlike MB)
      • the exophytic component of ependymomas tends to be high signal on T2WI MRI (with MB this is only mildly hyperintense)
      • calcifications: common in ependymomas, but only in < 10% of MB
2. cerebellar (pilocytic) astrocytoma (p.630): 27% Most start in cerebellar hemisphere. Often cystic with enhancing mural nodule
3. brainstem gliomas (p.633): 28% Usually present with multiple cranial nerve palsies and long tract findings
4. ependymoma (p.642): usually arise in floor of 4th ventricle
5. choroid plexus papilloma (p.648): majority of patients are <2 yrs old
6. atypical teratoid/rhabdoid tumor (AT/RT) (p.666)
7. metastasis: neuroblastoma, rhabdomyosarcoma, Wilm’s tumor
8. PHACES syndrome: acronym for a group of findings including Posterior fossa malformations, cervicofacial Hemangioma, Arterial anomalies of the head and neck, Coarctation of the aorta and cardiac defects, Eye anomalies and Sternal cleft. Ratio girls:boys = 9:1. Thought to begin during gestation weeks 8–10

89.2.2 Cerebellopontine angle (CPA) lesions

Lesions in general
Vestibular schwannoma, menigioma, and epidermoid account for most. For those lesions that may be cystic, see below.

1. vestibular schwannoma: (80–90% of CPA lesions); see below for differentiating from menigioma (p.1366)
2. menigioma: (5–10%); see below for differentiating from vestibular schwannoma (p.1366)
3. ectodermal inclusion tumors (p.761)
   a) epidermoid (cholesteatoma): 5–7% High signal on DWI MRI (p.761). Tumor passing from the posterior fossa to the middle fossa though the incisura is highly suggestive of epidermoid
   b) dermoid
4. metastases
5. neuroma from cranial nerves other than VIII (also see below for some differentiating features)
   a) trigeminal neuroma: expands towards Meckel’s cave
   b) facial nerve neuroma*: may arise in any portion of the VII nerve, with a predilection for the geniculate ganglion. Even in these tumors, hearing loss tends to precede facial paresis. Hearing loss may be sensorineural from VIII nerve compression from tumors arising in the proximal portion of VII (cisternal or internal auditory canal (IAC) segment), or it may be conductive from erosion of the ossicles by tumors arising in the second (tympanic, or horizontal) segment of VII. Facial palsy (peripheral) (p.576) may also develop, usually late
   c) neurinoma of lowest 4 cranial nerves (IX, X, XI, XII)
6. arachnoid cyst (p.248)
8. cholesterol granuloma (distinct from epidermoid) (p.761)
9. lipoma
10. aneurysm: PICA, AICA, vertebrobasilar
11. dolichobasilar ectasia
12. cysticercosis
13. extensions of:
   a) brain stem or cerebellar glioma
   b) pituitary adenoma
   c) craniopharyngioma
   d) chordoma & tumors of skull base
   e) fourth ventricle tumors (ependymoma, medulloblastoma)
   f) choroid plexus papilloma: from 4th ventricle through foramen of Luschka
   g) glomus tumor
      • glomus jugulare
      • glomus tympanicum
   h) primary tumors of temporal bone (e.g. sarcoma or carcinoma)

Cystic lesions of the CPA

CPA lesions from the above list that may be cystic or have a cystic component:

1. arachnoid cyst: same intensity as CSF on all MRI sequences, homogeneous
2. epidermoid cyst (p.270): high signal on DWMRI differentiates this from arachnoid cyst
3. dermoid cyst: high intensity areas on T1WI similar to fat; usually midline
4. cystic schwannoma
5. cholesterol granuloma: ≈ only lesion that is high signal on T1WI (due to blood breakdown products; exception: the rare “white” epidermoid). Also high signal on T2WI. Usually extradural, especially near petrous apex. Bone destruction is common
6. neurenteric cyst: nonenhancing. Low intensity on DWMRI
7. choroidal cyst
8. cysticercosis: enhancing nodule (scolex)

Differentiating neuromas of V, VII and VIII cranial nerves

All 3 of these tumors may present in the CPA and may cross from posterior fossa to middle fossa, but they tend to do so in different manners. Vestibular schwannomas show “transhiatal” extension by passing through the tentorial hiatus medially. Most trigeminal neuromas show “transapicopetrosal” extension by crossing into the middle fossa via the petrous apex (although some show transhiatal extension). When facial neuromas cross, they tend to spread across the midpetrosal bone, which is characteristic for facial neuromas spread across the midpetrosal bone is characteristic for facial neuromas. When a facial neuroma enlarges the IAC, unlike a vestibular schwannoma, it tends to erode the anterosuperior aspect of the IAC.

Differentiating vestibular schwannoma from CPA meningioma

1. vestibular schwannoma (VS) (AKA acoustic neuroma):
   a) clinical: progressive unilateral hearing loss, usually with tinnitus. Progression results in unsteadiness, with true vertigo being rare. The facial nerve is more resistant to stretching, thus facial nerve signs and symptoms occur late. Trigeminal nerve involvement may occur with tumors >3 cm (check corneal reflex), with tic douloureux-like symptoms being unusual
   b) imaging: often heterogeneous signal and nonuniform enhancement. Medium size tumors look like ice cream in a cone (IAC is the cone). Rarely calcified. Except for very small tumors, IAC is frequently enlarged. Look for an acute angle between the tumor and the petrous bone (meningiomas usually have an obtuse angle)
2. meningiomas: may mimic VSSs with these differences:
   a) clinical: since they often arise from the superior anterior edge of the IAC, early facial nerve involvement is more common, and hearing loss is usually late. Trigeminal neuralgia-like pain is more common than with VSs
   b) imaging: homogeneous signal and enhancement. The tumor may enter the IAC but it tends not to enlarge it. IAC often eccentric in tumor. Tumor is flat against petrous bone with an obtuse angle to the bone. Calcification and bony hypertrophy may occur (which occasionally narrows the IAC).
89.2.3 Petrous apex lesions

1. infection/inflammatory:
   a) osteomyelitis: may produce Gradenigo's syndrome (p.570)
   b) cholesterol granuloma (bright on T1WI epidermoid cyst are bright on DWI, neither enhance)
2. vascular lesions: aneurysm
3. neoplastic:
   a) squamous cell cancer
   b) glomus tumor
   c) chondrosarcoma: will displace the carotid from medial to lateral (almost every other tumor in this region encases the carotid)

89.2.4 Foramen magnum lesions

Differential diagnosis

See Foramen magnum lesions (p.1367) for nonneoplastic lesions. Most foramen magnum (FM) region tumors are extra-axial. This includes:

1. Extra-axial tumors
   a) meningioma: the anterior lip of the foramen magnum is the second most common site of origin of posterior fossa meningiomas. Meningiomas (p.698) comprise 38–46% of FM tumors\(^7,8\) and most are intradural
   b) Chordoma (p.778): a mass behind the dens compressing the spinal cord is a chordoma until proven otherwise
   c) neurilemmoma
   d) epidermoid
   e) chondroma
   f) chondrosarcoma
   g) metastases
2. Exophytic component of a brainstem tumor
3. Non-neoplastic lesions
   a) aneurysms or ectasia of the vertebral artery
   b) odontoid process in cases of basilar invagination (p.278)
   c) pannus from involvement of the odontoid with rheumatoid arthritis or old nonunion of fracture
   d) synovial cyst of the quadrate ligament of the odontoid\(^9\)

Presentation

In the pre-imaging era (i.e. before CT & MRI) these lesions were often diagnosed relatively late due to the unusual associated clinical syndromes and the rarity of visualizing this region on myelography.

Clinical findings

Symptoms:
1. sensory
   a) craniocervical pain: usually an early symptom, commonly in neck and occiput. Aching in nature. ↑ with head movement
   b) sensory findings: usually occur later. Numbness and tingling of the fingers
2. motor
   a) spastic weakness of the extremities: weakness usually starts in the ipsilateral UE, then the ipsilateral LE, then contralateral LE, and finally contralateral UE (“rotating paralysis”)

Signs:
1. sensory
   a) dissociated sensory loss: loss of pain and temperature contralateral to lesion with preservation of tactile sensation
   b) loss of position and vibratory sense, greater in the upper than the lower extremities
2. motor
   a) spastic weakness of the extremities
   b) atrophy of the intrinsic hand muscles: a lower motor nerve finding
   c) cerebellar findings may rarely be present with extensive intracranial extension
3. long tract findings
   a) brisk muscle stretch reflexes (hyperreflexia, spasticity)
b) loss of abdominal cutaneous reflexes
c) neurogenic bladder: usually a very late finding

4. ipsilateral Horner’s syndrome: due to compression of cervical sympathetics
5. nystagmus: classically downbeat (p.558) but other types can occur

It had been postulated that long tract findings were due to direct compression at the cervicomедul-
lar junction, and that lower motor nerve findings in the upper extremities were due to central
necrosis of the grey matter as a result of compression of arterial blood supply. Anatomic study sug-
gests that it is actually venous infarction at lower cervical levels (C8-T1) that is responsible for the
lower motor neuron findings.

89.3 Multiple intracranial lesions on CT or MRI

1. neoplastic
   a) primary
      • multicentric gliomas; \(\approx 6\)% of gliomas are multicentric, more common in neurofibromato-
        sis, see Multiple gliomas (p.619)
      • tuberous sclerosis (including giant cell astrocytomas); (usually periventricular)
      • multiple meningiomas
      • lymphoma
      • PNET
      • multiple neuromas (usually in neurofibromatosis, including bilateral vestibular
        schwannomas)
   b) metastatic: usually cortical or subcortical, surrounded by prominent vasogenic edema
      (p.803). More common tumors include:
      • lung
      • breast
      • melanoma: may be higher density than brain on unenhanced CT
      • renal cell
      • gastrointestinal tumors
      • genitourinary tract tumors
      • choriocarcinoma
      • testicular
      • atrial myxoma
      • leukemia

2. infection: mostly abscess or cerebritis. Most commonly due to:
   a) pyogenic bacteria
   b) toxoplasmosis: common in AIDS patients (p.371)
   c) fungal
      • cryptococcus
      • mycoplasma
      • coccidiomycosis
      • aspergilloosis
      • candidiasis
   d) echinococcus
   e) schistosomiasis
   f) paragonimiasis
   g) herpes simplex encephalitis (HSE): usually temporal lobe (p.364)

3. inflammatory
   a) demyelinating disease
      • MS: usually in white matter, periventricular, with little mass effect, margins are usually
        very sharp. Ring enhancing lesions can occur with tumefactive demyelinating lesions
        (p.179)
      • progressive multifocal leukoencephalopathy (PML): primarily in white matter. No enhance-
        ment. Patients are usually very sick
   b) gummas
   c) granulomas
   d) amyloidosis
   e) sarcoidosis
   f) vasculitis or arteritis
   g) collagen vascular disease, including:
      • periarteritis nodosa (PAN) (p.199)
4. vascular
   a) multiple aneurysms (congenital or atherosclerotic)
   b) multiple hemorrhages, e.g. associated with DIC or other coagulopathies (including anticoagulant therapy)
   c) venous infarctions, especially in dural sinus thrombosis (p.1308)
   d) moyamoya disease (p.1313)
   e) subacute hypertension (as in malignant HTN, eclampsia… → symmetric confluent lesions with mild mass effect and patchy enhancement usually in occipital subcortical white matter
   f) multiple strokes
      • lacunar strokes (l’etat lacunaire)
      • multiple emboli (e.g. in atrial fibrillation, mitral valve prolapse, SBE, air emboli)
      • sickle cell disease
      • vasculitis
      • intravascular lymphomatosis (p.711)

5. hematomas and contusions
   a) traumatic (multiple hemorrhagic contusions, multiple SDH)
   b) multiple “hypertensive” hemorrhages (amyloid angiopathy, etc.)

6. intracranial calcifications (p.1380)

7. miscellaneous
   a) radiation necrosis
   b) foreign bodies (e.g. post gunshot wound)
   c) periventricular low densities
      • Binswanger’s disease
      • transependymal absorption of CSF (e.g. in active hydrocephalus)

Evaluation. Deciding which of the following tests are needed to evaluate a patient with multiple intracranial lesions must be individualized for the appropriate clinical setting.

1. cardiac echo: to R/O SBE that could shed septic emboli
2. “metastatic workup” (p.806) including:
   a) CT of chest/abdomen/pelvis with and without contrast: has become a relatively standard part of the metastatic workup. It has largely supplanted CXR, lower GI (barium enema) and IVP.
      Rationale:
      • Chest: R/O primary bronchogenic Ca or pulmonary metastases of another Ca. Can demonstrate mediastinal lymphadenopathy. Also to R/O pulmonary abscess that could shed septic emboli.
      • Assesses for possible primary lesions: e.g. kidneys, GI, prostate
      • Evaluates for metastases to liver, adrenal, and even spine.
   b) mammogram in women
   c) PSA in men

89.4 Ring-enhancing lesions on CT/MRI

89.4.1 Abscess vs. tumor

See Fig. 89.1 and Fig. 89.2. Tumor: the enhancing ring may be incomplete and irregular. Abscess: ring is usually complete, often thinner and smoother than with tumor. Abscess: usually brighter than tumor on DWI MRI.

MRS should theoretically be ideal for differentiating tumor from abscess (abscess should show reduced NAA, Cr and choline, and “atypical peaks” may be present), but in practice is often not conclusive.

89.4.2 Short list

Multiple lesions: metastases or abscess are much more likely than astrocytoma.

In adults, the main differential (short list) is:

1. High grade glioma (glioblastoma)
2. Metastasis
3. Abscess
4. Lymphoma should also always be tacked on as a possibility
89.4.3 Long list

Mnemonic: “Magic Dr” (metastasis (including lymphoma), abscess, glioma, infarct, contusion, demyelination, radiation).

1. astrocytoma: usually glioblastoma multiforme
2. metastases (p.800): especially lung
3. abscess (p.320):
   a) may see visible growth over several days on serial imaging
   b) pyogenic abscesses are often (but not always) associated with fever and rapidly progressing neurologic deficit
   c) Nocardia abscesses (p.335) are often multiloculated and are usually associated with a lung lesion
4. others
   a) lymphoma (primary brain lymphoma or metastatic systemic lymphoma): wall is thicker than abscess.\textsuperscript{10} Incidence is increasing (p.712)
   b) radiation necrosis
   c) resolving intracerebral hematoma: on T1 gradient echo sequence, a continuous ring suggests hematoma, an interrupted ring suggests malignancy
   d) cystic lesions with enhancing wall or mural nodule (see also intracranial cysts):
      • cysticercosis cyst, see Neurocysticercosis (p.371)
      • hemangioblastoma
      • pilocytic astrocytoma
      • cystic acoustic neuroma
   e) trauma
   f) recent infarct
   g) thrombosed giant aneurysm

---

Fig. 89.1 MRI of right hemispheric cerebral abscess (bright on DWI)

Fig. 89.2 MRI of right hemispheric glioblastoma (dark on DWI)
89.5 White matter lesions

89.5.1 Leukoencephalopathy

Disease largely confined to the white matter. Demyelinating disease cause most. Appear as white matter low density on CT or low signal on T1WI MRI, and high-intensity on T2WI. Usually does not enhance. Unlike a stroke, changes tend to spare the cortex. Conditions such as metabolic derangements, leuko-araiosis, etc. tend to produce fairly symmetric findings.

Differential diagnosis:
1. anoxia/ischemia
2. demyelinating disease
   a) MS
   b) ADEM (p.182)
3. intoxication: cyanide, organic solvents, carbon monoxide
4. vitamin deficiencies: B12 with subacute combined degeneration
5. infectious, especially viral:
   a) progressive multifocal leukoencephalopathy (PML) (p.331)
   b) herpes varicella-zoster leukoencephalitis (p.366)
   c) HIV infection (AIDS): perivascular pattern of demyelination
   d) cytomegalovirus infection
   e) Creutzfeldt-Jakob disease: small and perivascular demyelination
6. metabolic derangements: hyponatremia (p.110), excessively rapid correction of hyponatremia (causing osmotic myelinolysis)
7. hereditary: metachromatic leukodystrophy, adult-onset Schilder’s disease
8. leuko-araiosis (p.138)
9. multiple myeloma (p.714)
10. low grade (WHO grade II infiltrating) glioma

89.5.2 Corpus callosum lesions

1. lymphoma
2. MS plaque
3. tumefactive demyelinating lesions (p.181)
4. lipoma
5. diffuse axonal injury from trauma

89.6 Sellar, suprasellar and parasellar lesions

89.6.1 General information

May enlarge, erode or destroy the sella turcica. Considerations in adults (adenoma is the most common enhancing pituitary lesion) are different than for children (adenomas are rare, craniopharyngioma and germinoma are more common). Includes (modified):

89.6.2 Tumors/pseudotumors

Tumors having epicenter within the sella

Pituitary tumor:
1. adenohypophyseal tumors
   a) adenoma
      • microadenoma: < 1 cm diameter (p.718)
      • macroadenoma: ≥ 1 cm diameter
      • invasive adenoma (p.721): Includes aggressive tumors of Nelson’s syndrome (p.724)
   b) pituitary carcinoma or carcinosarcoma (p.718)
2. neurohypophyseal tumors
   a) metastases: the most common tumor found in the posterior pituitary (presumably due to rich blood supply): breast and lung are most common primaries
   b) pituicytoma (p.728): the most common tumor arising from neurohypophysis/pituitary stalk (i.e. primary)
   c) astrocytoma: arising from stalk or posterior pituitary
Pituitary “pseudotumor”:
1. hyperplasia (enlargement)
   a) thyrotraph hyperplasia due to primary hypothyroidism\(^{13}\) (see Table 46.2) causing chronic pituitary stimulation by TRH. Typically: free T4 low or normal, TSH ↑↑, symmetrical sellar mass on MRI
   b) gonadotroph hyperplasia: due to primary hypogonadism
   c) somatotroph hyperplasia: due to ectopic GH-RH secretion
   d) lactotroph hyperplasia: in pregnancy
2. pituitary enlargement may occur in intracranial hypotension (p.391)
3. the pituitary gland of young women of childbearing potential is normally slightly enlarged

Juxtasellar or suprasellar tumors or masses: any of these lesions may extend into the sella
1. craniopharyngioma (p.763): in this region, these account for 20% of tumors in adult, 54% in peds
2. Rathke cleft cyst (p.756)
3. meningioma (parasellar, tuberculum sellae, or diaphragm sellae): to differentiate tuberculum sellae meningioma from pituitary macroadenoma on MRI (Fig. 89.3), 3 characteristics of meningioma are: 1) bright homogeneous enhancement with gadolinium (c.f. heterogeneous, poor enhancement with macroadenoma), 2) suprasellar epicenter (vs. sellar), 3) tapered extension of intracranial dural base\(^{14}\) (dural tail). Also, the sella is usually not enlarged, and even large suprasellar meningiomas rarely produce endocrine disturbances.\(^{15}\) The pituitary stalk is sometimes seen being pushed posteriorly by a meningioma. Tuberculum sellae meningiomas may be associated with sphenoid pneumosinus dilatans\(^{16}\) (enlargement of the underlying sphenoid sinus without bone erosion)
4. pituitary tumor (mostly adenomas) with extrasellar extension: tends to push carotids laterally (unlike meningioma which may encase carotid), more symmetric than meningioma
5. germ cell tumors (GCT) (p.659): choriocarcinoma, germinoma, teratoma, embryonal carcinoma, endodermal sinus tumor. In females, suprasellar GCTs are more common; in males pineal region is more common
   a) suprasellar GCT: triad of diabetes insipidus, visual deficit and panhypopituitarism.\(^{17}\) May also present with obstructive hydrocephalus
   b) simultaneous suprasellar and pineal lesions is diagnostic of GCT (so-called synchronous germ cell tumors (p.659))
6. glioma
7. hypothalamic glioma
8. optic nerve or chiasm (optic glioma) (p.631)
9. metastasis
10. chordoma
11. parasitic infections: cysticercosis
12. epidermoid cyst

![Fig. 89.3 Tuberculum sellae meningioma that could be mistaken for a pituitary adenoma. Contrast enhanced T1WI sagittal MRI](image-url)
13. suprasellar arachnoid cyst: see Arachnoid cysts (p.265)
14. sarcoidosis (p.189): hypothalamic involvement is a more likely site as a cause of anterior and/or posterior pituitary insufficiency
15. bone abnormalities
   a) giant cell tumor (p.794)
   b) chondromyxoid fibroma
   c) brown tumor of hyperparathyroidism
   d) bone spur
   e) extramedullary hematopoiesis
18. bone abnormalities
89.6.3 Vascular lesions
   a) aneurysm: ACoA, ICA (p.1334) (cavernous carotid or suprasellar variant of superior hypophyseal artery aneurysm), ophthalmic, basilar bifurcation. Giant aneurysms may produce mass effect
   b) carotid cavernous fistula (CCF) (p.1256)
89.6.4 Inflammatory
   a) (autoimmune) hypophysitis (see below):
      - distinguishing imaging characteristics are shown in Table 89.2
      - the most important clinical feature: pregnancy
      - the most important laboratory feature: diabetes insipidus (if DI is present, it is unlikely to be an adenoma)
   b) pituitary granuloma
19.89.6.5 Empty sella syndrome
   1. primary (p.773)
   2. secondary: following pituitary tumor resection (p.773)
89.6.6 Hypophysitis
AKA autoimmune hypophysitis (AH)
   Two main forms:
   1. lymphocytic (adenohypophysitis) AKA lymphoid adenohypophysitis: the more commonly encountered form. Inflammation of the pituitary stalk with lymphocytic infiltrate. Well established autoimmune etiology, although the antigens have not been identified. Primarily affects women in late pregnancy or early postpartum period
   2. granulomatous hypophysitis: more aggressive. No gender bias. No association with pregnancy. May be autoimmune, but pathogenesis not definitely known

Table 89.2 Imaging characteristics of hypophysitis vs. adenoma

<sup>a</sup>on CT scan
<sup>b</sup> the normal hyperintensity of the posterior pituitary on T1 WI MRI (p.737)
Because AH often mimics a nonsecretory pituitary macroadenoma (enhancing sellar mass on imaging, with negative endocrine tests), these lesions often undergo surgical resection instead of what may be more appropriate medical therapy (e.g. steroids, or discontinuing possible offending agents such as ipilimumab).

For distinguishing imaging characteristics, see Table 89.2.

89.7 Intracranial cysts

89.7.1 In general

Modified24:
1. arachnoid cysts (p.265): Typically lined with meningothelial cells
2. suprasellar cyst from dilated third ventricle
3. interhemispheric cyst from porencephaly
4. neuroectodermal cysts (glioependymal cysts): intraparenchymal, located near ventricles
5. old infarct: if it communicates with ventricle it is called a porencephalic cyst
6. tumor cysts (the solid portion may sometimes be isodense to brain on CT):
   a) ganglioglioma (p.652): usually solid but may appear cystic on CT
   b) pilocytic astrocytoma (p.629): usually has enhancing mural nodule
   c) neurilemmomas may be cystic
   d) supratentorial ependymomas are often cystic (p.643)
7. infectious
   a) abscess
   b) cysticercosis: see Neurocysticercosis (p.371)
   c) hydatid cyst: see Echinococcosis (p.375)
8. pineal cysts (p.658)
9. colloid cyst (p.756)
10. Rathke’s cleft cyst (p.756)
11. giant aneurysm
12. on CT, a low density non-enhancing tumor can mimic a cyst
13. chronic subdural hematoma or hygroma may mimic a cyst
14. posterior fossa: (for cysts of the CPA) (p.1366). Includes:
   a) cyst associated with Dandy-Walker malformation (p.256)
   b) epidermoid (p.760)
   c) enlarged cisterna magna may mimic a cyst
   d) cerebellar hemangioblastoma: often has an enhancing mural nodule (p.704)
   e) arachnoid cyst of posterior fossa
   f) neurenteric cyst (p.290)
   g) pilocytic astrocytoma of the cerebellum (p.629): usually has an enhancing mural nodule

89.7.2 Midline cavities

Three potential supratentorial midline cavities in the center of the brain and differentiating features are shown in Table 89.3.

</tr>
</tbody>
</table>

*including developmental delay, macrocephaly, Apert’s syndrome, abnormal EE
89.7.3 Cavum septum pellucidum (CSP)

AKA fifth ventricle, among others. A variable slit-like fluid-filled space between the leaflets of the left and right septum pellucidum. The compartment is usually isolated, although some communicate with third ventricle. The CSP is part of normal development, and persists until shortly after birth. Thus, it is present in all preemies. It is found in ≈10% of the adult population, usually representing an asymptomatic developmental anomaly. However, it is also commonly seen in boxers suffering from chronic traumatic encephalopathy (p.924).

89.8 Orbital lesions

89.8.1 General information

4 compartments of the orbit:
1. ocular (AKA globe, AKA bulbar)
2. optic nerve sheath
3. intraconal
4. extraconal

CT remains a strong imaging modality within the orbit (less susceptible to motion artifact than MRI because of the speed, images bony structures to good advantage).

89.8.2 Orbital lesions in adults

Orbital pseudotumor is the most common.

1. neoplastic
   a) discrete tumors that may occur adjacent to but not envelope the optic nerve sheath
      • cavernous hemangioma: the most common benign primary intra-orbital neoplasm. Choroidal hemangioma is seen in Sturge-Weber syndrome
      • fibrohistiocytoma
      • hemangiopericytoma
   b) capillary hemangioma: produces infantile proptosis. Regresses spontaneously
   c) lymphangioma: produces infantile proptosis. Does not regress
   d) melanoma: the most common primary ocular malignancy of adulthood
   e) retinoblastoma: congenital, malignant primary retinal tumor. 40% are bilateral, 90% are calcified (often a key differentiating feature; does not portend benignity as with other lesions). CT may show retinal detachment
   f) lymphoma of the orbit: causes painless proptosis. The 3rd most common cause of proptosis
   g) intraorbital meningioma
   h) primary optic nerve tumors
      • optic glioma
      • optic nerve sheath tumor (schwandoma)

2. congenital
   a) Coats disease: telangiectatic vascular malformation of retina which leaks a lipid exudate causing retinal detachment. May mimic retinoblastoma. Vitreous is hyperintense on MRI on both T1WI and T2WI due to lipid
   b) persistent hyperplastic primary vitreous
   c) retinopathy of prematurity (retrolental fibroplasia)

3. infectious
   a) toxocara endophthalmitis

4. inflammatory/collagen vascular disease: usually bilateral
   a) scleritis
   b) pseudotumor of the orbit: the most common intraconal lesion. Usually unilateral (p.569)
   c) sarcoidosis: usually affects the conjunctiva and lacrimal gland and spares connective tissues and intraorbital muscles
   d) Sjögren’s syndrome

5. vascular
   a) enlargement of the superior orbital vein: may occur in thrombosis of cavernous sinus or in carotid-cavernous fistula
   b) dural AVM

6. miscellaneous
   a) drusen: degenerated retinal pigment cells in the posterior globe that may resemble calcified masses on CT
b) thyroid ophthalmopathy: Graves' disease (hyperthyroidism & swelling of EOMs → painless proptosis). 80% of cases are bilateral. The ophthalmopathy is independent of the level of thyroid hormone (possibly an autoimmune process). NB: a swollen inferior rectus muscle may resemble an orbital tumor if seen only on lower CT cut through the orbit.

c) EOM enlargement can also occur with steroid use or occasionally with obesity.
d) fibrous dysplasia

89.8.3 Orbital tumors in pediatrics
1. dermoid cyst: 37% The most common lesion in children
2. hemangioma: 12% Most regress spontaneously without surgery
3. rhabdomyosarcoma: 9% The most common malignant tumor of the orbit
4. optic nerve glioma: 6%
5. lymphangioma: <7% Imaging resembles hemangioma. But will not regress spontaneously, requires surgery. Proptosis may worsen after a URI. May bleed into itself (chocolate cysts)

89.9 Cavernous sinus lesions
Modified:
1. primary tumors (rare)
   a) meningiomas
   b) neurinomas
2. tumors from adjacent areas that may extend into cavernous sinus (head and neck cancers may track intracranially along cranial nerves, especially V)
   a) meningiomas
   b) neurinomas
   c) chordomas
   d) chondromas
   e) Chondrosarcomas
   f) pituitary tumors
   g) nasopharyngeal carcinomas
   h) esthesioneuroblastomas
   i) nasopharyngeal angiofibromas
   j) metastatic tumors
3. inflammation: e.g. Tolsa-Hunt (p.569)
4. infection: mucormycosis (phycomycosis) (p.568). Usually in diabetics
5. vascular
   a) cavernous carotid aneurysm
   b) carotid-cavernous fistula (p.1256)
   c) cavernous sinus thrombosis

89.10 Skull lesions
89.10.1 General information
The most common benign tumors of skull are osteoma and hemangioma. Osteogenic sarcoma is the most common malignancy. See also specific skull tumors (p.775).

Evaluating roentgenographic skull luencies
There is enough overlap of features to prevent any systematic means of determining the etiology of all or even most radiographic skull luencies. The following features should be noted for any lucency, some are more helpful than others (modified):
1. multiplicity (single or multiple?): except for multiple venous lakes, the presence of 6 or more defects is usually indicative of a malignancy
2. origin (intradiploic, full thickness, inner or outer table only):
   a) most vault lesions originate intradiploically, so limitation to this space may merely signify early recognition of a lesion
   b) expansion of the diploë with bulging of one or both tables almost always signifies a benign lesion
   c) full thickness lesions affecting both tables congruently usually indicates malignancy, whereas non-congruent erosion is more common with benign lesions
3. edges (smooth or ragged):
   a) smooth edges, whether regular, distinct or indistinct: no predictive value
   b) irregular margins (especially ragged undermined edges): more suggestive of infection (osteomyelitis) or malignancy
   c) sharply demarcated, full thickness punched out defects: suggest myeloma
4. presence of peripheral sclerosis: circumferential bony sclerosis suggests benignity (may indicate slow expansion and longstanding nature). The ring of sclerosis is generally narrow except in fibrous dysplasia
5. presence or absence of peripheral vascular channels: presence is highly suggestive of benign lesions (seen in ≈ 66% of venous lakes and ≈ 50% of hemangiomas)
6. pattern within the lucency:
   a) hemangiomas classically show honeycomb or trabecular pattern (seen in ≈ 50% of cases) or sunburst pattern (seen in ≈ 11% of cases)
   b) fibrous dysplasia may show well defined islands of bone, or a grossly mottled appearance with randomly arranged cystic and dense areas
7. location on the cranial vault (high vs. low): poor correlation with benign vs. malignant lesions
8. pain: Langerhans cell histiocytosis lesions are often tender

NB: keep in mind that skull lesions may have an intracranial component. CT scanning is good for assessing bone (MRI is poor for this), however, CT may miss small intracranial lesions tucked within the convexity of the calvaria due to bone hardening artifact (MRI has better sensitivity in this setting).

Nuclear bone scan may be a helpful adjunctive test (see specific lesion for findings). Biopsy: indicated for questionable skull lesions. If the bone has not been destroyed by soft tissue, biopsy may be accomplished with a Craig needle, and the specimen may need decalcification by the pathologist before histologic evaluation can be completed.

89.10.2 Radiolucent lesion or bone defect in skull (AKA lytic lesions)

1. congenital or developmental
   a) epidermoid (cholesteatoma): sclerotic edge
   b) congenital: encephalocele, meningoencephalocele, dermal sinus
   c) fibrous dysplasia (p. 779). A benign condition in which normal bone is replaced by fibrous connective tissue. Tends to occur higher in calvaria. 3 types:
      • cystic: widening of the diploë usually with thinning of the outer table and little involvement of the inner table. Typically involves calvaria
      • sclerotic: usually involves skull base (especially sphenoid bone) and facial bones
      • mixed: appearance is similar to cystic type with patches of increased density within the lucent lesions
   d) hemangioma or AVM of bone or scalp
   e) pacchionian depression: arachnoid granulations (older terms: Pacchioni's granulation (after Italian anatomist Antonio Pacchioni) or pacchionian bodies) resorb CSF into vascular system and occasionally cause a bony lucency, usually near the superior sagittal sinus
   f) Albright’s syndrome
   g) congenital foramina: “holes” in skull traversed by emissary veins
   h) parietal thinning: usually a bilateral process
   i) frontal fenestrae
   j) venous lakes
   k) cerebral herniations: AKA occipital pacchionian granulations

2. traumatic
   a) surgical defect: burr hole, craniectomy
   b) fracture
   c) post-traumatic leptomeningeal cyst (p. 915)
   d) following trauma in children

3. inflammatory
   a) osteomyelitis: including tuberculosis
   b) sarcoidosis
   c) syphilis

4. neoplastic
   a) hemangioma: fine, honeycombed matrix. Classic x-ray finding: “starburst” appearance due to radiating bone spicules (may occur in as few as ≈ 11% of cases)
   b) intracranial tumor with erosion
c) lymphoma, leukemia
d) meningioma
e) metastasis: usually hot on bone scan
f) multiple myeloma, plasmacytoma (p.714). Usually cool on bone scan
g) sarcoma or fibrosarcoma of bone
h) skin tumor with invasion (rodent ulcer)
i) neuroblastoma
j) lipoma
k) epidermoid (may also be considered congenital, thus also see above)

5. miscellaneous
a) Langerhans cell histiocytosis (p.777). Perfectly round non-sclerotic punched out lesion, may be single (formerly called eosinophilic granuloma) or multiple, tender
b) Paget’s disease (when seen as a zone of osteolysis without osteoblastic sclerosis on skull films, this is defined as osteoporosis circumscripta). Usually “hot” on bone scan
c) aneurysmal bone cyst: rare. Arises in diploë and expands both tables which become thin but remain intact
d) brown tumor of hyperparathyroidism

89.10.3 Diffuse demineralization or destruction of the skull
Includes “salt and pepper skull.”

1. common
   a) hyperparathyroidism, primary or secondary
   b) metastatic carcinoma or neuroblastoma
   c) multiple myeloma
   d) osteoporosis

2. uncommon
   a) Paget’s disease (osteoporosis circumscripta)

89.10.4 “Hair-On-End” appearance in skull

1. common
   a) congenital hemolytic anemia (e.g. thalassemia, sickle cell, hereditary spherocytosis, pyruvate kinase deficiency)

2. uncommon
   a) hemangioma
   b) cyanotic congenital heart disease (with secondary polycythemia)
   c) iron deficiency anemia
   d) metastases: especially neuroblastoma, thyroid carcinoma
   e) multiple myeloma
   f) meningioma
   g) osteosarcoma
   h) polycythemia vera

89.10.5 Diffuse increased density, hyperostosis, or calvarial thickening

1. common
   a) anemia (sickle cell, iron deficiency, thalassemia, hereditary spherocytosis)
   b) fibrous dysplasia
      • leontiasis ossea (“lion-like facies”): a form of polyostotic fibrous dysplasia
   c) hyperostosis interna generalisata
   d) osteoblastic metastases (especially prostate, breast)
   e) Paget’s disease (begins with lytic zone and diploic thickening)
   f) treated hydrocephalus

2. uncommon
   a) chronic phenytoin therapy
   b) Engelman’s disease (progressive diaphyseal dysplasia)
   c) fluorosis
   d) hypervitaminosis D
   e) hypoparathyroidism, pseudohypoparathyroidism
   f) meningioma
g) osteogenesis imperfecta
h) osteopetrosis (p.1401)
i) secondary polycythemia
j) syphilitic osteitis
k) tuberous sclerosis

89.10.6 Focal increased density of skull base

1. common
   a) fibrous dysplasia
   b) meningioma

2. uncommon
   a) mastoiditis
   b) nasopharyngeal carcinoma
   c) osteoblastic metastasis
   d) osteoma of the outer table or diploe
   e) chondroma
   f) sarcoma of bone (e.g. osteosarcoma, chondrosarcoma)
   g) sphenoid sinusitis

89.10.7 Generalized increased density of skull base

1. common
   a) fibrous dysplasia
   b) Paget’s disease

2. uncommon
   a) severe anemia (e.g. thalassemia, sickle cell)
   b) Engelman’s disease (progressive diaphyseal dysplasia)
   c) fluorosis
   d) hyperparathyroidism, primary or secondary (treated)
   e) hyperparathyroidism D
   f) idiopathic hypercalcemia
   g) meningioma
   h) osteopetrosis (p.1401)

89.10.8 Localized increased density or hyperostosis of the calvaria

1. common
   a) anatomic variation (e.g. sutural sclerosis)
   b) fibrous dysplasia
   c) osteoma (p.775)
   d) meningioma
   e) hyperostosis frontalis interna (p.779)
   f) osteoblastic metastases (especially: prostate, breast)
   g) Paget’s disease (begins with lytic zone and diploic thickening)
   h) cephalhematoma
   i) depressed skull fracture

2. uncommon
   a) osteosarcoma
   b) chronic osteomyelitis, tuberculosis
   c) tuberous sclerosis
   d) osteoid osteomas: radiolucent nidus with surrounding zone of dense sclerosis
   e) osteoblastoma:
   f) ossifying fibromas: predilection for frontotemporal region
   g) radiation necrosis

89.10.9 Pneumocele

Pneumocele: enlargement of an air sinus often with bone erosion. Pneumosinus dilatans (p.1372) generally denotes enlargement of an air sinus without bone erosion, as may occur with tuberculum sellae or planum sphenoidale meningiomas.
Pneumocoeles occur primarily in the maxillary antrum. Involvement of frontal sinus, usually involves pneumosinus dilatans. Etiology is unknown, and may involve a trap-valve mechanism, ruptured mucocele, or possibly congenital. May occur with fibrous dysplasia.

Presentation of pneumocele or pneumosinus dilatans:
1. headache
2. neuralgia
3. facial asymmetry
4. frontal bossing (with frontal pneumosinus dilatans)
5. exophthalmous
6. CSF fistula (leak)
7. Treatment for maxillary pneumocele: opening the sinus into the nasal cavity via endoscopic approach. Watch for encephalocele.

89.11 Combined intracranial/extracranial lesions
Lesion causing mass outside skull with intracranial component.
1. intra-axial: rule of thumb – “there is no intra-axial lesion that grows out of skull”, however untreated fungating malignant gliomas may do this
2. extra-axial:
   a) meningioma
      • may arise in diploe, grows outward and inward
      • intracranial meningioma can grow through bone by destroying it
      • intracranial meningioma can induce hyperostosis that causes extracranial mass
   b) metastatic disease (e.g. GI carcinoma, and especially prostate Ca)
   c) bone (skull) lesion:
      • hemangioma
      • epidermoid
      • fibrous dysplasia (rare)
      • giant cell tumor (rare)
      • Ewing’s sarcoma (rare in skull)
      • aneurysmal bone cyst (5% occur in skull, occipital bone most common)

89.12 Intracranial hyperdensities
I.e. Differential diagnosis of an intracranial structure that is hyperdense with respect to brain (i.e. appear “whiter” than brain) on non-contrast CT):
1. acute blood
2. calcium
3. vessels with low flow
4. melanoma: may be slightly hyperdense to brain due to melanin

89.13 Intracranial calcifications
89.13.1 Single intracranial calcifications
1. physiologic
   a) choroid plexus: calcifications usually bilateral (see below)
   b) arachnoid granulation
   c) diaphragma sellae
   d) dural (falcine, tentorial, sagittal sinus)
   e) habenular commissure
   f) petroclinoid or interclinoid ligaments
   g) pineal: 55% of patients > 20 yrs age have a calcified pineal gland visible on plain skull x-ray
2. infection
   a) cysticercosis cyst: single or multiple, see Neurocysticercosis (p.371)
   b) encephalitis, meningitis, cerebral abscess (acute and healed)
   c) granuloma (torulosis and other fungi)
   d) hydatid cyst
   e) tuberculoma
   f) paragonimiasis
   g) rubella
   h) syphilitic gumma
3. vascular
   a) aneurysm, including:
      ● vein of Galen aneurysm
      ● giant aneurysm
   b) arteriosclerosis (especially carotid artery in siphon region)
   c) hemangioma, AVM, Sturge-Weber syndrome
4. neoplastic: calcifications usually suggest a more benign process
   a) meningioma (p.690)
   b) craniopharyngioma
   c) choroid plexus papilloma
   d) ependymoma
   e) glioma (especially oligodendroglioma, also astrocytoma)
   f) ganglioglioma
   g) lipoma of corpus callosum
   h) pinealoma
   i) hamartoma of tuber cinereum
5. miscellaneous
   a) hematoma: ICH, EDH or SDH. Calcifications usually only when chronic
   b) idiopathic
   c) tuberous sclerosis (p.606)

89.13.2 Multiple intracranial calcifications
1. common
   a) choroid plexus: the most common site for physiologic calcification (in lateral ventricles where it is usually bilateral and symmetric; rare in 3rd & 4th ventricles). Increases in frequency and extent with age (prevalence: 75% by 5th decade). Rare under age 3. Under age 10, consider possible choroid plexus papilloma. Involvement in the temporal horns is often associated with neurofibromatosis
   b) basal ganglia (BG): slight bilateral BG calcifications on CT are common, especially in the elderly. Considered a normal radiographic variant by some. They may be idiopathic, secondary to conditions such as hypoparathyroidism or long-term anticonvulsant use, or part of rare conditions such as Fahr’s disease (see below). BG calcifications >0.5 cm dia are possibly associated with cognitive impairment and a high prevalence of psychiatric symptoms (including bipolar and obsessive-compulsive disorders, but no patients had schizophreniform disorders)\(^\text{12}\)
2. uncommon
   a) Fahr’s disease: progressive idiopathic calcification of medial portions of basal ganglia, sulcal depths of cerebral cortex, and dentate nuclei\(^\text{13}\)
   b) hemangioma, AVM, Sturge-Weber syndrome, von Hippel-Lindau disease
   c) basal cell nevus syndrome (falx, tentorium)
   d) Gorlin’s syndrome. Associated findings: mandibular cysts, rib and vertebral deformities, short metacarpals. Medulloblastoma seen in several patients
   e) deposition of calcium in the media of medium-sized blood vessels without compromise of the lumen. Usually asymptomatic. May become symptomatic by the time the involvement is significant enough to be visible on plain x-ray in a young person
   f) cytomegalic inclusion disease
   g) encephalitis (e.g. measles, chickenpox, neonatal herpes simplex)
   h) hematomas (SDH or EDH, chronic)
   i) neurofibromatosis (choroid plexi)
   j) toxoplasmosis
   k) tuberculomas; tuberculous meningitis (treated)
   l) tuberous sclerosis
   m) hypoparathyroidism (including post-thyroidectomy cases\(^\text{14}\)) and pseudohypoparathyroidism
   n) multiple tumors (e.g. meningiomas, gliomas, metastases)
   o) cysticercosis cyst: may be single or multiple, see Neurocysticercosis (p.371)

89.14 Intraventricular lesions
89.14.1 General information
Intraventricular tumors represent only \(\approx 10\%\) of CNS neoplasms. A clue to differentiating a tumor located within the ventricle from an intraparenchymal tumor invaginating into the ventricle is a “cap” of CSF surrounding an intraventricular tumor on CT or MRI.
89.14.2 Differential diagnosis

(Percentages quoted here are from a series of 73 patients with an intraventricular lesion on CT seen at UCSC36).

1. astrocytoma: (20%) the most common lesion. Hydrocephalus (HCP) is present in 73% Hyperdense on non-contrast CT (NCCT) in 77%
   Locations in descending order of frequency:
   a) frontal horn
   b) third ventricle
   c) atrium (AKA trigone)
   d) fourth ventricle

2. colloid cyst: (14%) essentially seen only in anterior third ventricle at foramen of Monro (other sites have been described but are exceedingly rare). 50% are hyperdense on NCCT. MRI appearance is variable, and may occasionally be missed. Little or no enhancement on CT/MRI (p.756). DDx includes xanthogranuloma

3. meningioma: (12%) most in atrium, rarely in frontal horn. All hyperdense with dense uniform enhancement. May be calcified. Most have dense tumor blush on angiogram, most supplied from anterior choroidal artery, posterior choroidal less common. Thought to arise from arachnoidal cells within the choroid plexus

4. ependymoma: (10%) most in 4th ventricle, may occur in body of lateral ventricle. Often hyperdense on CT because of high cellularity

5. craniopharyngioma: (7%) primarily in 3rd ventricle. Most have punctate calcification. Squamous epithelial rests in region of lamina terminalis are felt to give rise to this uncommon variety of craniopharyngioma

6. medulloblastoma: (5%) often fill 4th ventricle. Hyperdense on CT with homogeneous enhancement

7. cysticercosis: (5%) may involve any ventricle or may be panventricular (NB: incidence related to geographic location).

8. choroid plexus papilloma: (5%) most common in lateral ventricle (may be bilateral), but also may be seen in 4th and occasionally in 3rd. Non-obstructive HCP may occur (possible CSF overproduction). Intense blush on angiogram

9. epidermoid: (4%) mostly in 4th ventricle. Hypodense on CT with no enhancement (tend to follow CSF signal). The most common 4th ventricular low density lesion in the U.S.

10. dermoid: (3%) common in 4th ventricle. May see free floating fat in ventricles suggestive of cyst rupture. Tendency to form in midline

11. choroid plexus carcinoma: (3%) common in atrium of lateral ventricle. May extended into adjacent brain parenchyma with edema and shift. Intense blush on angiogram. NB: very rare lesion

12. subependymoma: (3%) 4th ventricle or frontal horn. Typically isodense on CT with no enhancement. May have calcification or cystic degeneration (more common in ependymoma). Most commonly in floor of 4th ventricle near obex

13. ependymal cyst: (3%) common in lateral ventricle. Absence of communication demonstrated by water soluble contrast cisternography

14. arachnoid cyst: (1%) lateral ventricle. Absence of communication demonstrated by water soluble contrast cisternography

15. arteriovenous malformation (AVM): (3%)

16. teratoma: (1%) Located in anterior 3rd ventricle. Partially calcified with foci of fat density. Marked enhancement

17. central neurocytoma (p.645)

18. metastases: breast and lung reported

19. chordoid glioma of the 3rd ventricle

89.14.3 Features to help identify type of intraventricular lesions

By location within ventricular system

Table 89.4 shows the breakdown of lesion type by location within the ventricular system.

By location and age within lateral ventricle

See reference.38

See Table 89.5. This study excluded tumors that were clearly arising in the third ventricle or were predominantly parenchymal with intraventricular extension.
The teratoma and both PNETs occurred in age < 1 year, and all showed calcifications. Only one CPP occurred above age 5 years.

In adults > 30 years age, the only tumors found in the trigone were meningiomas. Subependymomas were the only nonenhancing tumor in this age group.

By location within third ventricle
1. anterior third ventricle
   a) colloid cyst
   b) sellar mass
c) sarcoidosis
d) aneurysm
e) hypothalamic glioma
f) histiocytosis
g) meningeoma
h) optic glioma

2. posterior third ventricle
   a) pinealoma (dysembryoma)
   b) meningeoma
   c) arachnoid cyst
d) vein of Galen aneurysm

**By enhancement**

All lesions enhanced except: cysts (ependymal and arachnoid), dermoids and epidermoids. There are differences of opinion of the tendency for subependymomas to enhance, Jelinek et al.\(^{38}\) found that they did not.

**By multiplicity**

Multiple lesions are more suggestive of: neurocysticercosis, metastases, or ruptured epidermoid cyst.

**89.15 Periventricular lesions**

**89.15.1 Periventricular solid enhancing lesions (in decreasing frequency)**

1. lymphoma; CNS involvement from systemic, or rarely primary brain (p. 710): must be included in differential diagnosis of any solid enhancing periventricular brain tumor. Very radiosensitive.
2. ependymoma (usually invaginates)
3. metastatic Ca: especially malignant melanoma or choriocarcinoma
4. ventriculitis
5. medulloblastoma (in pediatrics), AKA cerebellar sarcoma in adults
6. pineal tumor (dysembryoma type): usually midline, young patient
7. occasionally, glioblastoma can present like this

**89.15.2 Periventricular low density on CT, or high signal on T2WI MRI**

1. increased extracellular or intracellular water content (edema)
   a) in hydrocephalus: transependymal CSF absorption (p. 399)
   b) necrosis from infarction
   c) edema from tumor
2. uncommon late variants of adrenoleukodystrophy
3. vascular disorders
   a) subacute arteriosclerotic encephalopathy (Binswanger’s disease)\(^ {39,40}\)
   b) cerebral embolism
   c) vasculitis
   d) amyloid angiopathy
   e) low flow states
4. demyelination: including multiple sclerosis
5. leukoaraiosis\(^ {41}\): a term coined to describe white matter disease with symmetric (or nearly so) periventricular white matter changes on CT or MRI. May be asymptomatic or may present with findings including dementia. May be related to:
   a) Binswanger’s encephalopathy
   b) watershed infarction\(^ {42}\)
   c) normal aging\(^ {43}\): increases each decade after age 60, usually patchy
   d) hypoxia
   e) hypoglycemia\(^ {44}\)
6. heterotopias: islands of grey matter in abnormal locations
7. following radiation therapy (XRT)
89.16 Meningeal thickening/enhancement

89.16.1 Dural enhancement

See reference.45

Visible beneath the inner table of the skull. Unlike leptomeningeal enhancement, does not follow the gyral convolutions. May be either focal or diffuse:

1. focal
   a) adjacent to meningioma: so called “dural tail”
   b) pleomorphic xanthoastrocytoma: also can have “dural tail”
2. diffuse dural enhancement46: associated with extraaxial neoplastic processes in ≈ 65% Clinically: H/A, multiple cranial nerve palsies, seizures; may be indistinguishable from leptomeningeal metastases
   a) intracranial hypotension: diffuse pachymeningeal enhancement on cerebral MRI (p.389)
   b) bacterial meningitis
   c) primary CNS tumors: medulloblastoma, malignant meningioma
   d) sarcoidosis
   e) following craniotomy
   f) metastases (mostly carcinomas):
      • bony mets to skull: present in 10 of 13 patients
      • dural metastases
      • leptomeningeal
   g) following subdural hemorrhage47

89.16.2 Leptomeningeal enhancement

See reference.45

1. thin linear enhancement that closely follows the gyri
2. small nodules attached to the brain

89.17 Ependymal and subependymal enhancement

Some overlap with periventricular enhancement. Ependymal enhancement often heralds a serious condition.38 Main DDx is tumor vs. infectious process.

1. ventriculitis or ependymitis: ependymal enhancement occurs in 64% of cases of pyogenic ventriculitis.49
   a) Infection may occur in the following settings
      • following shunt surgery
      • after intraventricular surgery
      • with indwelling prosthetic devices (e.g. Ommaya reservoir)
      • with use of intrathecal chemotherapy
      • with meningitis
      • with viral ependymitis
      • in some cases of CMVencephalitis in immunocompromised patients
      • granulomatous involvement: esp. in immunocompromised patients; e.g. tuberculosis, mycobacterium, syphilis
   b) Infections may be48
      • bacterial (pyogenic) ventriculitis
      • tuberculous ventriculitis
      • cystic lesions suggest cystercerosis
2. carcinomatous meningitis: typically also produces meningeal enhancement (p.812)
3. multiple sclerosis: usually more periventricular (in the white matter)
4. tumors
   a) lymphoproliferative disorders
      • CNS lymphoma (p.710)
      • leukemia
   b) ependymoma
      • with tumor spread
      • transient enhancement reported in a child with ependymoma in the absence of tumor spread50
   c) Metastasis
   d) Germ cell tumors
5. tuberous sclerosis: subependymal hamartomas appear as nodules which occasionally enhance (p.606). These gradually calcify with age

6. in the presence of appropriate constitutional symptoms: rare causes of linear enhancement include: neurosarcoidosis, Whipple’s disease, metastatic multiple myeloma (usually nodular)

In immunocompromised patients, the enhancement pattern may help distinguish between the following (which tend to occur in this population):

1. thin linear enhancement: suggests virus (CMV or varicella-zoster)
2. nodular enhancement: suggests CNS lymphoma
3. band enhancement: less specific (may occur with virus, lymphoma, or tuberculosis (TB))

89.18 Intraventricular hemorrhage

Etiologies:
1. most occur as a result of extension of intraparenchymal hemorrhages
   a) in the adult:
      • spontaneous ICH: especially thalamic or putaminal hemorrhages (p.1336)
      • associated with AVM
   b) in newborns: extension of subependymal hemorrhage (p.1346)
2. pure intraventricular hemorrhage (IVH) is usually the result of a rupture of
   a) aneurysm: accounts for 25% of IVH in adults, and is second only to extension of intracerebral hemorrhage as the most common cause. IVH occurs in 13–28% of ruptured aneurysms in clinical series. More common with the following aneurysms: a-comm, distal basilar artery or carotid terminus, VA or distal PICA (p.1192) (for patterns)
   b) vertebral artery dissection (or dissecting aneurysms) (p.1323)
   c) intraventricular AVM
   d) intraventricular tumor
   e) SAH outside the ventricles refluxing into foramina of Luschka and/or Magendie

89.19 Medial temporal lobe lesions

May be responsible for seizures, especially “uncal fits” (temporal lobe seizures).
1. hamartoma
2. mesial temporal sclerosis (p.441): should see atrophy of the parenchyma in this area with dilatation of the temporal horn of the lateral ventricle
3. glioma: may be low grade. Look for mass effect and possibly enhancement

89.20 Basal ganglion abnormalities

1. generally symmetric abnormalities
   a) calcification (p.1381)
   b) Wilson’s disease (hepatolenticular degeneration): autosomal recessive disease causing accumulation of copper in tissues
   c) Huntington’s disease (or chorea): caused by >40 trinucleotide CAG repeats in the Huntington gene (4p16.3) which leads to the production of the protein huntingtin. Cell loss in caudate nucleus can be seen on CT or MRI
   d) manganese: symmetrical high signal abnormalities on T1WI primarily in the globus pallidus with essentially no findings on T2WI or GRASS (almost pathognomonic) (p.177)
   e) globus pallidus (low density on CT):
      • severe carbon monoxide intoxication
      • cyanide poisoning
      • hypoxia
   f) putamen
   • hypoglycemia: affects corpus striatum (caudate and putamen)
2. stroke

89.21 Thalamic lesions

Astrocytomas are the most common tumors.
1. Common neoplasms
   a) Adults
      • anaplastic astrocytoma
      • glioblastoma multiforme
      • metastasis
      • primary CNS lymphoma
   b) Pediatrics
      • anaplastic astrocytoma
      • astrocytoma (WHO grade II)
      • glioblastoma multiforme
      • pilocytic astrocytoma

2. Uncommon neoplasms
   a) Adults
      • astrocytoma (WHO grade II)
      • neurocytoma
      • oligodendroglioma
      • pilocytic astrocytoma
      • hamartoma
   b) Pediatrics
      • germinoma
      • oligodendroglioma
      • PNET
      • subependymal giant cell tumor

3. non-neoplastic (pediatric and adult)
   a) cavernous angioma
   b) granuloma
   c) heterotopias
   d) AVM
   e) infarct

89.22 Intranasal/intracranial lesions

Lesions within the nose that may communicate with the intracranial cavity:

1. infectious
   a) tuberculosis
   b) syphilis
   c) Hansen’s disease (leprosy)
   d) fungal infections, especially:
      • aspergillosis
      • mucormycosis: seen primarily in diabetics or immunocompromised patients (p.568)
      • Sporothrix schenckii
      • Coccidioides
   e) Wegener’s granulomatosis (p.199): necrotizing granulomatous vasculitis of the upper and lower respiratory tracts with glomerulonephritis and nasal destruction
   f) lethal midline granuloma (p.199): a locally destructive lymphomatoid infiltrative disease that may not have true granulomas, and may also cause local nasal destruction. However, renal and tracheal involvement do not occur as in Wegener’s granulomatosis
   g) polymorphic reticulosis: may be a nasal lymphoma. Possibly the same disease as lethal midline granuloma (see above)

2. mucocele: a retention cyst of an air sinus that results from an occluded ostium and may cause expansive erosion of the involved sinus. Often enhances with IV contrast (MRI or CT), and may contain mucus or pus

3. neoplasms
   a) carcinoma of the nasal sinus
      • squamous cell
      • glandular
   • nasopharyngeal carcinomas: may be related to Epstein-Barr Virus (EBV) infection
   • sinonasal undifferentiated carcinoma (SNUC): distinct from lymphoepithelioma (less keratinizing). Rare, aggressive carcinoma (more lethal variant of squamous cell carcinoma) with poor prognosis. Incidence may be higher with prior XRT and in woodworkers and nickel factory workers. May invade adjacent structures, those relevant to neurosurgeons: frontal fossa, and cavernous sinus. No relation to EBV. Treatment: tri-modal therapy (XRT, chemotherapy and salvage surgery)
b) esthesioneuroblastoma\textsuperscript{54} or aesthesioneuroblastoma AKA olfactory neuroblastoma: named for the stem cell of the olfactory epithelium (esthesioneuroblast). A malignant tumor arising from crest cells of the nasal vault, often with intracranial invasion. Very rare (≈ 200 reported cases). Presents with epistaxis (76%), nasal obstruction (71%), tearing (14%), pain (11%), diplopia, proptosis, anosmia and endocrinopathies.\textsuperscript{55} Treatment: surgical resection followed by XRT, ± chemotherapy

c) metastatic tumors: very rare, possibly with renal cell carcinoma

d) benign tumors

- frontal meningioma: rarely erodes into nasal cavity
- rhabdomyoma
- benign hemangiopericytoma
- cholesteatoma
- chordoma

4. congenital lesions

a) encephalocele: a nasal polypoid mass in a newborn should be considered an encephalocele until proven otherwise. Classifications:
- cranial vault
- frontal ethmoidal
- basal
- posterior fossa

b) nasal glioma: non-neoplastic glial tissue located within the nose, often conceptually and diagnostically confused with an encephalocele (Table 89.6). The term “glioma” is a misnomer, and nasal glial heterotopia is preferred. Does not communicate with the subarachnoid space

---

90.2 Atlantoaxial subluxation

1. incompetence of the transverse atlantal ligament (TAL): results in increased atlanto-dental interval (ADI) (p. 213)
   a) rheumatoid arthritis: erosion of insertion points of the TAL (p. 1134)
   b) traumatic
      • disruption (tear) of the TAL (rare)
      • avulsion of the insertion points of the TAL (as in comminuted C1 fx)
   c) congenital laxity of the TAL:
      • Down syndrome: 20% incidence (p. 1138)¹
      • may be associated with neurofibromatosis
   d) retropharyngeal infections: chronic tonsillitis (p. 968), Grisel syndrome
   e) chronic steroid use
2. incompetence of the odontoid process: ADI is normal
   a) odontoid fractures (p. 978)
   b) os odontoideum (p. 981)
   c) erosion of the odontoid due to rheumatoid arthritis (RA) (p. 1134)
   d) neoplastic erosion of the odontoid:
      • metastases to the upper cervical spine (p. 815)
      • other tumors of the axis
   e) Morquio syndrome: hypoplasia of the dens (p. 1151)
   f) congenital absence/dysplasia of the odontoid
   g) following transoral odontoidectomy: creates severe ligamentous instability (p. 1472)
   h) local infection

Note. Chronic AAS seen in conditions such as rheumatoid arthritis or Down syndrome may be significant yet asymptomatic. Treatment decisions in this group are difficult. Acute AAS is more commonly symptomatic and may be life threatening.

90.3 Abnormalities in vertebral bodies

See also lesions unique to the craniovertebral junction & upper cervical spine (p. 1151).

For abnormalities unique to the axis (C2), see below.

1. neoplasms; see more extensive list (p. 542)
   a) metastases: prostate, breast, lung, renal cell, thyroid, lymphoma & myeloma commonly go to bone. Four patterns (= all are low intensity on T1WI):
      • focal lytic (most common): T1WI=hypointense, T2WI=hyperintense
• focal sclerotic: hypointense on T1WI and T2WI
• diffuse homogeneous: T1WI=hypointense, T2WI=hyperintense or heterogeneous
• diffuse heterogeneous: mixed signal intensities on T1WI & T2WI

b) primary bone tumors; see more extensive discussion (p.792)
• vertebral hemangioma
• osteoblastoma

2. infection: osteomyelitis/discitis
3. fatty infiltrate or replacement of bone marrow: with age, hematopoietic red marrow of VBs is gradually replaced by yellow marrow in a splotchy pattern at a slower rate than in many other locations, e.g. distal appendicular bones. T1WI: yellow marrow (MRI characteristics similar to subcutaneous fat) is hyperintense to red marrow (caution: bright areas on T1WI may be fat, or may be a normal area next to a low intensity met). T2WI: yellow marrow is bright

4. degenerative changes (Modic changes), see Table 68.2
5. metabolic
   a) Paget’s disease: plain x-rays →enlargement of VBs with cortical thickening usually involving several contiguous levels (p.1121)
   b) osteoporosis: reduced bone density. Vertebral compression fractures may be seen
   c) ankylosing spondylitis (p.1123): osteoporotic VBs, calcified intervertebral discs (sparring the nucleus pulposus), and ossified ligaments, →square VBs with bridging syndesmophytes (“bamboo spine”). Starts in sacroiliac joints & lumbar spine

90.4 Axis (C2) vertebra lesions

1. tumors: rare. Possibilities include those that involve the spine at any location. Some factors pertinent to this location3:
   a) primary bone
      • chondroma
      • chondrosarcoma: rare in the craniovertebral junction. Lobulated tumors with calcified areas
      • chordoma: slow-growing radioresistant malignancy (p.778)
      • osteochondroma (chondroma)
      • osteoblastoma (p.792)
      • osteoid osteoma (p.792): more common in posterior elements than VB4
      • giant-cell tumors of bone: typically arise in adolescence. Lytic with bony collapse5
   b) metastatic: including
      • typical metastases that spread hematogenously to bone, including: breast cancer, prostate cancer, malignant melanoma, paraganglioma, renal cell carcinoma
      • extension of regional tumors: nasopharyngeal tumors, craniopharyngioma
   c) miscellaneous
      • plasmacytoma
      • multiple myeloma
      • Langerhans cell histiocytosis: osteolytic defect with progressive vertebral collapse. Occasion-ally occur in C26
      • Ewing’s sarcoma: malignant. Peak incidence during 2nd decade of life
      • aneurysmal bone cyst7

2. infection: osteomyelitis of the axis
3. pannus from old nonunion of fracture or from rheumatoid arthritis (RA)
4. erosive changes in the odontoid process with RA (p.1134)

90.5 Pathologic fractures of the spine

90.5.1 General information
Fractures due to metastatic involvement are hypointense on T1WI and hyperintense on T2WI. Benign VB collapse should be isointense to normal VBs on all sequences8,9 and the VB should look homogeneous. On T2WI or STIR images, the cortex of the VB (which should be dark border around the VB due to low water content of cortical bone) should be intact.

90.5.2 Etiologies
1. osteoporosis
2. neoplasm: short list
   a) metastases: common sources of spine mets: lung, breast, prostate, myeloma
b) Langerhans cell histiocytosis (p.777): may cause vertebra plana (see below)
c) lymphoma
d) hemangioma (p.794)

3. infection
4. avascular necrosis of the vertebral body
   a) Calve-Kummel-Verneuil disease (see below)
   b) with steroid use

90.5.3 Vertebra plana

Criteria:
1. uniform collapse of vertebral body into flat thin disc
2. increased density of vertebra
3. spares neural arches
4. normal disc and intervertebral disc space
5. intervertebral vacuum cleft sign (pathognomonic)
6. no kyphosis

Etiologies include:
1. Langerhans cell histiocytosis
3. hemangioma

90.6 Spinal epidural masses

See items marked with a dagger (†) under Myelopathy (p.1407).

90.7 Destructive lesions of the spine

90.7.1 Etiologies

1. neoplastic; see Differential diagnosis: spine & spinal cord tumors (p.783) for more:
   a) metastatic tumors with a predilection for bone: prostate, breast, renal cell, lymphoma, thyroid, lung…; see Spinal epidural metastases (p.814)
   b) primary bone tumors: chordomas (p.778), osteoid osteoma (p.792), hemangioma (p.794)
2. infection:
   a) vertebral osteomyelitis: occurs mostly in IV drug abusers, patients with diabetes mellitus, and hemodialysis patients. May have associated spinal epidural abscess. Also see Vertebral osteomyelitis (p.353)
   b) Discitis (p.356)
3. chronic renal failure: some patients develop a destructive spondyloarthropathy that resembles infection^10,11
4. ankylosing spondylitis (p.1123): bamboo spine (square VBs with bridging syndesmophytes)
5. lesions producing posterior scalloping of VB (mnemonic: AMEN)

Aacromegaly or achondroplasia
M Marfan syndrome or mucopolysaccharidosis
E Ehlers-Danols
N neurofibromatosis
also: dural ectasia
1. lesions producing anterior scalloping of VB
   a) aortic aneurysm
   b) lymphoma
   c) spinal TB

90.7.2 Differentiating factors

Of the many lytic or destructive lesions that involve the vertebra, destruction of the disc space is highly suggestive of infection which often involves at least two adjacent vertebral levels. Although tumors may involve adjacent vertebral levels and cause collapse of disc height, the disc space is usually not destroyed^12 (possible exceptions include: some vertebral
plasmacytomas, a reported metastatic cervical carcinoma, and there may occasionally be destruction of the disc in ankylosing spondylitis. Unlike pyogenic infections, the disc may be relatively resistant to tuberculous involvement in Pott’s disease. Also, since metastatic tumor involvement usually produces widespread bony involvement, it is less likely with involvement of a single bone.

90.8 Vertebral hyperostosis

2. osteoblastic metastases
   a) in men: prostate
   b) in women: breast
   c) lymphoma

90.9 Sacral lesions

Tumors:
1. metastases: the most common sacral neoplasm
2. primary neoplasms of the sacrum are uncommon and include:
   a) giant cell tumor (p.1412)
   b) chordoma
   c) teratomas:
      • adults: pre-sacral or sacrococcygeal teratomas may arise from cells sequestered from Hensen’s node in the caudal embryo. Rarely cause neurologic involvement (distinguishing this from chordoma). Sacrum may be normal in up to 50% (abnormal in almost all chordomas).
      Treatment is complete removal usually by general surgeon
      • peds: malignant pre-sacral teratoma is a rare tumor seen primarily in female children

Infection:
   Most infections of the sacrum or sacroiliac joint are due to contiguous spread from a suppurative focus

Arthritic disorders:
1. ankylosing spondylitis (p.1124): involves SI joint almost by definition
2. osteoarthritis

Sacral fractures, may be due to:
1. trauma
2. repetitive stress
3. sacral insufficiency (p.1415)

Congenital:
   sacral agenesis (caudal regression syndrome): rare (prevalence: 0.005–0.01% higher (0.1–0.2%) in children of diabetic mothers (16–20% of children with sacral agenesis have diabetic mothers)). Increased incidence of associated spinal abnormalities including: syrinx, tethered cord, lipoma, and lipomyelomeningocele.
1. Four types:
   a) Type 1: partial unilateral agenesis, localized to the sacrum or coccyx
   b) Type 2: partial bilaterally symmetric defects in the sacrum. Iliac bones articulate with S1, and distal segments of the sacrum and coccyx fail to develop
   c) Type 3: total sacral agenesis + iliac bones articulate with the lowest segment of the lumbar spine present
   d) Type 4: total sacral agenesis + iliac bones fused posteriorly along the midline
2. in cases of total sacral agenesis (types 3 & 4), MR findings include: absence of the sacrum and coccyx and variable absence of a portion of the lumbar spine, with a characteristic club-shaped configuration of the conus medullaris

Miscellaneous:
   osteitis condensans ilii: increased density in ilium, usually asymptomatic (incidental) finding. Occasionally may produce low back pain or tenderness
90.10 Enhancing nerve roots

1. tumor
   a) meningeal carcinomatosis
   b) lymphoma
2. infection: especially CMV (often seen in AIDS patients)
3. inflammatory
   a) Guillain-Barre
   b) arachnoiditis
   c) sarcoid

90.11 Nodular enhancing lesions in the spinal canal

1. neurofibromatosis (NFT)
2. tumor
   a) drop mets
   b) neurofibroma
   c) schwannoma

90.12 Intraspinal cysts

1. spinal meningeal cysts (p.1142)
2. cystic neurofibroma
3. ependymoma: may be cystic. In filum terminale: myxopapillary ependymoma (p.789)
4. syringomyelia (p.1144)
5. dilated central canal (p.1144)

90.13 Diffuse enhancement of nerve roots/cauda equina

(As distinct from nodular enhancement, see above)
1. Guillain-Barre (p.184)
2. meningitis
3. cytomegalovirus (CMV) (especially in AIDS)
4. lymphoma
5. sarcoid (look for hilar adenopathy)

91.2 Encephalopathy

Many etiologies are similar to that for coma (p.297). EEG may be helpful in distinguishing some etiologies (p.238).
1. a rare cause may be (spontaneous) intracranial hypotension (p.389)
2. hypertensive encephalopathy from malignant hypertension

91.3 Syncope and apoplexy

91.3.1 General information

Syncope may be defined as one or more episodes of brief loss of consciousness (LOC) with prompt recovery (this term is considered by many to signify a vasovagal episode). The uncommonly used term lipothymia may be less likely to imply an etiology. Prevalence may be as high as $\approx 50\%$ (higher in the elderly). Apoplexy is traditionally considered a form of hemorrhage, usually intracerebral. The recovery from apoplexy would therefore usually be slower than for syncope.

91.3.2 Etiologies

Adapted \(^1,2\). NB: in a large number of cases no cause can be determined.
1. vascular: a few myotonic jerks may be seen in cerebral ischemia
   a) cerebrovascular
      • subarachnoid hemorrhage (most commonly aneurysmal)
      • intracerebral hemorrhage
      • brain stem infarction
      • pituitary apoplexy (p.720) (rare)
      • verteobasilar insufficiency (VBI) (p.1305)
      • rarely with migraine
   b) cardiovascular
      • Stokes-Adams attacks: disorder of AV-node conduction in the heart resulting in syncope with bradycardia
      • carotid sinus syncope: minimal stimulation (e.g. tight shirt collar, syncope while shaving...) causes reflex bradycardia with hypotension, more common in patients with carotid vascular disease. Bedside carotid massage with ECG and BP monitor may diagnose\(^2\)
      • cardiac standstill: seen rarely in patients with glossopharyngeal neuralgia (p.492)
      • vasodepressor syncope (the common faint), AKA vasovagal response, and recently AKA neurocardiogenic syncope\(^1\): the most common cause of transient LOC. Hypotension usually with any of the following autonomic manifestations: pallor, nausea, heavy perspiration, pupillary dilatation, bradycardia, hyperventilation, salivation. Usually benign. Most common in age <35 yrs
      • orthostatic hypotension: drop in SBP $\geq 25$ mm Hg on standing
      • triggered syncope: includes micturition syncope, tussive syncope, weight lifting syncope... (most involve elevation of intrathoracic pressure)
2. infectious
   a) meningitis
   b) encephalitis
3. seizure (p.443): in general, there are involuntary movements and confusion afterwards, lasts at least several minutes. Todd’s paralysis may follow and usually resolves slowly over a period of a few hours. There may be irritative special-sense phenomena (visual, auditory, or olfactory hallucinations)
   a) generalized
b) complex partial  
c) akinetic seizure  
d) drop attack (loss of posture without LOC): seen in Lennox-Gastaut  
4. metabolic: hypoglycemia (may produce seizure, usually generalized)  
5. miscellaneous  
   a) intermittent ventricular obstruction: the classic example is a colloid cyst of the third ventricle (p. 756), but this mechanism is questionable  
   b) narcoleptic cataplexy: narcolepsy is characterized by somnolence and sudden attacks of weakness (cataplexy) when awake. Easy arousal and lack of post-ictal drowsiness distinguishes cataplexy from a seizure. The somnolence is treated with CNS stimulants (such as amphetamines or modafinil (Provigil®) 200 mg PO q AM), and cataplexy is treated with antidepressants  
   c) psychogenic  
6. intracranial hypotension: usually with CSF shunt when upright (p. 389)  
7. unknown: in ≈ 40% of cases no cause can be diagnosed  

91.3.3 Practical approach to syncope  

Introduction  
The core of diagnosis and management are the H&P, orthostatic vital signs, and the ECG, with a combined diagnostic yield of 50% covering:  
1. reflex mediated such as vasovagal or valsalva/stress-induced: 36 - 62%  
2. cardiac valvular etiology or arrhythmia: 10 – 30%  
3. orthostatic due to autonomic dysregulation, dehydration or polypharmacy: 2 – 24%  
4. cerebrovascular due to stroke: ≈ 1%  
5. seizure  

Evaluation  
1. history: includes  
   a) medication list: look for drugs that may cause orthostatic hypotension, especially blood pressure medication, beta blockers  
   b) precipitating factors: e.g. change in position, sensitivity to tight collars…  
   c) premonitory factors: e.g. sweating and tremulousness may signify hypoglycemia, bradycardia is associated with vasovagal events, tonic-clonic movements may occur with a seizure  
   d) post-ictal emergence: usually rapid after a simple faint, slower after seizure which may also exhibit Todd’s paralysis (p. 443)  
2. cardiovascular etiologies: Testing is also guided by H&P, vital signs & ECG:  
   a) cardiac arrhythmia evaluation: 12-lead ECG & 24-hour Holter monitor, and may lead to electrophysiologic (EP) testing/intervention  
   b) abnormal orthostatics warrants a formal tilt-table test  
   c) history of cardiomyopathy or CAD merits an echocardiogram and formal stress testing. These results determine the need for cardiac catheterization  
3. neurologic etiologies: comprise <1% of cases. In the absence of clinical evidence of a neurologic etiology, neurodiagnostic testing (EEG, CT scan, MRI/MRA, carotid doppler) have a diagnostic yield of 2 – 6%. These tests are warranted only when clinically indicated (seizures, altered consciousness, gradually resolving Todd’s paralysis, known history of cerebrovascular compromise). Tests include:  
   a) unenhanced brain CT: rules out most acute neurosurgical etiologies (bleed, hydrocephalus, edema which may be associated with tumor)  
   b) MRI without and with enhancement in cases with unexplained CT findings, or with a negative CT but high suspicion of a CNS etiology  
   c) seizure evaluation: when symptoms suggest possible seizure:  
      • EEG: usually a sleep deprived EEG. Not very sensitive  
      • 24 hour video EEG monitoring: in cases with high index of suspicion of seizures or nonepileptic seizures  

Management  
Admission and inpatient management is warranted for patients with diagnosed cardiac or neurologic syncope, either by suggestive history (family history of sudden death, syncope during exertion, witnessed seizure) or diagnostic testing (arrhythmia, severe orthostatic changes, hemodynamic instability).
91.4 Transient neurologic deficit

For apoplexy, etc., see Syncope and apoplexy (p.1396).

The first three etiologies listed below cover most cases of transient neurologic deficit:

1. transient ischemic attack (TIA) (p.1264): temporary neurologic dysfunction as a result of ischemia. Maximum deficit usually at onset. Most resolve in <20 mins

2. migraine: unlike TIA, tends to progress in a march-like fashion over several minutes. May or may not be followed by headache; see Migraine (p.175)

3. seizure: may be followed by a Todd’s paralysis (p.443)

4. TIA-like syndrome
   a) “tumor TIA”: a transient deficit in a patient with a tumor, may be clinically indistinguishable from an ischemic TIA. Intravascular lymphomatosis may mimic TIAs (p.711)
   b) TIA-like symptoms may occur as a prodrome (p.1336) to a lobar intracerebral hemorrhage in cases of cerebral amyloid angiopathy (CAA). Unlike typical TIAs, these usually consist of numbness, tingling or weakness that gradually spreads in a manner reminiscent of a Jacksonian-march and may cross-over vascular territories. Caution: antiplatelet drugs and anticoagulation may increase the risk of hemorrhage in patients with CAA (p.1334)
   c) chronic subdural hematoma: may cause recurrent TIA-like symptoms of the involved hemisphere (including transient aphasia with dominant hemisphere involvement, hemisensory or motor abnormalities). The duration of symptoms tends to be longer than the typical TIA. Postulated mechanisms include:
      ● electrical basis: the possibility of epileptic activity due (e.g. due to irritation of the cortex by blood breakdown products) has not been supported in the literature; however, spreading depression of Leao has been considered
      ● impairment of venous outflow by compression of surface veins
      ● compromised regional cerebral perfusion by indirect shifting of the anterior and posterior cerebral arteries
      ● transient ICP elevations → variations in cerebral perfusion pressure

4.1 Ataxia/balance difficulties

1. cerebellar origin: usually with involvement of UEs in addition to LEs
   a) cerebellar tumors
   b) cerebellar hemorrhage
   c) acute cerebellar ataxia: usually follows viral infection in a child <3 years. Usually self-limited with good prognosis for complete recovery

2. spinal cord: usually worse with eyes closed (loss of proprioceptive input)
   a) spinal stenosis
   b) neoplastic cord compression
   c) syringomyelia (may be part of Chiari malformation)

3. degenerative
   a) ataxia-telangiectasia syndrome
   b) ataxia oculomotor apraxia
   c) Friedreich’s ataxia
   d) spinocerebellar degeneration

4. metabolic/nutritional
   a) vitamin B12 deficiency
   b) drugs
      ● AEDs (especially phenytoin or carbamazepine)
      ● alcohol: acutely with intoxication and chronic
      ● heavy metal poisoning

5. conditions that may mimic ataxia
   a) weakness
   b) peripheral neuropathy
   c) dizziness: including orthostatic hypotension; see Dizziness and vertigo (p.572)

6. peripheral neuropathy:
   a) ataxia can occur with Guillain-Barré syndrome (p.185), especially Miller Fisher variant (p.186)
   b) balance difficulties are common with chronic immune demyelinating polyradiculoneuropathy (CIDP) (p.186)
91.6 Diplopia

1. cranial nerve palsy of any one or combination of III, IV (rare), or VI
   a) for multiple cranial nerve palsies, below
   b) VI palsy (p.567): can occur with increased intracranial pressure, e.g. in idiopathic intracranial hypertension (pseudotumor cerebri) (p.766), sphenoid sinusitis…; see other causes of abducens palsy (p.321)
   c) isolated muscle paresis of III suggests nuclear lesion or myasthenia gravis

2. intraorbital mass compressing extraocular muscles
   a) orbital pseudotumor (p.569)
   b) meningioma

3. Graves’ disease: hyperthyroidism + ophthalmopathy (p.1375)

4. myasthenia gravis

5. giant cell arteritis (p.196)

6. botulism: due to toxin from Clostridium botulinum (in adults: ingested or in wound). N/V, abdominal cramps, and diarrhea often precede neurologic symptoms. Neurologic involvement is typically symmetric. Dry mouth & cranial nerves palsies (diplopia, ptosis, loss of accommodation and pupillary light reflex) are followed by descending weakness. Bulbar paresis (dysarthria, dysphagia, dysphonia, flaccid facial muscles) follows. Muscles of the trunk/extremities and respiration progressively weaken in a descending fashion. Sensory disturbances are absent. Sensorium usually remains clear.

7. following head trauma: includes injury to EOMs, orbital hematoma, VI palsy from increased ICP

91.7 Anosmia

1. abrupt onset of anosmia
   a) severe upper respiratory infection with damage to the neuroepithelium: the most common cause
   b) head trauma: second most common cause. Anosmia occurs in 7–15% of patients with significant head trauma

2. gradual onset of anosmia
   a) allergic rhinitis and sinus disease: third most common cause of anosmia (anosmia in this setting may be intermittent)
   b) intracranial neoplasms: olfactory groove meningioma, see Foster Kennedy syndrome (p.99), esthesioneuroblastoma (p.1387)
   c) may also be associated with Alzheimer’s disease
   d) olfactory sense diminishes with age: ≈ 50% of patients 65–85 years of age have some loss of sense of smell
   e) metabolic abnormalities: vitamin deficiency
   f) physical blockage of nasal passages: nasal polyps…
   g) endocrine abnormalities: diabetes…
   h) chemical: alcohol abuse, exposure to solvents, cocaine (ischemic infarction of olfactory mucosa from vasoconstriction)

3. congenital anosmia: Kallmann syndrome (anosmia with hypogonadotrophic hypogonadism)

91.8 Multiple cranial nerve palsies (cranial neuropathies)

91.8.1 Framework

The differential diagnosis is legion. The following is a framework (modified): 

1. congenital
   a) Möbius syndrome: AKA congenital facial diplegia. Facial plegia is complete in ≈ 35%(in rest, affects upper face more than lower face, unlike central or peripheral facial palsy), associated with abducens palsy in 70% external ophthalmoplegia in 25% ptosis in 10% lingual palsy in 18%
   b) congenital facial diplegia may be part of facioscapulohumeral or myotonic muscular dystrophy

2. infectious
   a) chronic meningitis:
      • spirochetal, fungal, mycoplasma, viral (including AIDS)
      • mycobacterial AKA tuberculous (TB) meningitis: 6th nerve involved first and most frequently. CSF shows lymphocytic pleocytosis and hypoglycorrachia. Smears are usually negative and multiple cultures are needed to diagnose
b) stage II Lyme disease (p.576). Facial nerve weakness is common, sometimes bilateral (Lyme disease is the most common cause of facial diplegia in endemic areas). Other cranial nerve involvement is rare.
c) neurosyphilis: rare nowadays except with AIDS. Diagnosed by serologic testing
d) fungal infection
   - cryptococcal meningitis (p.376): CSF analysis for cryptococcal antigen and India ink prep can detect
   - aspergillosis: may extend to the orbit from sinuses and involve cranial nerves
   - mucormycosis (phycomycosis) (p.1269): produces cavernous sinus syndrome, usually occurs in diabetics
e) cysticercosis: especially with basal form; see Neurocysticercosis (p.371)
3. traumatic: especially with basal skull fractures. Lower cranial nerve palsies may occur (sometimes delayed in onset) with occipital condyle fractures (p.966) or atlanto-occipital dislocation (p.963)
4. neoplastic (brain stem compression and intrinsic lesions usually also produce long tract findings early). Also see Jugular foramen syndromes (p.100)
a) chordoma (p.778)
b) sphenoid-ridge meningioma
c) neoplasms of the temporal bone (often in conjunction with chronic otitis media and otalgia): adenoid cystic carcinoma, adenocarcinoma, mucopidermoid carcinoma
d) glomus jugulare tumors: often affects nerves IX, X, and XI. May cause pulsatile tinnitus; see Parangangioma (p.652)
e) carcinomatous or lymphomatous meningitis (p.811): CSF pleocytosis and elevated protein. Palsies are painless or associated with diffuse headache. Sensory palsies are common, resulting in deafness and blindness
f) invasive pituitary adenomas involving the cavernous sinus (p.720): extracranial cranial neuropathies tend to develop after visual field deficits in these tumors, and are less common when compared to other intracavernous solid tumors
17  
g) primary CNS lymphoma (p.712)
h) multiple myeloma involving the skull base (p.714)
i) intrinsic brain stem tumors: gliomas, ependymoma, metastases…
5. vascular
a) aneurysm: intracranial or cavernous sinus (p.1225)
b) brain stem stroke: usually also produces long tract findings (p.99)
   - Weber’s syndrome: Cr N III (usually pupil sparing) + contralateral hemiparesis
   - Millard-Gubler syndrome: Cr N VI + VII + contralateral hemiparesis
c) vasculitis: Wegener’s granulomatosis usually affects eighth nerve in addition to others
6. granulomatous
a) sarcoidosis: ≈ 5% have CNS involvement, usually as fluctuating single or multiple cranial neuropathies (fascial nerve is most common, and may be indistinguishable from Bell’s palsy). CSF pleocytosis (p.200) is common
7. inflammatory
8. neuropathies
a) Guillain-Barré syndrome (GBS) (p.184): cranial nerve involvement includes facial diplegia, oropharyngeal paresis. Peripheral neuropathy usually presents with ascending weakness, proximal muscle weakness > distal, and absent deep tendon reflexes
b) Miller-Fisher variant GBS: ataxia, areflexia & ophthalmoplegia. Serum marker: anti-GQ1b antibodies
c) idiopathic cranial polyneuropathy: subacute onset of constant facial pain, usually retro-orbital. Frequently precedes sudden onset of cranial-nerve palsies usually involving III, IV & VI, less frequently V, VII, and lower nerves (IX through XII). Olfactory and auditory nerves usually spared. Acute and chronic inflammation of unknown etiology similar to Tolosa-Hunt and orbital pseudotumor. Steroids reduce pain and expedite recovery
9. entrapment in abnormal bone
a) hyperostosis cranialis interna: a rare autosomal dominant abnormality of the bone of the base of the skull causing recurrent facial palsy and other cranial nerve palsies
18  
b) osteopetrosis: see below
c) Paget’s disease (p.1120) involving the skull: 8th nerve involvement (deafness) is most common. Optic nerve atrophy, and palsies of oculomotor, facial, IX, XI, olfactory nerves and others may also occur
19  
d) fibrous dysplasia (p.779)
91.8.2 Specific syndromes

Facial diplegia

Items culled from the above list that have facial diplegia (p.576) as a prominent finding:

1. congenital: Möbius syndrome, congenital facial diplegia
2. infectious: Lyme disease
3. neuropathies: Guillain-Barré syndrome
4. isolated 4th ventricle (p.576): compression at the facial colliculus
5. granulomatous: sarcoidosis

Cavernous sinus syndrome

Multiple cranial nerve palsies (involving any of the cavernous sinus cranial nerves: III, IV, V1, V2, VI) which primarily produce diplopia (due to ophthalmoplegia). Classically the third nerve palsy (e.g. from an enlarging cavernous carotid artery aneurysm) will not produce a dilated pupil because the sympathetics which dilate the pupil are also paralyzed. Facial pain or altered facial sensation may occur.

See list of lesions that may produce cavernous sinus syndrome (p.1376).

Osteopetrosis

AKA “marble bone disease” (there is also some confusion with the term osteosclerosis; osteosclerosis fragilis generalisata is the obsolete term for osteopetrosis). A rare group of genetic disorders of defective osteoclastic resorption of bone resulting in increased bone density, may be transmitted either as autosomal dominant or recessive. The dominant form is usually benign and is seen in adults and adolescents. The recessive (“malignant”) form is often associated with consanguinity, and is similar to hyperostosis cranialis interna (see above), but in addition to the proclivity for the skull, also involves ribs, clavicles, long bones, and pelvis (long-bone involvement results in destruction of marrow and subsequent anemia). Cranial nerves involved primarily include optic (optic atrophy and blindness are the most common neurologic manifestation), facial, and vestibulo-acoustic (with deafness), trigeminal nerve may also be involved. There may also be extensive intracranial calcifications, hydrocephalus, intracranial hemorrhage and seizures.

Bilateral optic nerve decompression via a supraorbital approach may improve or stabilize vision.

91.9 Binocular blindness

Bilateral occipital lobe dysfunction:

1. bilateral posterior cerebral artery flow impairment
   a) top of the basilar syndrome
   b) increased intracranial pressure
      • hydrocephalus with shunt malfunction
      • pseudotumor cerebri (idiopathic intracranial hypertension) (p.768)
      • cryptococcal meningitis: decreased visual acuity (p.376)
2. trauma: bilateral occipital lobe injury (e.g. contrecoup injury)

Seizures. Epileptic blindness

Migraine. Cortical spreading depression

Posterior ischemic optic neuropathy. Usually in the setting of shock

Bilateral vitreous hemorrhage. E.g. with SAH (Terson’s syndrome)

Functional. Conversion reaction, hysterical blindness...

91.10 Monocular blindness

Due to a lesion anterior to the optic chiasm.

1. Amaurosis fugax: often described as a “shade coming down” over one eye
   a) TIA: usually due to occlusion of the retinal artery (p.1271)
   b) giant cell arteritis (GCA) (p.195): usually due to ischemia of optic nerve or tracts (less commonly due to retinal artery occlusion)
2. trauma: optic nerve injury
3. ruptured carotid cavernous aneurysm: resultant carotid cavernous fistula increases intraocular pressure by impeding venous return
4. intraorbital pathology: tumors
5. injury within the globe: retinal detachment, ocular trauma
6. unilateral vitreous hemorrhage: e.g. with SAH (Terson’s syndrome)

91.11 Exophthalmos

91.11.1 General information

Alternate spelling: exophthalmus.

Definition: abnormal protrusion of the eyeball. Some authors reserve the term exophthalmos for cases due to endocrinopathies and use proptosis (of the eye) for other causes, but these terms are widely used interchangeably.

Criteria: different criteria are proposed. Anterior displacement of 18 mm (Hertel exophthalmometry can be used to measure clinically - requires intact lateral orbital bone). CT criteria: for most accurate results, the patient’s should have their eyes open and fixated on a point in the primary gaze position. position of equator of the globe (widest part) is distal to a line drawn from lateral orbit to medial canthus, >2/3 of the globe anterior to this line.

91.11.2 Pulsatile

1. carotid cavernous fistula (CCF) (p.1256)
2. transmitted intracranial pulsation due to defect in orbital roof
   a) seen unilaterally e.g. in neurofibromatosis type 1 (p.604)
   b) post-op following procedures that remove orbital roof or wall
3. vascular tumors

91.11.3 Non-pulsatile

1. tumor
   a) intraorbital tumor: may be due to mass effect from tumor or to compromised venous drainage from the orbit
      • optic glioma (p.631)
      • optic sheath neuroma
      • lymphoma
      • optic sheath meningioma
      • orbital involvement with multiple myeloma (p.714)
      • orbital invasion by invasive pituitary adenoma (p.771)
      • in peds: metastatic neuroblastoma
      • in peds: Langerhans cell histiocytosis (p.777) as part of Hand-Schüller-Christian (triad: DI, exophthalmos and lytic bone lesions (particularly of cranium))
   b) due to hyperostosis from a sphenoid ridge meningioma
2. Graves' disease (hyperthyroidism + exophthalmos) (p.1375): even though the exophthalmos is usually bilateral with this (80%), thyroid disease is still the most common cause of unilateral proptosis
3. enlargement of periorbital fat
4. infection: orbital cellulitis (usually has concomitant sinusitis)
5. inflammatory: orbital pseudotumor. Usually unilateral (p.569)
6. hemorrhage
   a) traumatic
   b) spontaneous
7. 3rd nerve palsy: can cause up to 3 mm proptosis from relaxation of the rectus muscles
8. cavernous sinus occlusion (may affect both eyes)
   a) cavernous sinus thrombosis (p.1309)
   b) cavernous sinus tumor obstructing venous outflow
9. pseudo-exophthalmos
   a) congenital macrophthalmos (bull's eye)
   b) lid retraction: e.g. in Graves’ disease (p.1403)
   c) coronal craniosynostosis can cause a “relative” proptosis (p.253)
91.12 Ptosis
AKA blepharoptosis. Drooping of the upper eyelid.
Distinguished from pseudoptosis (lid droop not resulting from weakness of levator palpebrae superioris (LPS)) which can be due to enophthalmos (globe displaced posteriorly, e.g. with orbital floor blow-out fracture), microphthalmia, blepharospasm, Duane syndrome.

Etiologies of ptosis:
1. congenital: most are simple (autosomal dominant inheritance), complicated ptosis is associated with other findings (e.g. ptosis with ophthalmoplegia)
2. traumatic: injury to eyelid, orbital roof fracture...
3. neurogenic:
   a) third nerve palsy (p.565)
      • involvement of main trunk of third nerve: can occur intradurally or within cavernous sinus. Ptosis may be an early sign of pituitary tumor expansion (apoplexy) (p.720)
      • involvement of the superior division of the third nerve within the orbit
   b) Horner’s syndrome (p.564): ptosis here is partial (may be a pseudoptosis since weakness is in tarsal muscles, not LPS), and the lower eyelid will higher than the uninvolved contralateral lower eyelid
4. myogenic ptosis
   a) botulinum toxin injection (e.g. Botox®)
   b) myasthenia gravis
5. mechanical ptosis
   a) tumors: neurofibroma, hemangioma, malignant melanoma, mets...
   b) extension of mucocele of frontal sinus
6. pharmacologic (drugs). Partial list:
   a) corticosteroids: including topical
   b) alcohol
   c) opium

91.13 Pathologic lid retraction
1. hyperthyroidism (p.1376)
2. psychiatric: schizophrenia...
3. steroids
4. Parinaud’s syndrome (p.99)

91.14 Macrocephaly
Macrocephaly means increased size of the head. Although sometimes used synonymously, some contend that the term macrocrania by convention refers to a head circumference > 98th percentile. Also, not to be confused with macrencephaly AKA megalencephaly (see below). In a pediatric practice the 3 most common etiologies in decreasing order of frequency: familial (parents have big heads), benign subdural fluid collections of infancy (p.904), and hydrocephalus.
1. with ventricular enlargement
   a) (hydrostatic) hydrocephalus (HCP), see for etiologies (p.394)
      • communicating
      • obstructive
   b) hydranencephaly (p.288)
   c) constitutional ventriculomegaly: ventricular enlargement of no known etiology with normal neurologic function
   d) hydrocephalus ex vacuo: loss of cerebral tissue (more often associated with microcephaly, e.g. with TORCH infections)
   e) vein of Galen aneurysms: see below
2. with normal or mildly enlarged ventricles
   a) “external hydrocephalus”: prominent subarachnoid spaces and basal cisterns; see External hydrocephalus (AKA benign external hydrocephalus) (p.400)
   b) subdural fluid
      • hematoma
      • hygroma
      • effusion benign and symptomatic
      • benign subdural collections of infancy (p.904)
c) cerebral edema: some consider this to be a form of pseudotumor cerebri.
   - toxic: e.g. lead encephalopathy (from chronic lead poisoning)
   - endocrine: hypoparathyroidism, galactosemia, hypophosphatasia, hypervitaminosis A, adrenal insufficiency...

d) familial (hereditary) macrocrania: parents also have large heads, the brains eventually “catch up”

e) idiopathic

f) megalencephaly (AKA macrencephaly): an enlarged brain (p.289)

g) neurocutaneous syndromes: usually due to increased volume of brain tissue (megalencephaly, see above).26 Seen especially in neurofibromatosis and congenital hypermelanosis (Ito’s syndrome). Less common in tuberous sclerosis and Sturge-Weber. Also seen in the rare hemimegalencephaly syndrome

h) arachnoid cyst (AKA subependymal or subarachnoid cyst): a duplication of the ependyma or arachnoid layer filled with CSF. Usually reach maximal size by 1 month of age and do not enlarge further. Treatment is required in ≈ 30% due to rapid enlargement or growth beyond first month. Cyst may be shunted or fenestrated. Prognosis with true arachnoid cyst is generally good (unlike porencephalic cyst) if no increased ICP or progressive macrocephaly during 1st year of life

i) arteriovenous malformation: especially vein of Galen “aneurysm” (p.1255). Auscultate for cranial bruit. With vein of Galen aneurysms, macrocephaly may be due to HCP from obstruction of the sylvian aqueduct.26 With other malformations, macrocrania may be due to increased pressure in venous system without HCP

j) brain tumors without hydrocephalus: brain tumors are rare in infancy, and most cause obstructive HCP. Tumors that occasionally present without HCP includes astrocytomas. May also be seen in the rare diencephalic syndrome, see tumor of anterior hypothalamus (p.632)

k) “gigantism syndromes”
   - Soto’s syndrome: associated with advanced bone age on x-ray, and multiple dysplastic features of face, skin and bones
   - exomphalometroglossia-gigantism (EMG) syndrome: hypoglycemia (from abnormalities in islets of Langerhans), large birth weight, large umbilicus or umbilical hernia and macroglottia

l) “craniocerebral disproportion” (p.903): may be the same as benign extra-axial fluid of infancy

m) achondroplastic dwarf: cranial structures are enlarged but the skull base is small, giving rise to a prominent forehead and an OFC ≥ 97th percentile for age, hypoplasia of midface, and stenosis at foramen magnum. Head growth follows different curve than normal (OFC ≥ 97th percentile for age is not unusual and does not necessitate shunting)

n) Canavan’s disease: AKA spongy degeneration of the brain, an autosomal recessive disease of infancy prevalent among Ashkenazi Jews. Produces symmetrical low attenuation of hemisphere white matter on CT and macrocephaly

o) neurometabolic diseases: usually due to deposition of metabolic substances in the brain. Seen in Tay-Sachs gangliosidosis, Krabbe disease...

3. due to thickening of the skull
   a) anemia: e.g. thalassemia
   b) skull dysplasia: e.g. osteopetrosis (p.1401)

91.15 Tinnitus

91.15.1 General information

May be either subjective (heard only by patient) or objective (e.g. cranial bruit, can be heard by examiner as well, usually with a stethoscope place over the cranium, orbit, or carotid arteries in the neck). Objective tinnitus is almost always due to vascular turbulence (from increased flow or partial obstruction).

91.15.2 Pulsatile tinnitus

Most cases are due to vascular lesions.

1. pulse synchronous:
   a) carotid cavernous fistula (p.1256)
b) AVM:
   - cerebral (pial) AVM
   - dural AVM (p.1251)
c) glomus jugulare tumor (p.654)
d) cerebral aneurysm: (rare) possibly with turbulent flow in giant aneurysm
e) hypertension
f) hyperthyroidism
g) idiopathic intracranial hypertension (pseudotumor cerebri) (p.766)
h) transmitted bruit: from heart (e.g. aortic stenosis), carotid artery stenosis (especially external carotid)
i) dehiscent jugular bulb or high riding jugular bulb: normal venous variant
j) rarely with posterior fossa tumors: CP-angle tumors e.g. vestibular schwannoma or meningioma, vascular intraparenchymal tumors e.g. hemangioblastoma (especially in CPA)
k) lesions that can present with a red tympanic membrane
   - aberrant carotid artery in middle ear
   - persistent stapedial artery: rare. Arises from aberrant ICA or from junction of horizontal and vertical petrous ICA. Foramen spinosum is absent on the affected side. Enlargement of anterior tympanic segment of seventh nerve canal
   - glomus tympanicum tumor (p.654)
l) sigmoid sinus diverticulum
2. non pulse-synchronous: asymmetrical enlargement of sigmoid sinus and jugular vein may produce a low grade hum

Workup for pulsatile tinnitus:
1. MRI without and with enhancement: to look for tumors, e.g. glomus jugulare
2. angiogram: include internal and external carotid injections
3. tests that are usually not helpful and should not be ordered routinely
   a) carotid ultrasound: nonspecific, not sensitive
   b) MRI/MRV: may miss small dural fistulas and do not give details needed for treatment for large ones

91.15.3 Non-pulsatile tinnitus
1. occlusion of external ear: cerumen, foreign body
2. middle ear infection (otitis media)
3. otosclerosis
4. stapedial muscle spasms: as occurs in hemifacial spasm
5. CP-angle tumors: including vestibular schwannoma (p.670)
6. Meniere’s disease (p.573)
7. labyrinthitis
8. endolymphatic sac tumors: e.g. as in von Hippel-Lindau disease (p.705)
9. drugs
   a) salicylates: aspirin, bismuth subsalicylate (Pepto Bismol®)
   b) quinine
   c) aminoglycoside toxicity: streptomycin, tobramycin (tinnitus precedes hearing loss)

91.16 Facial sensory changes
1. circumoral paresthesias
   a) hypocalcemia
   b) syringobulbia
2. unilateral facial sensory changes
   a) trigeminal nerve neuroma
   b) vestibular schwannoma (VS): to involve Cr. N. Va VS has to be >2 cm diameter; see symptoms from 5th nerve compression under vestibular schwannoma (p.671)
   c) compression of the spinal trigeminal tract (large compressive lesions may cause bilateral alteration of facial sensation) that chiefly manifests in diminution of pain and temperature sense with little effect on touch sense. The tract usually extends down into the spinal cord as far as = the C2 vertebral level (although it may occasionally extend down to C4)
91.17 Language disturbance

1. aphasia:
   a) injury to speech areas of brain
      • Wernicke’s aphasia (p.98): classically produces fluent aphasia (normal sentence length & intonation, devoid of meaning)
      • Broca’s aphasia (p.98): faltering, dysarthric
      • conductive aphasia (p.98): fluent spontaneous speech and paraphasias, but patients understand spoken or written words, and are aware of their deficit
   b) transitory aphasia following a seizure; see Todd’s paralysis (p.443)
   c) primary progressive aphasia of adulthood: idiopathic & degenerative

2. muteness of cerebellar origin
   a) primary progressive aphasia of adulthood: idiopathic & degenerative
   b) transitory aphasia following a seizure; see Todd’s paralysis (p.443)
   c) muteness of cerebellar origin

3. following transcallosal surgery: as a result of bilateral cingulate gyrus retraction or thalamic infarction due to vasospasm from a-comm aneurysm rupture or with large bilateral frontal lesions; may actually be abulia or with bilateral cingulate gyrus lesions

4. Following transcallosal surgery: as a result of bilateral cingulate gyrus retraction or thalamic infarction due to vasospasm from a-comm aneurysm rupture or with large bilateral frontal lesions; may actually be abulia or with bilateral cingulate gyrus lesions

92.2 Myelopathy

Items marked with a dagger (†) may present as a spinal epidural mass.

Congenital:
1. (Arnold)-Chiari malformation (p. 284): Type I often presents in early adulthood
2. tethered cord: often may not present until after some trauma
3. syringomyelia: may be congenital or post-traumatic in quadriplegics, usually presents with a central cord syndrome – see Syringomyelia (p. 1144) – or progressive myelopathy
4. neurenteric cyst (p. 290)
5. cord compression that occurs with some mucopolysaccharidoses: e.g. Morquio syndrome (due to atlanto-axial subluxation), Hurler syndrome
6. hereditary spastic paraplegia: family history is key. Diagnosis of exclusion ¹

Acquired:
1. cervical or thoracic spinal stenosis: often degenerative disease superimposed on congenitally narrow canal (congenital narrowing is frequent in achondroplastic dwarfs)
2. traumatic: including spinal shock, hematomyelia, spinal epidural hematoma (see vascular below), barotrauma, electrical injuries, compression by bone fracture†. May follow minor trauma in the setting of spinal stenosis
3. herniated intervertebral disc†: myelopathy more common in thoracic region, radiculopathy more common in cervical region (long tract signs are rare with herniated cervical disc)
4. kyphosis
5. extramedullary hematopoiesis† (p.171): hypertrophy of marrow → cord compression. Primarily in chronic anemias (e.g. thalassemia major)

6. bony compression secondary to incompetence of odontoid process or transverse atlantal ligament†. May be congenital, traumatic (p.978), neoplastic, or inflammatory (especially rheumatoid arthritis)

7. epidural lipomatosis† (p.1150): hypertrophy of epidural fat most often due to years of exogenous steroid therapy

8. ossification of the posterior longitudinal ligament (OPLL) (p.1127) 

9. arachnoiditis ossificans: a rare condition (only ≈ 43 case reports as of 1998) involving calcification of the arachnoid membrane. In the T-spine, may occur as ossified plaques or in a cylindrical form surrounding the spinal cord. May be difficult to detect on MRI and myelography. Plain unenhanced CT may be optimal for diagnosis

10. vertebral Paget’s disease† (p.1120)

11. idiopathic spinal cord herniation (p.1150) 5,6: rare. Thoracic spinal cord herniates through an anterior dural defect frequently producing a Brown-Séquard syndrome or spastic paraparesis

Neoplastic:
1. spine/spinal cord tumors† (p.783) (for details)
   a) extradural (55%):
      • primary tumors (rare) include: neurofibromas, chordomas, osteoid osteoma, aneurysmal bone cyst, vertebral hemangioma
      • if age >40 yrs, suspect extradural lymphoma (primary or secondary) or leukemic deposits (chloroma), especially with pre-existing diagnosis of hematopoietic or lymphatic disorder
      • epidural metastases (p.814) become increasingly common after age 50 yrs. Occurs in up to 10% of cancer patients. 5–10% of malignancies present initially with cord compression
   b) intradural-extradural (40%): meningiomas, neurofibromas
   c) intradural-intradural: primary cord tumors (p.784) (ependymoma, astrocytoma) and rarely intramedullary mets

2. carcinomatous meningitis (p.811): neurologic deficit usually cannot be localized to a single level

3. paraneoplastic syndrome (p.542): including effects on spinal cord or on peripheral nerves

Vascular:
1. hematoma/hemorrhage
   a) spinal epidural hematoma† (p.1131): usually associated with anticoagulation therapy
      • traumatic: following LP or epidural anesthesia (p.1131)
      • spontaneous*: rare. Includes hemorrhage from spinal cord AVM (p.1131) or from vertebral hemangioma (p.1140)
   b) spinal subarachnoid hemorrhage: as in spinal epidural hematoma (p.165), this may also be post-traumatic (e.g. following LP10,11) or secondary to spinal cord AVM
   c) spinal subdural hematoma
   d) hematomyelia

2. spinal cord infarction: uncommon with the elimination of syphilitic endarteritis. Most often in the territory of the anterior spinal artery, sparing posterior columns. Most commonly ≈ T4 level (watershed zone)
   a) atherosclerosis of radicular artery in elderly patient with hypotension is now the major cause of this rare condition
   b) clamping aorta during surgery (e.g. for abdominal aortic aneurysm)
   c) hypotension (relative or absolute) during surgery in the sitting position in the presence of spinal stenosis.12 May be improved by avoiding absolute hypotension, using awake fiber-optic intubation and positioning, intraoperative SSEP monitoring and inducing hypertension if changes occur with positioning, avoidance of sitting position, and avoiding hyperflexion, hyperextension and traction
   d) aortic dissection
   e) embolization of spinal arteries

3. spinal cord vascular malformations† (p.1140): 10–20% present as sudden onset of myelopathy usually in patients <30 yrs,13 myelopathy may be secondary to:
   a) mass effect from AVM: spinal AVMs account for <5% of lesions presenting as cord “tumors”
   b) rupture → SAH, hematomyelia, or epidural hematoma
   c) watershed infarction due to “steal”
   d) spontaneous thrombosis (necrotizing myelopathy of Foix-Alajouanine disease (p.1141)) 14: presents as spastic → flaccid paraplegia, with ascending sensory level

4. radiation myelopathy: due to microvascular occlusion (p.1563)
5. secondary to iodinated contrast material used for mesenteric or aortic angiography. Especially when angiogrammed in presence of hypotension, where cardiac output is shunted away from viscera and into spinal radicular arteries. Treatment: place patient sitting, remove $\geq 100\,\text{ml}$ of CSF via LP and replace with equal amount of saline over 30 mins\textsuperscript{15}

Autoimmune:
1. post-viral (or post-vaccination): may actually be etiology of auto-immune process (i.e. transverse myelitis). Viral prodrome present in $\approx 37\%$ of cases of ATM. Viral infection is usually most damaging to gray matter (e.g. poliomyelitis)

Demyelinating:
1. acute (idiopathic) transverse myelitis (ATM) (p. 187). Peak incidence during first 2 decades of life. Abrupt onset of LE weakness, sensory loss, back pain, and sphincter disturbance indistinguishable from spinal cord compression. Thoracic region most common. CT and myelogram are normal. MRI may demonstrate. CSF $\rightarrow$ pleocytosis and hyperproteinemia
2. multiple sclerosis (MS): diagnosed in only 7\% of patients presenting as acute transverse myelopathy. Although more common in young adults, MS can occur at any time in life. Myelopathy of MS is usually insidious, and is usually incomplete (i.e. some sparing). Affects myelin, thus sparing gray matter. Abdominal cutaneous reflexes are almost always absent in MS
3. Devic syndrome (neuromyelitis optica (NMO)): a variant of MS characterized by acute bilateral optic neuritis and transverse myelitis (extending $\geq 3$ levels,\textsuperscript{16} often causing cervical myelopathy). Spinal cord edema may become so severe as to cause complete block on myelography. More common in Asia and India than U.S. or Europe. Compared to classic MS: the myelopathy tends to be more severe (pathology: more necrosis as opposed to incomplete demyelination) and with less chance of recovery. Distinct serum IgG antibodies (NMO-IgG) may help differentiate from MS\textsuperscript{17}

Metabolic/toxic:
1. (subacute) combined system disease (CSD) (AKA subacute combined columnal degeneration): due to vitamin B$12$ (cyanocobalamin) deficiency.
   a) etiologies:
      • dietary deficiency of B$12$ (B$12$ is a water soluble vitamin present in meats and animal products)
      • pernicious anemia: intestinal malabsorption of B$12$ in the distal ileum due to lack of secretion of intrinsic factor (a small polypeptide) by gastric parietal cells\textsuperscript{18}
      • other gastric disorders: low gastric pH e.g. in Zollinger-Ellison syndrome can inhibit attachment of intrinsic factor to ileal receptors
   2. clinical: onset is gradual and uniform. Begins with symmetrical paresthesias in feet or hands (posterior column involvement) $\rightarrow$ leg stiffness, weakness, and proprioceptive deficits with unsteadiness that is worse in the dark $\rightarrow$ spasticity $\rightarrow$ paraplegia $\rightarrow$ bowel and bladder dysfunction. Dementia (confusion, memory impairment, irritability… occurs in advanced cases due to cerebral white matter changes. Visual disturbances with or without optic atrophy may be due to optic nerve demyelination
   3. labs:
      a) serum B$12$: the most sensitive test. However, normal B$12$ levels do not R/O B$12$ deficiency. If there are neurologic symptoms then check malonic acid or other markers of B$12$ deficiency such as methylmalonic acid (also check homocysteine to R/O folate deficiency)
      b) CBC: most (but not all) patients will have a macrocytic (megaloblastic) anemia. Folic acid deficiency also produces megaloblastic anemia. Folic acid corrects the anemia, even with CSD, but not the neurologic deficits which may actually worsen.
      c) Schilling test: determines the cause of the B$12$ deficiency even if B$12$ injections have already been given (radiolabeled cyanocobalamin is given orally, followed by a parenteral flushing dose of nonradioactive vitamin, and the percentage of radioactivity is measured in the urine over 24 hours, performed once without and then once with added intrinsic factor, and then once following antibiotic therapy)
   4. imaging: T2WI MRI may demonstrate increased signal within the white matter of the spinal cord, predominantly in the posterior columns but may also be seen in spinothalamic tracts
5. treatment: B$12$ injections q 1–3 months or large doses of oral preparations\textsuperscript{19} (other transport systems independent of intrinsic factor results in absorption of $\approx 1\%$ of orally administered B$12$, doses of 300–100,000 mcg result in absorption of more than the daily requirement of 1–2.5 mcg)
6. toxins: e.g. local anesthetics used for spinal anesthesia rarely cause myelopathy
Infectious:
1. (para) spinal abscess, AKA spinal epidural abscess or epidural empyema (p.349) †: often history of staphylococcus infection, usually a skin furuncle. Vertebral osteomyelitis often accompanies. Produces local tenderness, back pain, fever, elevated ESR.
2. vertebral osteitis/osteomyelitis (p.353) †
3. pyogenic discitis †: spontaneous or following procedures (p.356)
5. tuberculosis: Pott’s disease, see Tuberculous vertebral osteomyelitis (p.354)
6. spinal meningitis with pachymeningitis
7. viral:
   a) herpes varicella-zoster: rarely causes necrotizing myelopathy
   b) Herpes simplex type 2: may cause ascending myelitis
   c) cytomegalovirus: may cause transverse myelitis
8. syphilitic involvement: may cause tabes dorsalis, syphilitic meningomyelitis, or spinal vascular syphilis. Diagnosed by serum and CSF serology
9. parasitic cysts †
10. some forms of Creutzfeldt-Jakob disease (CJD) with predominant initial muscle wasting may mimic spinal cord disease or ALS (p.367)

Peripheral neuromuscular disorder:
1. Guillain-Barré syndrome (GBS) (p.184): rapidly ascending weakness (mimics cord compression) with areflexia and near normal sensation
2. chronic dysimmune neuropathies: presumed to be immune mediated:22
   a) chronic immune demyelinating polyradiculoneuropathy (CIDP) (p.186): similar to GBS but can progress over a longer period of time
   b) multifocal motor neuropathy (MMN): characterized by asymmetric muscle wasting, cramping & LE twitching. May mimic ALS, but is treatable (with IVlg or immunosuppression)
3. myopathies: including steroid myopathy (usually affects proximal > distal muscles)

Motor neuron diseases:
1. amyotrophic lateral sclerosis (ALS) (p.183): upper and lower motor neuron disease. Slight spasticity of LES (extreme spasticity is rare), atrophic weakness of the hands and forearms, fasciculations in the UEs, absence of sensory changes (including lack of pain), sphincter control usually preserved
2. primary lateral sclerosis: age >50. No LMN signs. Slower progression than ALS (yrs to decades). Pseudobulbar palsy (p.178) is common.

† items with dagger may also present as a spinal epidural mass

92.3 Sciatica
92.3.1 General information
Definition: pain in the distribution of the sciatic nerve. The sciatic nerve is comprised of components of nerve roots of L4-S3. The nerve passes out of the pelvis through the greater sciatic foramen along the back of the thigh. In the lower third of the thigh it divides into the tibial and common peroneal nerves.

92.3.2 Etiologies
The most common cause of sciatica is radiculopathy due to a herniated lumbar disc.24 The differential diagnosis is similar to that for myelopathy (see above) but also includes:
1. congenital:
   a) meningeal cyst (perineural cyst): see Spinal meningeal cysts (p.1142)
   b) conjoined nerve root (p.275): initially dismissed as a possible cause of radiculopathy, but current thinking recognizes that these may be symptomatic possibly by tethering
2. acquired:
   a) spinal stenosis/spondylosis/spondylolysis/spondylolisthesis
   b) juxtafacet cyst: includes synovial cyst and ganglion cyst (p.1143) 25: detection is increasing with the use of MRI

† items with dagger may also present as a spinal epidural mass
c) nerve root sheath cyst: may be congenital or acquired. May arise near axilla of nerve root and cause compression of adjacent roots. Treatment: excise cyst and oversew the ostium
d) arachnoiditis ossificans (p.1408): rare. In the lumbar region may occur as columnar, cylindrical, or irregularly shaped masses. May produce low back pain, radiculopathy, or cauda equina syndrome
e) heterotopic ossification around the hip
f) injection injuries from misplaced IM injections
g) compartment syndrome of the posterior thigh
h) injury complicating total hip arthroplasty
i) radiation injury following treatment of nearby tumors

3. Infectious:
   a) discitis (p.356): usually causes excruciating pain with any movement
   b) Lyme disease (p.334)
c) herpes zoster: a rare cause of radiculopathy. Lumbar-sacral dermatomes are involved in ≈ 10–15% of zoster cases. Pain is usually independent of position. Typical herpetic skin lesions usually follow onset of pain by 3–5 days. 1–5% develop motor weakness (usually in arms or trunk). Sacral zoster can cause detrusor paralysis, producing urinary retention. 55% of those with motor symptoms have good recovery, 30% have fair to good recovery

4. Neoplastic:
   a) spine tumors: multiple myeloma (p.714), metastases (p.821)
   b) bone or soft-tissue tumors along the course of the sciatic nerve: may result in erroneous laminectomy for herniated lumbar disc. Pain is usually insidious in onset, and not positional (see below)
   - intra-abdominal or pelvic neoplasm
   - tumors of the thigh
   - tumors in the popliteal fossa or calf

5. Inflammatory:
   a) trochanteric bursitis (p.1101): may produce pseudoradiculopathy. Rarely extends to the posterior thigh or as far distally as the knee
   b) myositis ossificans of the biceps femoris muscle

6. VasculAr:
   a) sciatica may be mimicked by intermittent (i.e. vascular) claudication
   b) psoas hematoma: usually in patient on anticoagulant. Sometimes drainage is required

7. Referred pain of nonspinal origin: not dermatomal. Nerve root tensions signs (p.1101) are usually negative. Includes:
   a) pyelonephritis
   b) renolithiasis including ureteral obstruction
   c) cholecystitis
   d) appendicitis
   e) endometritis/endometriosis
   f) posterior perforating duodenal ulcer
   g) inguinal hernia, especially if incarcerated
   h) aortic dissection (p.1414)

8. Piriformis syndrome (PS): controversial. Piriformis muscle originates on anterior S2–4 VBs, sacro-tuberous ligament and passes through the greater sciatic notch to attach to the greater trochanter of the femur. It is innervated by L5-S1. It is the principle external rotator of the extended hip. It may irritate or compress the sciatic nerve (AKA pseudosciatica, can mimic symptoms of a herniated disc). The superior gluteal nerve is spared as it has a take-off proximal to the muscle. Conversely, PS may occur secondary to lower lumbar radiculopathy. Produces pain in the sciatic distribution and weakness of external rotation and abduction of the hip. Signs: Freiberg test (pain with forced internal rotation of the hip with thigh extension) or the Pace test (pain on resisted abduction/external rotation of the hip). No well designed studies of treatments. Advocated therapies include: PT, stretching, injection of the muscle localized by digital rectal exam taking care not to inject the sciatic nerve itself & piriformis muscle section. Sometimes long-lasting relief can follow injection with local anesthetic. Use of botulinum toxin (Botox®) injections has been described

9. More peripheral involvement (i.e. neuropathy) that may be confused with radiculopathy. Including:
   a) femoral neuropathy mistaken for L4 radiculopathy (see below)
   b) proximal sacral plexus lesion mistaken for S1 radiculopathy (see below)
   c) diabetic neuropathy (p.545) including diabetic amyotrophy
d) tumors (see below)
92.3.3 Extraspinal tumors causing sciatica

Pain characteristics: pain is almost always insidious in onset.\(^{30}\) It may be intermittent initially, but eventually all patients develop pain that is constant, progressive and unaffected by position or rest.\(^{30}\) Significant night pain is described in ≈ 80%.

Straight leg raising was positive in most, but in more than half the pain was localized to a specific point along the course of the nerve, distal to the sciatic notch.\(^ {30}\) Conservative treatment brings either no or only temporary relief.

Approximately 20% will have a previous history of tumor (usually neurofibromatosis or previous malignancy). Malignancies include\(^ {30}\): metastatic lesions, primary bone sarcomas (chondrosarcoma…), soft-tissue sarcomas (liposarcoma…). Benign tumors include: lipoma, neurofibroma, schwannoma, aneurysmal bone cyst of the sacrum, giant cell tumor of the sacrum, tenosynovial giant cell tumor.

In two-thirds of cases, a detailed medical history and physical exam allowed localization and even determining the nature (bone tumor vs. soft-tissue) of the lesion.\(^ {30}\) Radiographs that show the entire pelvis and the proximal femur will demonstrate almost all tumors in these locations.\(^ {30,32}\)

92.3.4 Features differentiating radiculopathy in sciatica

General information

Sciatica may result from nerve root involvement within the spinal canal (e.g. with lumbar disc herniation). Clinically this produces a nerve root syndrome; see Nerve root syndromes (p.1049). Spinal imaging studies (MRI, myelogram/CT) will usually detect nerve root compression here. More peripheral involvement may be difficult to image.

L4 involvement

Femoral neuropathy is often mistakenly identified as an L4 radiculopathy. Distinguishing features are shown in Table 92.2.

L5 involvement

Peroneal nerve palsy may be mistaken for L5 radiculopathy (p.1416).

S1 involvement

Outside the spinal canal, S1 can also be involved as it enters the sacral plexus, e.g. by a pelvic tumor. In plexus lesions, EMG will show sparing of the paraspinal muscles (nerves to paraspinal muscles exit in the region of the neural foramen) and the gluteus maximus and medius (superior and inferior gluteal nerves take-off just distal to the paraspinal nerves).

92.4 Acute paraplegia or quadriplegia

92.4.1 General information

Entities causing spinal cord compression usually present as: paraplegia or -paresis (or quadriplegia/ paresis), urinary retention (may require bladder ultrasound or checking a post-void residual to detect), and impaired sensation below level of compression. May develop over hours or days. Reflexes may be hyper- or hypo-active. There may or may not be a Babinski sign. Excluding trauma, the most common cause is compression by tumor or bone.

92.4.2 Etiologies

Some overlap with myelopathy.

1. in infancy (may produce “floppy infant syndrome”)
   a) spinal muscular atrophy (the most severe form is called Werdnig-Hoffmann disease and is usually fatal within months): autosomal recessive congenital disease of childhood with degeneration of anterior horn cells. Only rarely evident at birth (where it presents as a paucity of movement), produces weakness, areflexia, muscle and tongue fasciculations with normal sensation. Severe cases progress over the first year or two to quadriplegia
   b) spinal cord injury during parturition: a rare sequela of breech delivery
   c) congenital myopathies: e.g. infantile acid maltase deficiency (Pompe disease)
   d) infantile botulism: ileus, hypotonia, weakness, mydriasis, Clostridium botulinum bacteria and toxin in feces

2. traumatic spinal cord injury
   a) major trauma: diagnosis is usually evident
   b) minor trauma: may cause cord injury in setting of spinal stenosis, may → central cord syndrome; see Central cord syndrome (p.944)
   c) atlantoaxial dislocation: from major trauma or due to instability from tumor or rheumatoid arthritis

3. congenital
   a) extradural spinal cord compression by bone secondary to cervical hemivertebra (symptoms not present at birth, may develop decades later, occasionally after minor trauma)
   b) cervical stenosis (p.1088) (usually with superimposed spondylosis): quadriplegia or central cord syndrome may follow minor trauma
   c) achondroplastic dwarfism: spinal stenosis (animal model: dachshund)
   d) syringomyelia: usually presents with central cord syndrome

4. metabolic
   a) combined system disease* (p.1409)
   b) thallium poisoning: usually causes sensory and autonomic symptoms, quadriplegia and dystarthis may be seen in severe cases
   c) central pontine myelinolysis (p.115)

5. infectious
   a) epidural spinal infection (abscess or empyema)*
   b) post-viral (or post-vaccination): may be a transverse myelitis*

6. peripheral neuromuscular disorder*
   a) Guillain-Barré syndrome (p.186): classically an ascending paralysis, but paraparesis mimicking a spinal cord lesion is an unusual variant
   b) myopathies

7. neoplastic*: spinal cord tumors

8. autoimmune*

9. vascular
   a) acute pontomedullary infarction: age usually >50 yrs. Patient is quadriplegic, alert, with bulbar palsies (eye movement abnormalities, impaired gag and speech)
   b) spinal cord infarction*: including AVM, radiation myelopathy...

10. miscellaneous compressive*: including epidural hematoma, bony compression, epidural lipomatosis

11. functional: hysteria, malingering

12. bilateral cerebral hemisphere lesion (involving both motor strips): e.g. post-cerebral irradiation or parasagittal lesion. Will not have sensory level

* For items with asterisk, see Myelopathy (p.1407) for details.
92.5 Hemiparesis or hemiplegia

92.5.1 General information

May be produced by anything that interrupts the corticospinal tract from its origin in the pyramidal cells of Betz in the motor strip down to the cervical spine. This results an upper motor neuron paralysis (see Table 29.4) which should also produce long tract findings, including Babinski sign ipsilateral to hemiplegia.

92.5.2 Etiologies

Lesions of the cerebral hemisphere in the region of the contralateral motor strip. Large lesions may also involve sensory cortex producing reduced sensation ipsilateral to the hemiparesis

1. tumor (neoplasm): primary or metastatic
2. traumatic: epidural or subdural hematoma, hemorrhagic contusion of the brain, compression by depressed skull fracture
3. vascular:
   a) ischemic: embolic, low flow (due to atherosclerosis, arterial dissection...)
   b) hemorrhagic: intracerebral hemorrhage, aneurysmal SAH...
4. infection: cerebritis, abscess

Lesions of the contralateral internal capsule. Produces pure motor hemiplegia without sensory loss. Most common etiology is ischemic lacunar infarct

Lesions of the brainstem. Ischemic infarct, hemorrhage, tumor

Lesions of the cervicomedullary junction. Foramen magnum lesions (p.1367).

Unilateral spinal cord lesions. Above C5 ipsilateral to the weakness producing a Brown-Séquard syndrome (p.947) with contralateral sensory loss to pain and temperature. See etiologies (p.947).

Hypoglycemia. Can sometimes be associated with hemiparesis that clears after administration of glucose

Note. In a patient with unexplained hemiparesis/hemiplegia, especially after trauma, consider carotid dissection.

92.6 Low back pain

92.6.1 General information

The following considers primarily low back pain (LBP) without radiculopathy or myelopathy, although some overlap occurs. Trauma is usually obvious and is not discussed. See Sciatica (p.1410) for differential diagnosis of that and also Low back pain and radiculopathy (p.1414) for evaluation.

92.6.2 Acute low back pain

Similar to list for myelopathy (p.1407). Most cases are non-specific (e.g. lumbosacral sprain), only 10–20% can be given a precise pathoanatomical diagnosis:

Patients writhing in pain. Should be evaluated for an intraabdominal or vascular condition (e.g. pain of aortic dissection is typically described as a “tearing” pain): patients with neurogenic LBP tend to remain as still as possible, possibly needing to change positions at intervals

Unrelenting pain at rest:
1. spinal tumor (intradural or extradural) (p.1032)
   a) primary or metastatic spine tumor: suspected in patients with pain duration >1 month, unrelied by bed rest, failure to improve with conservative therapy, unexplained weight loss, age >50 yrs
b) nocturnal back pain relieved by aspirin is suggestive of osteoid osteoma or benign osteoblastoma (p.792) 36

2. infection (especially in IV drug abusers, diabetics, post spinal surgery, immunosuppressed patients, or those with pyelonephritis or UTI post-GU surgery). Fever is somewhat insensitive for spinal infections. Spine tenderness to percussion has 86% sensitivity with bacterial infections, but a low specificity of 60% 35. Types of infections include:

a) discitis
b) spinal epidural abscess: should be considered in patients with back pain, fever, spine tenderness, or skin infection (furuncle)

c) vertebral osteomyelitis

3. inflammatory

4. sacroilitis: may produce pain and tenderness over one or both SI joints. Pelvic x-rays may show sclerosis of one or both sacroiliac joints.

a) bilateral & symmetric
   • ankylosing spondylitis (p.1123): morning back stiffness, no relief at rest, improvement with exercise. 34 Usually seen in males with symptom onset before age 40 yrs. Positive Patrick’s test (p.1048) and pain on compressing the pelvis with the patient in the lateral decubitus position
   • Reiter syndrome (after Hans Reiter, a German bacteriologist): a reactive arthritis (usually 1–3 weeks following certain bacterial infections) with involvement of at least one other non-joint area (urethritis, uveitis/conjunctivitis, skin lesions, mucosal ulcerations…). 75% are HLA-B27 positive
   • may occur in Crohn’s disease
b) bilateral & asymmetric
   • psoriatic arthritis
   • rheumatoid arthritis: adult & juvenile forms

c) unilateral
   • gout
   • osteoarthritis
   • infection

Evolving neurologic deficit. (Cauda equina syndrome: perineal anesthesia, urinary incontinence or urgency or retention, progressive weakness) all require emergent diagnostic evaluation to rule-out treatable conditions such as:

1. spinal epidural abscess (p.349)
2. spinal epidural hematoma (p.1131)
3. spinal tumor (intradural or extradural) (p.783)
4. massive central disc herniation (p.1051)

Pathologic fracture. Acute pain in patients at risk for osteoporosis or with known Ca should prompt evaluation for pathologic fractures

1. lumbar compression fracture: see Osteoporotic spine fractures (p.1008)
2. sacral insufficiency fracture: especially in rheumatoid arthritis patients on chronic steroids, often with no antecedent history of trauma. May cause back pain and/or radiculopathy. Often missed on plain films, best seen on CT, but may also be detected on bone scan

Coccydynia (p.1038). Pain and tenderness around the coccyx

Tears in the anulus fibrosus. (“Anular tears”) (NB: also present in 40% of asymptomatic patients between 50–60 yrs age, and 75% between 60–70 yrs 40)

Rarely following subarachnoid hemorrhage. (SAH) due to irritation of lumbar nerve roots and dura; usually accompanied by other signs of SAH (p.1156)

Myalgia. May be a side-effect of “statins” (drugs used to lower serum concentration of LDL cholesterol) with or without elevation of serum creatinine phosphokinase, sometimes with accompanying weakness and rarely with severe rhabdomyolysis and myoglobinuria leading to renal failure (risk may be increased with renal or hepatic dysfunction, advanced age, hypothyroidism, or serious infection) 41

Drug induced:

1. statins: see above under myalgia
2. phosphodiesterase type 5 (PDE5) inhibitors used for erectile dysfunction: all may be associated with LBP, but the incidence is higher with tadalafil, etiology unknown. Usually occurs 12–24 hours post-dose and resolves by 48 hours. Most respond to simple analgesics.

92.6.3 Subacute low back pain

10% of patients with LBP have symptoms that persist >6 weeks. Differential diagnosis includes causes of acute LBP (above) and also:

1. continued pain at rest should prompt evaluation for spinal osteomyelitis (especially with fever and elevated ESR) or neoplasm if not already done

2. plain spine x-rays may show possibly causative conditions, although many or all of the following may also be seen in asymptomatic patients:
   a) spondylolisthesis (p.1098)
   b) spinal osteophytes
   c) lumbar stenosis
   d) Schmorl’s node or nodule (p.1060): disc herniation through cartilaginous end-plate into vertebral body (NB: may also be seen in 19% of asymptomatic patients)

Chronic low back pain

After 3 months, only ≈ 5% of patients with LBP will continue to have persistent symptoms. A structural diagnosis is possible in only ≈ 50% of these patients. These patients account for 85% of the cost in lost work and compensation.

Differential diagnosis includes causes of acute and subacute LBP listed above, as well as:

1. degenerative conditions
   a) degenerative spondylolisthesis (p.1099)
   b) spinal stenosis (affecting the spinal canal)
   c) lateral recess syndrome

2. spondyloarthropathies
   a) ankylosing spondylitis: look for erosive changes adjacent to SI joint and positive test for HLA-B27 antigen
   b) Paget’s disease of the spine: vertebral involvement is very common in a patients with Paget’s disease

3. osteitis condensans ili: increased density in ilium, usually asymptomatic (incidental) finding.

   Occasionally may produce low back pain or tenderness. Usually found in women who have been pregnant

4. psychological overlay: including secondary gain (financial, emotional…)

92.7 Foot drop

92.7.1 General information

**Key concepts**

- weak anterior tibialis (foot extension) innervated by deep peroneal nerve (L4, 5)
- most common etiologies: L4/L5 radiculopathy, common peroneal nerve palsy
- in a patient with foot drop, check posterior tibialis (foot inversion) and gluteus medius (internal rotation of flexed hip) – both are spared in peroneal nerve palsy and both should be involved with L4/5 radiculopathy
- EMG can assist in localization and prognostication

Definition: weakness of anterior tibialis (primarily L4 and to a lesser extent L5), often accompanied by a weak extensor digitorum longus and extensor hallucis longus (primarily L5 with some S1 contribution), all of which are innervated by the deep peroneal nerve.

92.7.2 Underlying substrates of foot drop

The most common dilemma is to distinguish foot drop due to radiculopathy from that due to peroneal nerve palsy (usually common peroneal nerve). With common peroneal nerve (CPN) palsy, there
is sparing of posterior tibialis (foot inversion, innervated by posterior tibial nerve) and gluteus medius (internal rotation of the thigh with the hip flexed, innervated by superior gluteal nerve, primarily L5 with some L4, the takeoff is shortly after the roots exit from neural foramen). With L4 or L5 root lesions these muscles will also be weak, see Fig. 92.1.

Flail foot results from paralysis of dorsiflexors plus plantarflexors, e.g. in sciatic nerve dysfunction as can occur during surgery for hip fracture/dislocation or injection injuries (IM injections should be give superiorly and laterally to a line drawn between the posterior superior iliac spine and the greater trochanter of the hip). NB: the peroneal division of the sciatic nerve tends to be more vulnerable to injury than the tibial division.

92.7.3 Etiologies of foot drop
Three major categories: 1) muscular, 2) neurologic, 3) anatomic.
1. peripheral nerve palsies (more common). See Table 92.3 and Fig. 92.1.
   a) peroneal nerve injury (also, see Common peroneal nerve palsy (p.535) for details including etiologies). Branches that may be involved:
      • deep peroneal nerve: isolated foot drop with minimal sensory loss (except possibly in great toe web space)
      • superficial peroneal nerve: weakness of peroneus longus and brevis (foot eversion) with no foot drop. Sensory loss: lateral aspect of lower half of leg and foot
      • common peroneal nerve: combination of above (i.e. foot drop + weak foot eversion, with sparing of tibialis posterior (foot inversion). Sensory loss: lateral aspect of lower half of leg and foot)
   b) L5 radiculopathy: (or, less commonly, L4). The most common cause is HLD at L4–5, other etiologies include: lumbar spinal stenosis at L4–5, sacral ala fracture (p.1014)
      • results in pain and/or sensory changes in L5 (or L4) dermatome
      • weakness with radiculopathy tends to be more pronounced in distal muscles (e.g. anterior tibialis) than in proximal (e.g. gluteus maximus)
      • painless foot drop is unlikely to be due to radiculopathy; consider peroneal neuropathy, diabetic neuropathy, lesion anywhere along pyramidal tract, motor neuron disease…
   c) lumbar plexus injury
   d) lumbosacral plexus neuropathy (p.544)
   e) injury to lateral trunk of sciatic nerve

a x denotes that the indicated muscle is involved (i.e. weak)
b see footnote (b) under Fig. 92.1
f) peripheral neuropathy: weakness tends to be greater distally, producing wrist or foot drop. Classic example: Charcot-Marie-Tooth (p. 541), findings tend to be rather dramatic in spite of the fact that it often doesn't seem to bother the patient very much

g) early in the course of motor neuron disease (ALS)

h) heavy metal poisoning

2. central nervous system causes (foot drop here is usually painless)
   a) cortical lesion (UMN): parasagittal lesions in region of motor strip (sensation will be spared if the lesion does not extend posteriorly to the sensory cortex). There may be a Babinski sign or hyperactive Achilles reflex (so-called “spastic foot drop”). Usually painless
   b) spinal cord injury: including cervical spinal myelopathy

3. non-neurogenic causes
   a) muscular dystrophy
   b) lead toxicity: in children may cause foot drop with no sensory loss
   c) anterior compartment syndrome

92.7.4 Clinical

Loss of dorsiflexion causes foot slap with the front of the foot when the heel strikes the ground while walking. Also during the swing phase of gait the front of the foot may snag the ground (especially on

<tr>
<td>quadriceps femoris innervated by the femoral nerve</td>
<td>(same as above)</td>
<td>weakness of knee extension (L2, L3, L4)</td>
</tr>
<tr>
<td>muscles innervated by L5 branches that exit the lumbar plexus very close to the neural foramina</td>
<td>involvement indicates very proximal lesion (e.g. nerve root or very proximal (paravertebral) lumbar plexus)</td>
<td>weakness of: 1. gluteus medius (L4, L5, S1): internally rotate thigh 2. gluteus maximus (L5, S1, 2): dig heel into bed while supine</td>
</tr>
<tr>
<td>L5 innervated muscles (via sciatic nerve) proximal to the take off of the common peroneal nerve\a</td>
<td>if muscles listed above are intact, involvement of muscles to the right localizes the lesion to sciatic nerve above mid thigh (e.g injury to sciatic nerve at the greater sciatic notch)</td>
<td>1. slight weakness of biceps femoris (lateral hamstrings) (L5, S1, 2): flex the knee (with thigh flexed) 2. gastrocnemius weakness (foot plantarflexion) unless injury only to peroneal division of sciatic nerve\b</td>
</tr>
<tr>
<td>Muscles innervated by (posterior) tibial nerve</td>
<td>sparing of these with foot drop indicates lesion distal to take off of common peroneal nerve (foot drop with weak foot inversion may be L4 or 5 radiculopathy)</td>
<td>weakness of tibialis posterior (L4, L5): invert foot (foot should be plantarflexed to eliminate anterior tibials)</td>
</tr>
<tr>
<td>anterior tibialis innervated by deep peroneal nerve</td>
<td>involvement does not narrow down etiology until other muscles are examined</td>
<td>weakness of ankle dorsiflexion (foot drop)</td>
</tr>
<tr>
<td>muscles innervated by superficial peroneal nerve</td>
<td>preservation of these with foot drop localizes the lesion to the deep peroneal nerve</td>
<td>weakness of the peroneus longus and brevis (L5, S1): evert the foot</td>
</tr>
</tbody>
</table>

**Abbreviations:**
- CPN = common peroneal nerve
- DPN = Deep Peroneal nerve
- IGN = inferior gluteal nerve
- SGN = superior gluteal nerve

\a: Note: EMG can differentiate root lesion from plexus by detecting involvement of paraspinal muscles which occurs in root but not in plexus lesions since dorsal rami exit proximal to plexus

\b: The peroneal of the sciatic nerve is more vulnerable to injury than the tibial division for several reasons. It is thus not unusual to see isolated peroneal nerve injuries above the knee e.g. from hip dislocation or fractures, stab wounds, injection injuries, etc.

---

Fig. 92.1 Physical exam to localize the lesion in a patient with LE weakness
uneven surfaces) which may cause tripping; thus patients develop steppage gait (exaggerated thigh & knee flexion) on the affected side. Associated weakness of tibialis posterior, when present (e.g. with L5 radiculopathy) destabilizes the ankle permitting eversion which also predisposes to falls and to ankle fractures. Chronic foot drop may produce achilles tendon contracture with talipes equinus. Wasting of the extensor digitorum brevis may be seen.

92.7.5 Evaluation
1. bloodwork: glucose, ESR
2. EMG: can help differentiate L5 radiculopathy from peroneal nerve palsy, plexus lesion (Fig. 92.1) or motor neuron disease (p. 182) (for details). EMG is not reliable until symptoms have been present at least ≈ 3 weeks
3. For suspected radiculopathy: MRI (or CT/myelogram if MRI is not possible)

92.8 Weakness/atrophy of the hands/UEs
92.8.1 Hand/UE weakness or atrophy with relatively preserved function in the LEs
1. cervical spondylosis (p.1083): often causes sensory disturbance
2. cervical radiculopathy (p.1069)
3. amyotrophic lateral sclerosis (ALS): no sensory involvement. One of the few causes of clinically prominent fasciculations. See details of ALS (p.1410), other distinguishing features (p.1410), fibrillations (p.505)
4. spinal cord pathology
   a) central cord syndrome (p.944): typically causes more involvement (weakness, sensory disturbance) in the UE than the LE
   b) syringomyelia (p.1144): usually burning dysesthesias of the hands with dissociated sensory loss
5. brachial plexus injury (p.550)
6. brachial plexus neuropathy (includes Parsonage-Turner syndrome) (p.542)
7. peripheral nerve problems, including
   a) carpal tunnel syndrome (p.519)
   b) ulnar neuropathy (p.526)
   c) other peripheral nerve entrapment syndromes (p.515)
8. foramen magnum lesions (p.1367): can cause (Bell’s) cruciate paralysis due to compression above the pyramidal decussation which produces bilateral UE weakness and possibly atrophy of the hands with sparing of the LEs (in the differential diagnosis for central cord syndrome).
   Compression on one side may produce the similarly named but clinically different hemiplegia cruciata (spastic palsy of one UE and the contralateral LE)
9. thoracic outlet syndrome (p.554)
10. botulism (p.1399)
11. pharyngeal-cervical-brachial variant of Guillain-Barré syndrome (p.186)

92.8.2 Atrophy of the first dorsal interosseous muscle
Etiologies: either C8/T1 nerve root or ulnar nerve involvement (either may be focal or diffuse). There are 4 main differential diagnoses:
1. ulnar neuropathy: check median nerve to see if findings extend to a nearby but separate nerve
   a) at the elbow (p.531)
   b) at Guyon’s canal (p.531)
2. nerve root involvement:
   a) cervical radiculopathy: C8 or T1
   b) nerve root avulsion: weakness + sensory loss with normal SNAP on EMG (p.243) usually with a history of precipitating trauma
3. lower brachial plexus involvement
   a) thoracic outlet syndrome (p.554)
   b) Pancoast tumor (p.542)
4. neurodegenerative disorders
92.9 Radiculopathy, upper extremity (cervical)

See Weakness/atrophy of the hands/UEs (p.1420). In addition to those items:

1. primary shoulder pathology: characteristically, pain is aggravated by active and/or passive shoulder movement. In general, shoulder pathology does not produce pain referred to the neck
   a) rotator cuff tear
   b) bicipital tendonitis: tenderness over biceps tendon
   c) subacromial bursitis: there may be tenderness over the AC joint
   d) adhesive capsulitis
   e) impingement syndrome: the “empty can test” is usually positive (each arm held out in front, 30° lateral to straight forward, thumbs pointing down, as in emptying out a soda can. Examiner pushes down on the patient’s hands while the patient resists. Test is positive if it reproduces pain)

2. shoulder pain is very common in polymyalgia rheumatica (p.198), typically worsens with movement

3. interscapular pain: a common location for referred pain with cervical radiculopathy, may also occur with cholecystitis or some shoulder pathologies

4. MI: some cases of cervical radiculopathy (especially left C6) may present with symptoms that are suggestive of an acute myocardial infarction

5. complex regional pain syndrome AKA reflex sympathetic dystrophy (p.497): may be difficult to distinguish from cervical radiculopathy. Stellate ganglion blocks may help.

92.10 Neck pain (cervical pain)

This section deals primarily with axial neck-pain without radicular features. For radicular features, see Radiculopathy, upper extremity (cervical) above.

1. cervical spondylosis (including facet arthritis)

2. cervical sprain: including whiplash associated disorder

3. fracture of the cervical spine: with upper cervical spine fractures (e.g. odontoid), patients characteristically hold their head in their hands, especially when going from recumbent to upright position
   a) traumatic
   b) pathologic (tumor invasion, rheumatoid arthritis)

4. occipital neuralgia (p.515)

5. herniated cervical disc:
   a) lateral herniated disc: if symptomatic, tends to produce more radicular symptoms in the UE than actual neck pain
   b) central disc herniation: if symptomatic, tends to produce myelopathy, does not produce any neck pain whatsoever in many cases

6. abnormalities of the craniocervical junction:
   a) Chiari I malformation (p.277)
   b) atlantoaxial subluxation

7. fibromyalgia: idiopathic chronic pain syndrome characterized by widespread nonarticular muscularkeletal pain, nodularity and stiffness without pathologic inflammation. Possible link to neuroendocrine dysfunction. Affects 2% of the population, female: male ratio is 7:1. No diagnostic laboratory study. May be associated with psychiatric illness and multiple non-specific somatic complaints including malaise, fatigue, impaired sleep, GI complaints and cognitive impairment

8. Eagle’s syndrome: elongation of the styloid process. Surgical resection can ameliorate the pain.
   Two variants:
   a) typical variant: history of tonsillectomy. Pharyngeal pain, dysphagia and otalgia
   b) second variant: AKA carotid artery-styloid process syndrome. Carotiddynia radiating into ipsilateral eye and vertex

9. crystal deposition diseases: gout, pseudogout, hydroxyapatite (HA) or calcium pyrophosphate dihydrate (CPPD) crystal deposition diseases. May appear as a crown-like density encompassing the odontoid process (crowned-dens syndrome) representing calcifications in the transverse ligament, seen best on cervical CT. May be treated with a short course of prednisolone (e.g. 15 mg/d) followed by NSAIDs
92.11 Burning hands/feet

1. spinal cord syndromes:
   a) central cord syndrome (CCS) (p.944)
   b) burning hands syndrome (p.937): a possible variant of CCS, described in football-related cervical spine injury
   c) numb-clumsy hand syndrome (p.1085): seen in cervical myelopathy
2. complex regional pain syndrome (CRPS) AKA reflex sympathetic dystrophy (p.497)
3. peripheral neuropathy
   a) diabetic amyotrophy AKA Bruns-Garland syndrome (p.545)
4. erythermalgia AKA erythromelalgia: rare disorder characterized by erythema, edema, increased skin temperature, and burning pain of the hands and/or feet. Usually refractory to medical management, some success reported with epidural bupivacaine, lidocaine patches, or cold soaks
   a) primary erythermalgia: etiology is idiopathic
   b) secondary erythermalgia: associated with autoimmune and rheumatologic factors
5. vascular:
   a) occlusive arterial disease: atherosclerosis, Raynaud’s syndrome
   b) venous insufficiency

92.12 Muscle pain/tenderness

1. fibromyalgia: see above
2. myopathy
3. statin induced myopathy: can vary from mild (with symptoms of muscles aches, symptoms usually abate rapidly after discontinuation of the statin although, occasionally up to 2 months may be required) to severe (with rhabdomyolysis which can → nephropathy)
4. diffuse severe sensitivity to light touch is a marker of nonorganic pain

92.13 Lhermitte’s sign

92.13.1 General information

Technically, a symptom (not a sign). Electrical shock-like sensation radiating down the spine usually provoked by neck flexion (shocks radiating up the spine are sometimes referred to as reverse Lhermitte’s sign). Classically attributed to MS, but may occur in any process involving primarily the posterior columns of the spinal cord.

92.13.2 Etiologies

1. multiple sclerosis (MS) (p.179)
2. cervical spondylosis
3. subacute combined degeneration (p.1409): check for vitamin Bl2 deficiency
4. cervical cord tumor
5. cervical disc herniation
6. radiation myelopathy (p.1563)
7. Chiari type I malformation (p.277)
8. central cord syndrome (p.944)
9. SCIWORA (spinal cord injury without radiographic abnormality) (p.999)

92.14 Swallowing difficulties

1. mechanical: the term globus describes a sensation of a lump in the throat
   a) ossification of the anterior longitudinal ligament (OALL) (p.1129)
   b) diffuse idiopathic skeletal hyperostosis (DISH) (AKA Forestier disease) (p.1129): An enthesopathy
   c) post-op following ACDF
      • it is normal to have a little swelling and fullness early post-op
      • may be increased with multiple levels and with anterior plating
      • as a complication from post-op hematoma
2. neurologic

93 General Information

93.1 Introduction

This section provides information useful in the O.R. that apply to a number of different topics. Some items that are pertinent to only one topic will be found in that section instead (e.g. transsphenoidal tumor removal is found in the section on pituitary tumors).

REMEMBER: before performing any invasive procedure, know the patient’s coagulation status (history of anticoagulant and/or antiplatelet function medications, and if indicated: PT, PTT, INR, platelet count and platelet function assay, FDP...).

93.2 Intraoperative dyes

This section covers visible dyes that may be useful in the operating room. For radio-opaque dyes, see Contrast agents in neuroradiology (p.219). There is little information available in the literature regarding the intrathecal (IT) use of the following agents.

Indigo carmine: a blue dye which has been used intrathecally to locate CSF leaks. There are few published reports, and no accounts of adverse effects. In 1933 a report of IT injection of 5 ml of 0.6% indigo carmine solution produced blue-green discoloration of the CSF draining through a fistula into the nose within 15 minutes, lasting for 5 hours, with no indication of toxicity. It is excreted in the urine (and not in mucous membranes). The consensus is that it should be relatively safe for IT use, but the manufacturer did not recommend this application.

Methylene blue: methylene blue is probably cytotoxic and appears to become fixed to neural tissue. It should therefore not be used as a stain in neurosurgical operations or diagnostic tests. CNS damage (some permanent) occurred in 14 patients given an IT injection of a 1% solution. Symptoms included: paraparesis, quadriplegia, multiple cranial nerve involvement (including anosmia and optic atrophy), dementia and hydrocephalus.

Fluorescein: although intrathecal injection (e.g. to look for CSF leak) has been used by ENT surgeons with apparently acceptable results, there is a risk of seizures. 2.5% fluorescein is diluted 1:10 with CSF or saline and ≈ 6 ml is injected into the spinal subarachnoid space (or 0.5 ml of 5% fluorescein mixed with 5–10 ml of CSF³). Fluorescein has also been used IV (adult dose: 1 amp IV) to help mark areas of the brain where there is breakdown of the blood brain barrier (BBB), e.g. in tumors (p.596), however, fluorescein is eventually excreted in mucus, urine, etc., and just about everything turns orange. It has also been used to perform intraoperative “visible angiograms” during the removal of AVMs.

Indigocyanine green (ICG): used for intraoperative angiography (p.1597).

93.3 Operating room equipment

93.3.1 Operating microscope – observer’s eyepiece

For spine cases, the ideal location of the observer eyepiece is usually directly opposite the surgeon. For intracranial work, the observer’s (assistant’s) eyepiece is placed to right of operator’s except in the following cases where it is placed to the left:

1. transsphenoidal surgery (when the surgeon stands to the patient’s right)
2. right posterior fossa craniotomy in the lateral oblique (suboccipital) position

93.3.2 Head stabilization

General information

Options include

1. Non-pin head stabilization: When absolute head fixation is not indicated, the following options avoid some of the complications associated with pin-based head fixation (see below):
   a) Horse-shoe head rest
   b) Doughnut fashioned out of stockinette
   c) Prone-view® for prone position e.g. during posterior spine surgery
2. Pin-based head-fixation: The most common system is the Mayfield head-holder.
Pin-based head-fixation

Indications for pin stabilization:
1. Not recommended for use in age <3 years, use pediatric pins with care in ages 3–10 years (this age cutoff is not based on scientific evidence, most reported complications occur in age >3 years)
2. Craniotomies:
   a) Most intracranial vascular operations: a radiolucent head-holder should be used if intraoperative angiogram is to be performed
   b) Often for tumor operations, especially if there is need for a self-retaining retractor system that attaches to the Mayfield head-holder (e.g. Budde halo)
   c) When intraoperative image-guidance (IG) systems are used (an alternative here is to use mask-based or strap-on registration array holders)
3. Cervical spine: often used for posterior cervical operations (laminctomies, instrumentation, fusions…)

Application of pin head holder:
1. “Skull block” (p.1434) (blockade of scalp innervation) may be administered prior to pin placement. Critical for awake craniotomies (for the wake-up), and for vascular cases and cases with increased ICP where the block blunts the precipitous increase in blood pressure that may otherwise accompany pinning which may → increased ICP. For technique, see Typical sequence of anesthesia (p.1434).
2. Plan pin placement
   a) The manufacturer recommends that the pins be placed within a band-like area similar to a “sweatband” worn just above the orbits and the pinna
   b) Avoid placing pins on the thin temporal squamosa, and use with caution over the frontal sinus
   c) The single pin is typically placed anteriorly when the patient is in the supine position (Fig. 94.5), for a posterior fossa approach in the prone position, if the craniotomy is on one side the single pin is placed on that side
   d) The pins in the dual pin “rocker” should be equidistant from the centerline for maximal stability
3. Appropriately sized sterile pins are placed in the head-holder:
   a) Children <3 yrs age: increased risk of calvarial penetration or depressed skull fractures. A padded cerebellar head rest should be used instead
   b) Children ≥3 yrs age and <10 yrs age: special pediatric pins should be employed (these pins have a “shoulder” to insure shorter depth of penetration)
4. The pins are often coated with appropriate antibiotic ointment
5. The clamp is squeezed together, allowing the ratchet gears to slide, until the pins are initially seated in the skull
6. The knob housing the tension spring and gauge is tightened (each ring = 20 lbs)
   a) Adults: tighten until the third ring (60 lbs) is visible; up to 80 lbs has been described
   b) Pediatrics: less pressure should be applied, 30–40 lbs has been suggested.

Complications of pin head-fixation:
1. Malposition of pins:
   a) Through unintended anatomic structures: pinna, orbit, superficial temporal artery, shunt hardware, prior craniotomy defect
   b) Poor fixation by not properly placing pins close to “equator” resulting in movement during surgery (with risk of cervical spine injury, injury to structures being operated on due to the sudden movement, loss of image guided registration) and possible skin laceration
2. Skin penetration by pins: can cause injury to intracranial structures, infection including delayed abscess, epidural hematoma...
   a) Overtightening of pins
   b) Incorrect pin selection: see above
   c) Soft skull: in elderly patients, poorly calcified skulls, pediatric patients
3. Skin necrosis: especially with pediatric pins due to the “shoulder” of the pins
4. Skull fracture: including “ping-pong ball” fractures in young children
5. Slippage of any of the joints or connections to the O.R table
6. Clamp breakage: inspect the head-holder for cracks prior to each application, store properly and maintain per the manufacturer’s specifications
7. bleeding from pin site: usually when the head-holder is removed. If bleeding does not stop after a minute or so of pressure, a suture or surgical staple may be used

93.4 Surgical hemostasis

93.4.1 Basic options

1. thermocoagulation
   a) electrical coagulation:
      • bipolar cautery: current passes only between the tips of the cautery device. Used for precise coagulation. When used directly on or near to the brain or nerves, the current setting is typically reduced from that employed for general use
   b) thermal units: e.g. AccuTemp® disposable eye cautery units (particularly useful to coagulate dura when inserting a ventriculostomy in the ICU)
   c) laser: especially neodymium:yttrium-aluminum-garnet (Nd:YAG) laser

2. mechanical
   a) bone wax: originated by Sir Victor Horsely. Inhibits bone formation
   b) ligature: less commonly used in neurosurgery than other specialties
   c) “silver clips” (e.g. HemoClips®)

3. chemical hemostasis: see below

93.4.2 Chemical hemostasis

See review for more information. Some key points:

1. gelatin sponge (Gelfoam®): no intrinsic coagulating effect. Absorbs 45 times its weight in blood which causes it to expand and tamponade bleeding. Absorbable. May be combined with thrombin as patties or as powder (e.g. FLOSEAL®, SurgiFlo®)

2. oxidized cellulose (Oxycel®) and oxidized regenerated cellulose (Surgicel®): absorbable. Acidic material that reacts with blood to form a reddish brown “pseudoclot.” Bactericidal to over 20 different organisms. May retard bone growth. Oxycel® interferes with epithelialization more than Surgicel®

3. microfibrillar collagen (Avitene®): promotes adhesion and aggregation of platelets. Loses effectiveness in severe thrombocytopenia (<10,000/ml). May be used on bone bleeding. Remove excess material to reduce risk of infection

4. thrombin (Thrombostat®): does not depend on any intermediate physiological agent. Caution: although thrombin may cause significant edema when placed on brain where the pia has been disrupted, practical experience indicates this is uncommon

93.5 Craniotomy general information

93.5.1 Cranial perforators

Perforators are one means used to create burr holes which enable the surgeon to access the brain for intracranial procedures. Many brands of perforators are designed with a slip clutch that disengages the drill and stops the outer shaft from spinning and entering the skull once the central part of the drill penetrates the inner table. While these clutches are generally reliable and immensely helpful, there is a possibility of malfunction such that the outer shaft continues to rotate and if it penetrates the inner table, the entire drill can plunge into the brain. In 8 months of 2005 the FDA received reports of 200 injuries as a result of the drill failing to disengage. The FDA released a number of recommendations to reduce the risk of injury, excerpts of which are shown here:

- select the appropriate perforator based on the skull thickness (pediatric vs. adult)
- keep the perforator perpendicular to the skull throughout the drilling process
- do not rock, rotate, or change the angle of the device during drilling
- avoid using excessive pressure on the drill. Brace the hand holding the drill on the other hand which should rest on the patient’s skull, and thereby prevent plunging if the drill completely penetrates the skull
- use caution when:
  - drilling through areas of irregular bone contour, curvature or variations in thickness
drilling on skulls of infants/children, the elderly, or any other patient who might have softer bone consistency (including osteogenesis imperfecta...)

- perforating bone in an area where the bone might be diseased or incompetent or have loose fragments

93.5.2 Intraparenchymal cyst aspiration

When a cystic tumor or intracerebral hemorrhage is being operated on, an attempt should be made to insert a ventricular needle into the lesion and aspirate some but not all of the cyst contents. This often produces significant decompression. Avoid evacuating all of the contents otherwise the lesion might be difficult to find. The needle may then be left in place to allow localization of the lesion (or the needle track can be followed, which may occasionally be difficult).

93.5.3 Intra-operative brain swelling

Background

Under certain circumstances during surgery, the brain may start to severely swell out of the craniotomy wound. Etiologies of this emergency situation include:

1. extraparenchymal bleeding: from a vessel or intraoperative aneurysm rupture, remotely situated epidural/subdural hematoma
2. intracerebral hemorrhage
3. venous outflow obstruction
4. vasodilatation induced by hypercarbia
5. severe diffuse cerebral edema following stroke or traumatic brain injury (TBI)

Management

First efforts should be aimed at ruling out and correcting the aforementioned causes as well as some adjunctive measures. Most maneuvers are similar to those used in controlling an ICP crisis. During the process, it is critical to try to avoid having the brain compress itself against the craniotomy bone edges which can lacerate the cortex and can also further compromise cortical veins which impairs venous outflow causing more brain edema and swelling which accelerates the vicious cycle.

1. elevate the head of the patient (e.g. with reverse Trendelenburg of the O.R. table)
2. make sure the jugular veins are not kinked: this may require rotating the head by loosening the pivot that connects the table adapter to the Mayfield head holder and rotating the head to a more neutral position
3. rule-out hypercarbia: make sure the endotracheal tube is not kinked, check the patient’s end-tidal pCO2
4. measures to lower ICP and protect the brain
   a) give Mannitol 1 gm/kg IV bolus
   b) drain CSF if an option: from adjacent cistern or lumbar drain
   c) have anesthesiologist hyperventilate to a PCO2 of 30–35 mm Hg
   d) have anesthesiologist induce burst suppression
5. emergently intubate patients who are undergoing awake craniotomy
6. consider intraoperative ultrasound if rapidly available to rule-out hematoma (intracerebral, EDH, SDH) which could potentially be immediately evacuated
7. during the above steps, place a moist sponge on the surface of the brain and gently but firmly apply evenly distributed pressure to push the brain back into the wound
8. if all else is failing, the craniotomy flap can be enlarged as much as possible to create a decompressive craniotomy. Enlarging the skin incision to do so is preferable to having too small a bony opening which risks brain compression/laceration against the edges. The skin is closed without the bone flap and without dural closure as in a decompressive craniectomy (p. 1467)
9. a last ditch life-saving measure for continued uncontrollable swelling which is to be taken under advisement with eloquent cortex: use a gloved hand to sweep the herniating brain out of the wound (i.e. remove it from the patient)

93.5.4 Craniotomy pre- and post-op management

Risks

Many risks cannot be generalized for all craniotomies and are specific to various tumors, aneurysms, etc. General information:
1. post-operative hemorrhage
   - overall risk of post-operative hemorrhage: 0.8–1.1%
   - The most common indication for craniotomy in these series was for meningioma, followed by trauma, aneurysm, and then intrinsically supratentorial tumors.
   - 43–60% of the hematomas were intraparenchymal, 28–33% epidural, 5–7% subdural, 5% intrasellar, 8% mixed, 11% confined to superficial wound. Overall mortality was 32%
   - Hematoma may occur at the surgical site or in remote locations, e.g. intracerebellar hemorrhage after pterional and temporal craniotomies

2. in craniotomy for brain tumor:
   - risk of anesthetic complications: 0.2%
   - increased neurologic deficit in 1st 24 hours post-op: ≈ 10%
   - wound infection: 2%

3. postoperative headache (p.1431)

**Pre-op orders**

1. For tumor: if patient on steroids, give 50% higher dose 6 hrs before and on-call to O.R. (stress doses); if not on steroids give dexamethasone 10 mg PO 6 hrs before and on call to O.R. (in A.M., give with sip water)

2. antiepileptic medication
   - if there is a history of seizures:
     - if already on antiepileptic drugs (AEDs) continue same doses
     - if not on AEDs, load with Keppra 500 mg or oral PHT (may give 300 mg PO q 4 hrs × 3 doses (total 900 mg) to load orally)
   - if no history of seizures
     - if surgery does not require a cortical incision (e.g. aneurysm) then AEDs are generally not used
     - if a cortical incision is anticipated, option to load with AEDs as above

3. prophylactic antibiotics: (optional) ideally 30–60 minutes before incision. For most antibiotics, it is given in the O.R. before the skin incision. For antibiotics that take a long time to infuse (e.g. vancomycin) it may help to order it to be given “on call to O.R.”

4. DVT prophylaxis: pneumatic compression boots or knee-high TED® hose

**Post-op orders**

Guidelines (individualize as appropriate) for patient to be extubated

1. admit PACU, transfer to ICU (neuro unit if available) when stable
2. VS: q 15 min x 4 hrs, then q 1 hr. Temperature q 4 hrs x 3 d, then q 8 hrs. Neuro check q 1 hr
3. activity: bed rest (BR) with HOB elevated 20–30°
4. knee high TED hose or pneumatic compression boots
5. I & O q 1 hr (if no Foley: straight cath q 4 hrs PRN bladder distension)
6. incentive spirometry q 2 hrs while awake (do not use following transsphenoidal surgery)
7. diet: NPO except minimal ice chips and meds as ordered
8. IVF: NS + 20 mEq KCl/L @ 90 ml/hr
9. O₂: 2 L per NC
10. meds:
   - dexamethasone (Decadron®): if not on chronic steroids, give 4 mg IV q 6 hrs. Otherwise give stress doses based on patients current dose and length of treatment
   - H₂ antagonist, e.g. ranitidine 50 mg IVPB q 8 hrs
   - Anti-epileptic drug (AED) especially when cerebral cortex is violated: typically Keppra® (levetiracetam): 500 mg PO or IV q 12 hours. If there is no prior history of seizure, typically discontinue after ≈ 1 week
   - Cardene® drip: titrate to keep SBP < 160 mm Hg and/or DBP < 100 mm Hg (use cuff pressures, may use A-line pressures if they correlate with cuff pressures)
   - codeine 30–60 mg IM q 3–4 hrs PRN H/A
   - acetaminophen (Tylenol®) 650 mg PO/PD q 4 hrs PRN temperature > 100.5° F (38 C)
   - continue prophylactic antibiotics if used: (e.g. cefazolin (Kefzol®) 500–1000 mg IVPB q 6 hrs x 24 hrs, then D/C)
11. labs:
   - CBC once stabilized in ICU and q d thereafter
   - renal profile once stabilized in ICU and q 12 hrs thereafter
   - ABG once stabilized in ICU and q 12 hrs x 2 days, then D/C (also check ABG after any ventilator change if patient on ventilator)
12. call M.D. if any deterioration in crani checks, for T>101° (38.5 C), sudden increase in SBP, SBP<120, U.O.<60 ml/2-hrs

13. post-op CT: non-contrast post-op head CT is performed if the patient does not return to baseline neurologic function within a reasonable amount of time, also, performed routinely at many institutions following all craniotomies

93.5.5 Postoperative deterioration

General information

When the postoperative neurologic status is worse than pre-op, especially in a patient who deteriorates after initially doing well following surgery, emergency evaluation and treatment is indicated.

Possible etiologies:

1. hematoma (p.1429)
   a) intracerebral hemorrhage (ICH)
   b) epidural hematoma: at or remote from surgical site
   c) subdural hematoma

2. cerebral infarction
   a) arterial
   b) venous infarction: especially with surgery on or around the venous sinuses (p.1466)

3. postoperative seizure: may be due to inadequate anticonvulsant levels, and may be exacerbated by any of the above (see below for management)

4. acute hydrocephalus

5. pneumocephalus; also see Pneumocephalus (p.887):
   a) tension pneumocephalus: see Tension pneumocephalus (p.888)
   b) simple pneumocephalus: the simple presence of air in the cranium can cause neurologic symptoms even if not under tension (as would commonly occur following the now outdated pneumoencephalogram). Symptoms include: lethargy, confusion, severe headache, nausea & vomiting, seizures. Air may be located over the cerebral convexities, in the p-fossa, and/or in the ventricles and usually resorbs with symptomatic improvement in 1–3 days

6. edema: may improve with steroids
   a) worsening of cerebral edema: moderate post-op worsening of cortical function of immediately adjacent brain is not unexpected in many operations, and is usually transient. However, reversible etiologies (such as subdural hematoma (SDH)) must be ruled out
   b) traction or manipulation of cranial nerves may cause dysfunction that may be temporary.

Division of cranial nerves can cause permanent dysfunction

7. persistent anesthetic effect (including paralytics): unlikely in a patient who deteriorates after initially doing well post-op. Consider reversing medication given during surgery (caution re hypertension and agitation), e.g. naloxone, flumazenil (p.298), or reversal of pharmacologic muscle block (p.136)

8. vasospasm: following SAH or may be due to manipulation of blood vessels

Postoperative seizure management

1. intubate if patient does not rapidly regain consciousness, is not protecting airway, or has labored respirations

2. CT scan: rule out hematoma (intracerebral or extra-axial) or hydrocephalus

3. anticonvulsants:
   a) draw blood for appropriate anticonvulsant level
   b) bolus with additional anticonvulsants: do not wait for levels

93.5.6 Postoperative headache

General information

Persistent headache (H/A) is well described following posterior fossa craniectomy (incidence range: 0–83%[17]). The time course in one series[18] was: 23% at 3 mos, 16% at 1 yr, and 9% at 2 yrs.

Persistent H/A may also be observed following supratentorial craniotomy[19] (prevalence 1 year after anterior temporal lobectomy for seizures: 12%[18]). The “syndrome of the trephined” was first described in the French literature during World War I, and consisted of: headache and sometimes pulsatile pain (usually localized to the area of the skull defect), amnesia, inability to concentrate, insomnia... similar in some ways to postconcussive syndrome (p.923).
These H/A have been attributed to: traction on the dura when the bone is not replaced, tension on the dura due to tight dural closure, temporalis or nuchal muscle dissection, nerve entrapment in the closing sutures or in the healing scar, intradural blood and/or bone dust, CSF leak.\textsuperscript{19}

**Prevention**

No single method or group of methods has been successful in completely eliminating the complaint of post-op H/A.\textsuperscript{20,21} Until further research can further advance the understanding of the cause and prevention of these H/A, it seems reasonable to employ the following measures as much as possible in an attempt to minimize these debilitating symptoms: restoring function of the temporalis or suboccipital musculature, rigid fixation of bone flaps, cranioplasty for large craniectomies, meticulous tension-free dural closure (using duraplasty when necessary), and keeping intradural blood clot and bone dust to the minimum possible.\textsuperscript{22} Cranioplasty following posterior fossa surgery for vestibular schwannoma reduced the incidence of post-op H/A from 17\% to 4\%.\textsuperscript{23}

**Treatment**

Initially, symptomatic treatment is indicated. Referral to a H/A specialist may be appropriate when it becomes apparent that the H/A are not resolving spontaneously after \approx 3 months.\textsuperscript{22}

**93.6 Intraoperative cortical mapping (brain mapping)**

**93.6.1 General information**

Indications: typically used to locate motor strip, sensory cortex, or speech centers intraoperatively for surgery in and around these eloquent areas. Localization of these areas based on visible anatomy alone is unreliable. These techniques are typically employed in seizure surgery as well as in treating lesions in areas of eloquent brain.

Some techniques require an awake patient, with the surgery being done under local anesthesia with sedation. Motor and sensory cortex can also be localized in anesthetized patients using SSEPs (see below).

**93.6.2 Phase reversal method for localizing primary sensory and motor cortex**

**General information**

Utilizes intra-operative SSEPs to localize primary sensory and motor cortex in patients under general anesthesia (as opposed to using brain mapping techniques in awake patients).\textsuperscript{24,25}

**Technique**

See anesthesia requirements for intraoperative EP monitoring (p.107). A strip grid is placed on the surface of the brain perpendicular to the anticipated orientation of the central sulcus. SSEP stimulation is performed while recording through the strip grid. Phase reversal of the N20/P20 peak between a pair of electrodes in the strip grid indicates that those electrodes straddle the central sulcus (Fig. 93.1) with primary motor cortex located anteriorly, and sensory cortex posteriorly. The grid is then repositioned and the test is run again to verify the findings.

**93.6.3 Awake craniotomy**

**General information**

Usually employed for brain mapping, especially for speech areas. Numerous techniques and protocols have been described. Typically, the patient is temporarily anesthetized with short acting agents (inhalational and/or injectable). This is supplemented with local anesthetic. The craniotomy is then performed and the patient is allowed to wake up while the brain is exposed to permit neurophysiologic testing during surgery. If (short-acting) paralytics are used, it is critical to reverse these agents 15–30 minutes prior to applying the electrical stimulation and that a train-of-four muscle twitch can be elicited.
**Booking the case: Awake craniotomy**

Also see defaults & disclaimers (p. 27) and pre-op counselling (see below).

1. **position:** depends on lesion location, with pin headholder (for image guided navigation if used)
2. **equipment:**
   a) microscope if needed e.g. for tumor dissection
   b) image guided navigation system (if used)
   c) ultrasonic aspirator (for tumors)
3. **anesthesia:** pre-op consult for “awake craniotomy” & skull block
4. consult neurology or neuropsychology to be available during surgery for intra-op neurologic testing for “awake craniotomy”
5. EEG techs to perform intra-op EEG and provide brain stimulator
6. **post-op:** ICU
7. **consent** (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery on the brain to be performed with periods where the patient will be woken up for testing, (plus whatever else is planned, e.g. removal of tumor, removal of seizure source...)
   b) alternatives: the same surgery under general anesthesia, nonsurgical management, (for some diagnoses, e.g. tumor, radiation therapy)
   c) complications: (usual craniotomy complications: stroke, bleeding, coma, death, infection, seizures), difficulty accurately mapping the desired areas of the brain

**Indications**

1. surgery in eloquent brain (near motor strip (Brodmann’s area 4 in Fig. 1.1) or speech/language centers (Wernickes & Broca’s areas)) or thalamus, including tumors and epileptic foci
2. removal of brainstem tumors
3. some seizure surgery to look for seizure focus

**Contraindications to awake craniotomy**

1. patient unlikely to be able to cooperate: very young or very elderly patients, confused patients, those with significant speech deficits already present or language barrier

**Patient counselling pre-op**

Patients need to be aware of what the sequence of events will be and what will be expected of them. It may be helpful to have them practice reading some typical material that will be used in the O.R.
Patients over age ≈ 40 usually need reading glasses to see written material, and they should have their own available in the O.R., although the temples (earpieces) usually can’t be accommodated. The patient should be advised that there may be some pain involved.

**Patient positioning for surgery**

Significantly more time must be spent on patient positioning to ensure that they will be as comfortable as possible without moving. Extra padding is employed. Access to the patient’s face is necessary for the anesthesiologist and the neurophysiologist.

**Typical sequence for anesthesia**

See reference \(^{26}\)

1. in the pre-op holding area, load with Precedex® (dexmedetomidine) 0.5 mcg/kg IV over 20 minutes followed by intra-op infusion at 0.4–1.0 mcg/kg/hr

2. induction of anesthesia utilizes propofol 3 mg/kg IV followed by laryngeal mask airway (LMA) placement

3. skull block\(^4\): injection of local anesthetic (e.g. 30 ml of 0.5% bupivacaine) to permit the skin incision and also rigid head fixation with pins (as required for image navigation devices, and situations where no head movement can be tolerated during surgery) without pain at the time of the wake-up. Injection at 4 regions on each side as shown in Fig. 93.2:

![Diagram of skull block infiltration sites](image)

Fig. 93.2 Infiltration sites for skull block
supraorbital & supratrochlear nerves: 2 ml injected 1.5 cm above the supraorbital foramen above the medial third of the orbit. NB: if you are going to use surface matching to register the patient for image guidance (e.g. BrainLab or Stealth), injecting here may deform the skin and affect the registration accuracy. Consider injecting a lower volume of higher concentration agent (e.g. 2% lidocaine)

auriculotemporal nerve: 5 ml injected 1.5 cm anterior to the tragus. Caution: to avoid anesthetizing the facial nerve, inject just deep to the subcutaneous tissue

postauricular branches of the greater auricular nerve: 2 ml 1.5 cm posterior to the antitragus

greater, lesser & third occipital nerves: inject 5 ml with a 22 gauge spinal needle at the mastoid process and proceed along the nuchal ridge until the midline is reached

4. start inhalational anesthesia with 0.5 MAC desflurane with the patient breathing spontaneously while the scalp incision, craniotomy, and dural opening are performed (the dura is pain sensitive, the brain is not)

5. as the dural opening is begun, the desflurane is turned off and a remifentanil infusion of 0.1–0.2 mcg/kg/min IV is started

6. by the time the dural opening is completed, the desflurane has usually worn off and the LMA can be removed

7. remifentanil is then titrated for pain control

8. neurophysiologic testing can usually be performed at this time (e.g. below)

9. the operation may often be carried to completion with the patient awake, although once the intracranial part of the operation is completed, more pain relief may be desired and general anesthesia may be needed for pain control or agitation (LMA may suffice here)

93.6.4 Speech mapping

General information
Typical settings for a constant current generator using a bipolar electrode are shown in Table 93.1. If a voltage based unit is used, start at 1 volt and increase.

Techniques for speech mapping
There are numerous methodologies. One protocol:

1. requires awake craniotomy

2. once temporal lobe is exposed, a recording electrode strip is place on the brain surface

3. using a bipolar stimulator, start with a low current (e.g. 2 mA) and begin stimulate an area of cortex for 3–5 seconds, and observe for afterdischarges (akin to a focal seizure) on the recording strip. If no afterdischarges, increase the current in 2 mA increments up to a maximum of ≈ 10 mA. If afterdischarges occur, back off by 1–2 mA and then test that area for speech changes as follows

4. stimulate cortex while patient names objects shown on picture cards (automatic verbalization, such as counting, is robust and may persist). Observe for effects ranging from total speech arrest to paraphasic errors

5. repeat the above steps at the next area (first finding threshold for afterdischarges and then stimulating while testing)

93.7 Cranioplasty

93.7.1 Indications

1. cosmetic restoration of external skull symmetry
2. relief of symptoms due to craniotomy defect (p. 1431)
3. protection from trauma (blunt or penetrating) in area of post-craniotomy or posttraumatic skull defect

93.7.2 Timing

In certain cases, no consensus is possible. To avoid the risk of infection, some authors recommend delaying cranioplasty with a “foreign body” (e.g. tantalum mesh) at least 6 months after an open (i.e. contaminated) wound or one that traverses the nasal sinuses. Others perform primary closure at the time of repair of the skull fracture. In “clean” cases (e.g. repair of defect after removing hemangioma of the skull) there is little argument against immediate cranioplasty.

93.7.3 Material

Options for material include:
1. the patient’s own bone if it was previously removed in a sterile fashion and saved either in a sterile manner under refrigeration, or in an abdominal pocket at the time of craniectomy
2. materials that can be formed by the surgeon
   a) methylmethacrylate: mixed in the O.R., molded to desired shape, and allowed to set before being attached to the skull usually with plates (alternatively, sutures or wire may be used). Setting is an exothermic reaction and ample irrigation and preferably removal from the operative site during the process avoids undesirable transmission of heat to the brain
   b) mesh: may be made of titanium or tantalum.
3. pre-fabricated custom flaps may be made by a number of commercial vendors using thin-cut CT scans to generate computer models of the defect and, if available, to use the contralateral side as a “mirror image” model for the desired shape
   a) methylmethacrylate
   b) PEEK (poly-ether-ether-ketone)
   c) titanium
4. split thickness calvaria

When foreign material is used, some recommend perforating the flap with a dozen or so drill holes to prevent the accumulation of fluid (either underneath the flap, or between the flap and the skull). This cannot be done with tantalum plates.

Localizing levels in spine surgery

Identifying the correct level in spine surgery may be extremely challenging in certain situations. With the proliferation of minimally invasive spine techniques and the associated reduction in the structures that are directly visualized, the reliance on intraoperative imaging to determine the spinal level has increased.

Potential pitfalls which increase the chances of error, including:
1. pre-op, pathology is usually identified on MRI, and there are problems in translating MRI images to imaging available in the O.R.
   a) thoracic lesions: pre-op MRI usually counts from the top (C2) down, and in surgery it is often necessary to count from the bottom up, the count could be off if there are not 5 lumbar vertebra and 12 pairs of ribs
   b) lumbar spine: a well developed S1–2 disc (so-called lumbarized S1) or an L5 vertebra fused to the sacrum (sacralized L5) can confuse the count
2. not all patients have 12 ribs, or 5 “lumbar” vertebrae. In the modal (most common) human spine, there are 24 presacral vertebrae, however some individuals have 23 and others have 25 (variations include: 11 or 13 rib bearing vertebrae, or a lumbosacral transitional vertebrae; the terminology of a “lumbarized S1 vertebrae” or a “sacralized L5 vertebrae” is imprecise and confusing). A HLD at the ultimate disc space (usually L5-S1) most often impinges on the 25th nerve root (however, in the variant cases, it may actually impinge on the 24th or 26th root).
3. patients may have variant or ambiguous anatomy (e.g. a well-developed S1–2 disc space, an enlarged L1 transverse process which mimics a rib)

4. some “landmarks” used for localizing levels are unreliable or changeable

5. plain radiographs (and fluoroscopy) has difficult imaging the upper thoracic and sometimes the lower cervical spine
   a) on lateral imaging, the shoulder often obscure lower cervical/upper thoracic levels
   b) on AP imaging, the pronounced kyphosis of this region requires cranio-caudal angulation of the x-ray beam, which throws off imaging at other levels

6. spinous processes of lumbar and especially thoracic levels are below the corresponding VB

7. changes may occur between the time of the pre-op imaging and the surgery

Aids in determining spinal levels:
1. image guided systems, when available
2. some O.R. suites have intra-op MRI or CT (or CT-like modalities, e.g. O-arm™ by Medtronic or ARCADIS® C-arm by Siemens) or image guided spine technology
3. pre-op plain x-rays: lumbar (for lumbar pathology) and lumbar + thoracic (for thoracic pathology) to verify there are 12 thoracic vertebrae and 5 lumbar
4. on lateral lumbar spine x-rays, the top of the iliac crests are even with the L4 spinous process or the L4–5 interspinous space
5. on sagittal MRI there are generally no numbering cues, but on axial MRI, the sacral ala are reliably identifiable and this can be used to identify L5-S1 disc space
6. counting methods (if possible, using more than 1 method is highly recommended)
   a) counting up from T12 or L5 on fluoro: be sure there are 12 ribs. You can “bridge” from lumbar or lower thoracic spine to higher thoracic levels using an instrument on the patient as a marker, or you can count up to one level (e.g. T9) and then while a hemostat is placed at this level on the fluoro screen, under real-time fluoro the machine is slowly moved up the spine and the hemostat is moved along with T9 (to count up from L5, verify there are 5 lumbar (i.e. non-rib bearing) presacral vertebrae). Radiation safety: avoid live fluoro as much as possible
   b) AP view: starting at T12 (lowest rib) or from L5
   c) lateral view: starting at the L5 and counting up
   d) counting down from T1 (first rib) on AP fluoro: the fluoro machine may need to be angled caudally from the anterior position because of the thoracic kyphosis. Sometimes counting pedicles helps
   e) by palpation: with thoracotomy, in the upper T-spine you can palpate the ribs from the inside from T1 and count down. The rib inserts at the upper end of the thoracic vertebra near the junction with the VB above (e.g. the T5 rib joins T5 close to the T4–5 disc space)

93.8 Bone graft

93.8.1 Use of bone graft extenders/substitutes as an adjunct to fusion

**Practice guideline: Bone graft extenders and substitutes**

Level I[^3]: autologous bone or recombinant human bone morphogenic protein (rhBMP-2) bone graft substitute is recommended in the setting of an ALIF in conjunction with a threaded titanium cage

Level II[^4]:
- rhBMP-2 in conjunction with hydroxyapatite and tricalcium phosphate may be substituted for autograft in some cases of posterolateral fusion
- calcium phosphate is recommended as a bone graft extender, especially when combined with autologous bone
93.8.2 Assessing surgical lumbar fusion

See Practice guideline: Radiographic assessment of fusion (p.1438).

Practice guideline: Radiographic assessment of fusion

Level I\(^9\): static x-rays alone are not recommended
Level II\(^9\):
- in the absence of rigid instrumentation, lack of motion between vertebrae on lateral flexion/extension x-rays is highly suggestive of successful fusion
- technetium-99 bone scanning is not recommended

Level III\(^9\): radiographic techniques, often in combination, may be used when failed lumbar fusion is suspected, including: static and flexion/extension x-rays, CT scan

Practice guideline: Correlation between fusion and outcome

Level III\(^9\): the correlation between fusion and clinical outcome is not strong, and in any given situation fusion status may be unrelated to outcome

93.8.3 Bone graft properties

General information

For spine fusions, components of bone graft that are important for fusion:
1. osteoinduction: recruitment of mesenchymal cells and the stimulation of these cells to develop into osteoblasts and osteoclasts
2. osteogenesis: formation of new bone by host or graft mesenchymal stem cells transformed into osteoblasts
3. osteoconduction: the structure of the graft that acts as a scaffold upon which new bone and blood vessels form
4. mechanical stability: the structural anatomical biomechanical support provided, e.g. following discectomy, corpectomy or resection of vertebral tumor

Table 93.2 summarizes the properties of various bone graft materials (adapted\(^{31,32,33}\)). See the sections that follow for more details.

Autograft

Common donor sites: iliac crest, rib, fibula, bone removed during decompression. Characteristics:
1. PROS: no histocompatibility or disease transmission issues
2. CONS:
   a) persistent post-op donor site pain: occurs in as many as 34% of patients (the severity of which was graded as "unacceptable" in 3%)
   b) increased surgical risks of:
      • blood loss
      • wound infection
      • fracture
      • cosmetic deformity
      • increased operative time to procure
      • numbness from nerve injury (e.g. cluneal nerves see below)
      • hematoma
3. subtypes
   a) cancellous bone: provides all graft components except mechanical stability
   b) cortical bone:
      • provides superior and immediate mechanical strength
      • has diminished osteoinduction and osteoconduction capacity
   c) corticocancellous bone: e.g. tricortical iliac crest wedge. Contains all bone graft components
   d) vascularized autograft:
      • technically challenging
      • best suited for areas that are scarred, irradiated, or that span long segments
   e) autologous bone marrow:
      • source of osteoprogenitor cells and osteoinductive substrates
      • diminished donor site risks
      • no osteoconductive nor structural properties

Allograft

Acquired through organ procurement agencies. Primarily frozen or freeze dried. Donor sites include: ilium, tibia, fibula, femur, rib.
1. PROS: eliminates risks associated with harvesting autograft
2. CONS:
   a) small but real risk of disease transmission
   b) provide only osteoconduction (lacks osteoinduction and osteogenesis)
   c) availability may vary from time-to-time
3. subtypes
   a) tricortical block, bicortical plug, or unicortical dowel
   b) corticocancellous: matchsticks, crushed
   c) cancellous: cubes, block, crushed, bone powder
4. uses: allografts are acceptable for structural grafts such as in anterior spinal interbody fusion, where compressive forces are applied to the graft. However, for onlay grafts such as for posterior cervical fusion, the lack of osteoinductive and osteogenetic properties is a critical shortcoming

Demineralized bone matrix (DBM)

Prepared by acid extraction, reducing antigenicity, but preserving some osteoconductive and variable osteoinductive properties.
1. available as putty, gel, chips, granules or powder
2. primarily used as an adjunct to other grafting materials
3. CONS:
   a) increased cost
   b) variable efficacy between preparations and batches of the same preparation
   c) no mechanical or structural properties

Bone morphogenic proteins (BMP)

(AKA bone morphogenetic proteins). Biological compounds that induce the transformation of mesenchymal stem cells into osteoblasts (osteoinduction) with the potential to induce ectopic bone formation. There are ≈ 20 different proteins from the transforming growth factor-β family. Produced using recombinant DNA technology.
1. A carrier matrix is required to retain the soluble factor at the graft site (i.e., to prevent the BMP from diffusing into adjacent tissues, thereby reducing the desired effect and possibly inducing bone growth at undesired foci)

2. FDA approved in U.S. only for ALIF. Other uses are "off label"

3. Available preparations: rhBMP-2 (Infuse® by Medtronic)

4. PROS: increases fusion rates

5. CONS:
   a) expensive
   b) ectopic bone formation, bone resorption (so-called osteolysis) or remodelling at the graft site
   c) In anterior cervical spine surgery: neck swelling with airway compromise, hematoma, painful seroma

Collagen

Used primarily as a carrier for other osteoinductive, osteoconductive, or osteogenetic materials and as a composite with other graft extenders

1. PROS: contributes to vascular ingrowth, mineral deposition, and growth factor binding

2. CONS:
   a) minimal structural support
   b) potential immunogenicity

Ceramics

Includes tricalcium phosphate, calcium carbonate & hydroxyapatite.

1. PROS: no risk of disease transmission

2. CONS: only recommended for use as bone graft extenders (i.e., must be combined with autograft, bone marrow aspirate, BMP...)

93.8.4 Bone graft procurement

Iliac crest

Anterior iliac bone graft

Should be obtained at least \( \approx 3–4\,\text{cm} \) lateral to the anterior superior iliac spine (ASIS) to avoid the lateral femoral cutaneous nerve and to reduce the risk of avulsion fractures of the remaining ilium. When a tricortical graft is taken, keep the dissection in the subperiosteal plane and avoid electrocautery on the medial (inner) surface when detaching the iliacus muscle to avoid injury to the ilioinguinal, iliohypogastric and lateral femoral cutaneous nerves.

Posterior iliac crest bone graft

May be used to obtain corticocancellous strips or plates for onlay bone grafts, or tricortical grafts which may be used as strut grafts or for Cl–2 arthrodesis.

Posterior bone grafts (Fig. 93.3) are taken from the medial \( 6–8\,\text{cm} \) of the iliac crest to avoid the superior cluneal nerves (which cross the posterior iliac crest \( \approx 8\,\text{cm} \) lateral to the posterior superior iliac spine) with resultant buttock numbness or the development of painful neuromas. A vertical incision just medial to the posterior superior iliac spine usually works well.

The spine may sometimes be found on corpulent patients by locating the “dimple of Venus” (fossae lumbales laterales – indentation sometimes visible superior to the gluteal cleft, directly superficial to the sacroiliac joint) and incising slightly lateral to it. Avoid mistaking the sacrum for the iliac spine.

The gluteus maximus is dissected off the lateral surface subperiosteally. To avoid fractures extending into the iliac crest, a wide osteotome should be used to create a “stop cut”; alternatively, a sagittal saw may be used. Avoid penetration through the inner cortical surface of the crest so as not to enter the pelvis and possibly cause an intra-abdominal hematoma. Another potential complication is fracture extension into the greater sciatic notch with possible injury to the gluteal arteries and sciatic nerve among others. Once the graft is removed and cancellous bone is gouged out, the exposed bone surfaces should be waxed and closed system drainage should be used to reduce the risk of local hematoma formation.

Fibula

Autogenous fibular graft provides a high arthrodesis rate, but may be associated with significant morbidity, and so may be best reserved for salvage procedures. Preserve the proximal fibular head
to avoid injury to the peroneal nerve. At least 7 cm of distal fibular should be maintained to preserve ankle stability.\textsuperscript{34}

### 93.9 Stereotactic surgery

#### 93.9.1 General information

The term stereotactic (Greek: stereo = 3-dimensional, tactic = to touch) surgery was initially used in animals, and was based on atlases of three dimensional coordinates compiled from dissections. The term was then used for surgery performed in humans, usually for thalamic lesioning to treat Parkinsonism (see Surgical treatment of Parkinson’s disease (p. 1524)), where the target site to be lesioned was located relative to landmarks with intraoperative pneumoencephalography or contrast ventriculography. Use of this procedure fell off dramatically in the late 1960’s with the introduction of L-

dopa for Parkinsonism.\textsuperscript{39}

Current techniques would be more appropriately termed image-guided stereotactic surgery. In the first part of the procedure, a CT scan or MRI (or occasionally, angiogram) is performed. For increased precision, some sort of “fiducial” markers or frame is attached to the patient’s head during this image acquisition phase. Acceptable accuracy can often be obtained using high resolution thin cut imaging slices (usually with a 0 angle of the gantry) and then surface matching algorithms in the guidance system will match the pre-op CT/MRI to the patient’s head.

The second part of the procedure usually takes place in an operating room. The patient is “registered” with the pre-op images, and then tracking cameras follow the movement of instruments with appropriate attachments to show in “real-time” the location of the instrument with respect to the pre-op image. An important limitation to be aware of is the fact that the pre-op images are “historical” and are not updated as the surgical procedure alters the anatomy of the patient. For example, even the administration of mannitol can cause brain shifts that may cause the target of the surgery to move away from its pre-op location by several millimeters.
93.9.2 Indications for stereotactic surgery

1. biopsy (also, see below)
   a) deeply located cerebral lesions: especially near eloquent brain
   b) brain stem lesions: may be approached through the cerebral hemisphere\(^\text{46}\)
   c) multiple small lesions (p.333) (e.g. in some AIDS patients)
   d) patient medically unable to tolerate general anesthesia for open biopsy

2. catheter placement
   a) drainage of deep lesions: colloid cyst, abscess
   b) indwelling catheter placement for intratumoral chemotherapy
   c) radioactive implants for interstitial radiation brachytherapy\(^\text{47}\)
   d) shunt placement: for hydrocephalus (rarely used) or to drain cyst

3. electrode placement
   a) depth electrodes for epilepsy
   b) “deep brain stimulation” for chronic pain (requires electrophysiologic stimulation)

4. lesion generation
   a) movement disorders: Parkinsonism (p.1526), dystonia, hemiballismus
   b) treatment of chronic pain
   c) treatment of epilepsy (rarely used)

5. evacuation of intracerebral hemorrhage
   a) using an Archimedes’ screw device\(^\text{42,43}\)
   b) with adjunctive urokinase\(^\text{44,45}\) or recombinant tissue-plasminogen activator (p.1344) \(^\text{46}\)

6. stereotactic “radiosurgery” (p.1564) (see Stereotactic radiosurgery & radiotherapy)

7. to localize a lesion for open craniotomy (e.g. AVM,\(^\text{37}\) deep tumor)
   a) using a ventricular-type catheter
   b) using a blunt biopsy needle or introducer\(^\text{48}\)
   c) systems using visible light laser beam for guidance

8. transoral biopsy of C2 (axis) vertebral body lesions\(^\text{49}\)

9. “experimental” or unconventional applications
   a) stereotactic clipping of aneurysms\(^\text{50}\)
   b) stereotactic laser surgery
   c) CNS transplantation\(^\text{51}\): e.g. for Parkinsonism (p.1525)
   d) foreign body removal\(^\text{52}\)

93.9.3 Stereotactic biopsy

This section presents information regarding stereotactic brain biopsy (SBB) in general. For SBB in specific conditions, see the index entry for that condition. Biopsy may be through a small “cookie cutter” craniotomy, or through a smaller burr hole with a needle. Although it may be performed under local or general anesthesia, it is more commonly done under general.

Contraindications

1. coagulation disorders
   a) coagulopathies: bleeding diatheses, iatrogenic (heparin or coumadin)
   b) low platelet count (PC): PC < 50,000/ml is an absolute contraindication, it is desirable to get the PC ≥ 100,000

2. inability to tolerate general anesthesia and to cooperate for local anesthesia

Yield

The yield rate (i.e. the ability to make a diagnosis from a SBB) reported in large series in the literature ranges from 82–99% in nonimmunocompromised (NIC) patients, and is slightly lower in AIDS patients at 56–96%. Higher yield rates in AIDS may result from improved surgical technique and histologic evaluation.\(^\text{55}\)

The yield rate is higher for lesions that enhance with contrast on CT or MRI (99% in NIC patients) than with lesions that do not enhance (74%).\(^\text{54}\)

Complications

The most frequent complication is hemorrhage, although most are too small to have clinical impact. The risk of a major complication (mostly due to hemorrhage) in NIC patients ranges from 0–3% (with most < 1%), and 0–12% in AIDS.\(^\text{54}\) Higher complication rates seen in AIDS patients in some series may
be due to reduced platelet count or function, and to vessel fragility in primary CNS lymphoma. In NIC patients, multifocal high grade gliomas had the highest complication rate.

Infection is an infrequent complication with needle biopsy.

References

General Information 1443

94 Specific Craniotomies

94.1 Posterior fossa (suboccipital) craniectomy

94.1.1 Indications
To gain access to the cerebellum, cerebellopontine angle (CPA), to one vertebral artery, posterior brainstem, fourth ventricle, pineal region, or, using extreme lateral posterior fossa approach to the antero-lateral brain stem. See paramedian (p.1447) and midline (p.1450) suboccipital craniectomies for details.

94.1.2 Position

Options

Position options include:
1. sitting position: see below
2. lateral oblique (p.1446): patient three-quarters oblique (almost prone),
3. semi-sitting
4. supine with shoulder roll, head almost horizontal
5. prone
6. Concorde position: prone, thorax elevated, neck flexed and tilted away from the side on which the surgeon will be standing

Sitting position

Used less frequently than in the past because of associated complications and acceptable alternative positions (except for some specific circumstances). However, some experts feel that the risks of the sitting position have been greatly overstated.

Advantages
1. improved drainage of blood and CSF out of surgical site
2. enhanced venous drainage which helps reduce venous bleeding and also ICP
3. easy ventilation due to unencumbered chest
4. patient’s head may be kept exactly midline, aiding operator orientation, and reducing risk of kinking of vertebral arteries

Disadvantages/risks
1. possible air embolism (see below)
2. fatigue of operators hands
3. increased surgical risks from placement of CVP catheter (required to treat possible AE): e.g. pneumothorax with subclavian vein catheterization, thrombosis
4. risk of post-op hematoma at the operative site may be increased since potential venous bleeders may remain occult while the patient is sitting, but may manifest when patient returns to a horizontal position post-op. However, one study found no such increased incidence
5. risk of post-op subdural hematoma: 1.3% of p-fossa cases
6. possible brachial plexus injury: prevent this by not allowing patient’s arms to hang at the side. Instead, fold them across abdomen
7. midcervical quadriplegia: presumably due to flexion myelopathy. The combination of the sitting position with hypotension or neck flexion with possible compression of the anterior spinal artery, ± cervical bar, and elevation of the head thus reducing the arterial pressure may all contribute
8. sciatic nerve injury (piriformis syndrome): prevent this by flexing patient’s knees (reduces tension on sciatic nerve)
9. extent of post-op pneumocephalus is more pronounced, and may increase the risk of tension pneumocephalus; see Pneumocephalus (p.887)
10. venous pooling of blood in the LEs under anesthesia may cause relative hypovolemia and should be counteracted by binding the LEs prior to positioning
11. decreased cerebral blood flow due to lower hemodynamic arterial pressure

Air embolism (AE): A potentially fatal complication of any operation when an opening to air occurs in a non-collapsible vein (e.g. diploic vein or a dural sinus) when there is a negative pressure in the
vein (e.g. when the head is elevated above the heart). Air is entrained in the vein and can become trapped in the right atrium of the heart which may impair venous return causing hypotension. May also produce cardiac arrhythmias. Paradoxical air embolism can occur in the presence of a patent foramen ovale or pulmonary AV fistula, and may produce ischemic cerebral infarction.

Greater negative pressures occur in the sitting position due to the extreme elevation of the head, but AE can occur in any operation with the head elevated higher than the heart. Incidence: a wide range has been quoted in the literature, and depends on the monitoring method used: ≈ 7–25% incidence with the sitting position using Doppler monitoring is an estimate.

For operations with a significant risk of AE, a right atrial CVP line is recommended (to aspirate air), and monitoring for air embolism; options include: transesophageal echo (the most sensitive), precordial Doppler monitoring. (Although technically the risk of air embolism includes any case where the head is higher than the right cardiac atrium, practically it is limited to cases where the head of the bed is ≈>30° which is mostly limited to the sitting position for posterior fossa tumors.)

Diagnosis and treatment:
AE should be suspected in any operative case in which the surgical site is higher than the heart when there is any unexplained hypotension or decrease in EtCO₂

- transesophageal echocardiography (TEE). Bubbles can be seen on the 2D echo display
  pros: considered the most sensitive monitoring modality
  cons: significant false positive rate, expensive, invasive, requires experience and vigilance
- precordial doppler U/S; probe may be placed over 2nd to 4th intercostal space either to right or left of sternum, or posteriorly between the scapula and spine. AE is heralded by a change in sonic intensity and character at first by a superimposed irregular high-pitched swishing sound, and then as more air is entrained so called “mill wheel” or machinery sounds dominate
  pros: the most sensitive of the non-invasive techniques
  cons: difficult in morbidly obese patients and in certain patient positions (e.g. prone or lateral), interference from other sounds in the OR, requires vigilance

The earliest indication of AE may be a rise in the end-tidal nitrogen (requires mass-spectrometer on monitor), then a fall in the end tidal pCO₂ occurs. Machinery sounds in the precordial Doppler also suggest AE. Hypotension may develop. Measures shown in Table 94.1 should be immediately instituted.

### Lateral oblique position

AKA “park bench” position.
- Axillary roll for the down side arm (see Fig. 94.1) (or, position the patient so that the down side arm extends over the edge of the table and is held in place by a sling formed by the Mayfield table attachment with copious padding)
- Upper arm supported on pillows or towels (avoid using a Mayo stand which restricts the ability to laterally tilt the OR table during surgery)
- Adhesive tape to gently pull down on the upper shoulder
- Bring the patient’s back as close to the side edge of the table as possible (usually limited by the travel of the head clamp) to bring the patient closer to the surgeon
- Elevate thorax 10-15°
- Tilt the vertex of the head towards the floor (see below)
- Optional spinal drainage (usually for large tumors)
- Pillow between the legs
- Secure patient with adhesive tape over pads so the table can be “airplaned” (rolled) during the operation

Procedures, Interventions, Operations
For access to the porus acusticus or more caudally (e.g. for vestibular schwannomas; not necessary for microvascular decompression for trigeminal neuralgia).

Get the shoulders out of the way by flexing the neck as much as possible while maintaining patent airway (aided by use of non-kinking wire-reinforced ET tube, so-called “armored tube”). The upper shoulder is retracted caudally by adhesive tape (avoid excess traction which may injure brachial plexus).

Head positioning
A Mayfield head-clamp is placed with the single pin on the side of the lesion, slightly anterior to a true-lateral on the skull (Fig. 94.2.). The head is then rotated 20–30° face-down from the horizontal.

94.1.3 Paramedian suboccipital craniectomy

Indications
1. access to the cerebellopontine angle (CPA)
   a) CPA tumors, including:
      • vestibular schwannoma
      • CPA meningioma
      • epidermoid
b) microvascular decompression  
  • trigeminal neuralgia  
  • hemifacial spasm  
  • miscellaneous: geniculate neuralgia, glossopharyngeal neuralgia

2. lesions of one cerebellar hemisphere:  
   a) tumors: metastases, hemangioblastomas…  
   b) hemorrhage within cerebellar hemisphere

3. access to vertebral artery  
   a) aneurysms: PICA, vertebrobasilar junction  
   b) vertebral endarterectomy

4. access to antero-lateral brainstem tumors (extreme lateral p-fossa approach)  
   a) foramen magnum tumors, including: chondomas, meningiomas

Position, skin incision, craniectomy, approach…

See list of alternatives (p. 1445). See lateral oblique position (p. 1446).

Skin incision

Linear (paramedian) incisions  
Access to CPA. For microvascular decompressions and small CPA tumors, a linear incision provides adequate exposure and involves less trauma to overlying muscles, and may be easier to get water-tight closure than with midline incision. For all of the following, the linear skin incision is located 5 mm medial to the mastoid notch (a palpable landmark, Fig. 94.3):  
1. “5–6–4” incision (incision placed 5 mm medial to mastoid notch, extending from 6 cm above notch to 4 cm below). High enough to expose transverse sinus:  
   a) for approach to fifth nerve: microvascular decompression for trigeminal neuralgia
2. “5–5–5” incision (5 mm medial, extending 5 cm up to 5 cm down), used for approach to seventh/eighth nerve complex:  
   a) microvascular decompression for hemifacial spasm  
   b) small vestibular schwannoma
3. “5–4–6” incision (5 mm medial, extending 4 cm up to 6 cm down): used for approach to lower cranial nerves:  
   a) glossopharyngeal neuralgia

“Hockey-stick” incision  
Useful for cerebellar hemispheric lesions as well as for larger CPA lesions where getting the muscles out of the way will facilitate maneuvering instruments about the posterior fossa. Incision is made in the midline starting at ≈ C2 spinous process, proceeding superiorly to just above the inion, and then laterally to just beyond the mastoid tip (Fig. 94.4). A short optional caudal curve may be made laterally to further remove the muscle from the operative field.

Craniectomy

Landmarks  
The location of the inferior margin of the transverse sinus is quite accurately estimated at two finger-breathths above the upper limit of the mastoid notch (usually just above the superior nuchal line). This should be the upper limit of the skull opening.

For microvascular decompression  
Craniectomy ≈ 2 cm diameter placed in the angle between transverse and sigmoid sinuses.

For small tumors (<2.5 cm)  
Craniectomy ≈ 4 cm diameter placed in the angle between transverse and sigmoid sinuses.

For large tumors  
A larger craniectomy may be needed, the size of which is limited by:  
1. transverse sinus superiorly  
2. foramen magnum inferiorly (which may be opened as prophylaxis against tonsillar herniation in the event of p-fossa edema post-op)
Fig. 94.3 Paramedian suboccipital craniectomy

Fig. 94.4 "Hockey-stick" skin incision
3. sigmoid sinus laterally (opening mastoid air cells is acceptable, but to prevent CSF leak, these must be packed with bone wax and muscle (or bone dust from craniectomy), and may be covered with reflected dura or fascia)
4. midline medially (unless the tumor extends across the midline)

For approach to lower cranial nerves
(e.g. for glossopharyngeal neuralgia).
Cranietomy is extended inferiorly to ≈ 1/2 cm above foramen magnum.

Burr hole for emergency ventriculostomy
Optionally placed prophylactic occipital burr hole (Frazier burr hole) usually for intraparenchymal cerebellar tumors or any situation where post-op swelling or hydrocephalus is likely (not commonly used for microvascular decompression or small vestibular schwannomas).
Location: 3–4 cm from midline. In adults, 6–7 cm above the inion; in pediatrics, 2–3 cm above the transverse sinus (i.e. ≈ 3–4 cm above the inion).
See Post-op management (p. 1451) for use.

Approach to the CPA
The angle of approach determines which portion of the posterior fossa is visualized.
1. retracting the cerebellum inferiorly (working in the junction of the tentorium and petrous bone) gives access to the region of the trigeminal nerve, e.g. for microvascular decompression for trigeminal neuralgia
2. medial retraction gains access to the region of the porus acusticus, e.g. for vestibular schwannomas
3. superior retraction gains access to the lower cranial nerves, e.g. for geniculate neuralgia

94.1.4 Midline suboccipital craniectomy

Indications
Access to the midline or both sides of the posterior fossa
1. midline posterior fossa lesions
   a) cerebellar vermian and paravermian lesions, including: vermian AVM, cerebellar astrocytoma near the midline
   b) tumors of the fourth ventricle: ependymoma, medulloblastoma
   c) pineal region tumors
   d) brainstem lesions: brainstem vascular lesions (e.g. cavernous angioma)
2. decompressive craniectomies
   a) for Chiari malformation
   b) cerebellar tumors: metastases, hemangioblastoma, pilocytic astrocytoma...

Position, skin incision, craniectomy, approach...
See positioning (p. 1446).

Skin/fascia incision
Midline incision from ≈ 6 cm above inion to ≈ C2 spinous process. Take the incision a little higher if a Frazier burr hole is to be done (can then utilize the same skin incision). The skin incision should leave the muscles and fascia intact. It is often difficult to place Raney clips on the skin in this region. To facilitate water-tight closure, the fascia is “T’d” at the top, leaving a cuff of tissue on the occiput just above the superior nuchal line.

Craniectomy
Craniectomy implies removal of bone (often piecemeal) with no intention of replacing it. Although craniotomy with replacement of bone flap at end of procedure has been used successfully, there is some concern that if there is post-op swelling, the inelastic bone flap may cause more pressure to be transmitted to the brain stem.
Usually taken down to foramen magnum. For cerebellar hemisphere tumors, many remove the posterior arch of C1 (caution re vertebral arteries on superior aspect of C1).

**Approach**

A “Y” shaped durotomy is often used. If the lesion has a cystic component, aspiration through a ventricular needle is used to partially decompress it.

### 94.1.5 Extreme lateral posterior fossa approach

Allows access to antero-lateral region of brain stem. Differs from above in that the skin incision is designed to get the bulk of the skin and muscle flap out of the way.

**Key:** remove the lip of the foramen magnum as far laterally as possible, best done with a diamond drill.

### 94.1.6 Cranioplasty for suboccipital craniectomy

Methylmethacrylate cranioplasty as part of the closure following suboccipital crani for vestibular schwannoma reduced the incidence of post-op H/A from 17% to 4%.

### 94.1.7 Post-op considerations for p-fossa crani

**Post-op check**

In addition to routine, the following should be checked:

1. respirations: rate, pattern (see Intubation below)
2. follow closely for hypertension (see below)
3. evidence of CSF leak through wound

**Post-op management**

**Intubation**

Post-op intubation for 24–48 hours is sometimes maintained on a precautionary basis: many complications often have respiratory arrest as the initial manifestation (see below), and the patient may deteriorate precipitously from this point. There is a trade-off as the stimulus of the endotracheal tube may exacerbate hypertension and patient agitation, and so sedation is often required, which may obscure the neuro exam and depress respirations. If the patient wakes up extremely well from an uncomplicated p-fossa crani and it is not late at night, most surgeons will extubate.

**Hypertension**

Hypertension should be avoided at all costs to prevent bleeding from tenuous vessels (e.g. nitroprusside should be prepared prior to termination of the operation, and should be hanging and ready to titrate to keep SBP ≥ 160 mm Hg during the reversal of anesthesia and post-op).

Physician should be called for any sudden changes in BP post-op (may indicate elevated pressure in posterior fossa, see below).

**Post-op complications**

**Posterior fossa edema and/or hematoma**

In the posterior fossa, a small amount of mass effect can be rapidly fatal due to the paucity of room and the immediate transmission of pressure directly to the brain stem. It can also occlude CSF circulation through the aqueduct and cause acute hydrocephalus with the attendant risk of tonsillar herniation. Increased pressure in the p-fossa is usually heralded by sudden increases in BP or changes in respiratory pattern (pupillary reflexes, level of consciousness and ICP are not affected until late). See Table 94.2 for emergency treatment measures.

Table 94.2 Emergency treatment for p-fossa swelling

<table>
<thead>
<tr>
<th>Treatment</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Rapid intubation, ventricular tap (through previously placed burr hole, if possible, see below), and reoperation is indicated. The wound should be opened immediately wherever patient is (recovery room, ICU, floor...). CT scanning may cost valuable minutes; it is rarely appropriate to delay treatment for this (must be judged on an individual basis).</td>
<td></td>
</tr>
</tbody>
</table>

...
To expedite ventricular taps, a prophylactic occipital burr hole (Frazier burr hole) is often placed during posterior fossa surgery to permit drainage of CSF from the lateral ventricles in the event of acute hydrocephalus from blockage of the 4th ventricle or aqueduct. If acute hydrocephalus develops (e.g. from a hematoma), an emergent percutaneous ventricular tap with ventricular needle (or, if not available, spinal needle) is performed, passing the needle through the burr hole aiming for the middle of the forehead. In the presence of acute hydrocephalus, CSF should be encountered at a depth of 3–5 cm. NB: this maneuver may provide a few more minutes while preparing for the definitive treatment of re-opening the wound; however, hydrocephalus may not initially be present since it takes some time to develop.

Suboccipital pseudomeningocele
An “internal” CSF fistula. Incidence following suboccipital craniectomy: 8^{21}-28%^{22}
May be asymptomatic, but also may be associated with H/A, nausea/vomiting, local pain/tenderness. Some are soft and compressible, others may be tense.

Indications for operation:
1. external leak (CSF fistula, see below)
2. threatening integrity of incision
3. cosmetic deformity
4. causing symptoms

Treatment options (up to 67% require permanent CSF drainage^{23}):
1. noninvasive measures: expectant management, fluid restriction, head wrapping, keeping HOB elevated, acetazolamide. Steroids may be used if aseptic meningitis is suspected
2. percutaneous aspiration: “tap and wrap”^{19 (p 436)}^{24} Risks introducing bacteria, causing infection
3. direct surgical exploration with multilayer re-closure^{19 (p 436)}
4. lumbar drain: effective only if pseudomeningocele communicates with the subarachnoid space. May produce acute posterior fossa syndrome (H/A, nausea, vomiting, ataxia...)^{21} especially if the pseudomeningocele doesn’t communicate. Symptoms usually resolve with prompt discontinuation of lumbar drainage.{^{21,22} Other potential complications: vagal nerve palsy, tonsillar herniation, subdural hematoma, kinking of PCA → stroke. Drainage options:
   a) external drain (temporary)
   b) lumboperitoneal shunt (permanent)
5. ventricular drainage
   a) EVD (temporary)
   b) shunt (permanent)

CSF fistula
Occurs in 5–17% of cases. A potential source of meningitis, thus CSF leak must be treated immediately.

Etiologies: controversial. May include:
1. abnormal CSF hydrodynamics (i.e. hydrocephalus). Maneuvers to stem the leak will likely fail until the CSF is shunted or hydrodynamics normalize
2. poor wound closure: probably blamed more often than it is the actual cause
3. subarachnoid scarring

May be associated with meningitis (aseptic or infectious), multiple operations. Formation may be facilitated by coughing/sneezing, postural changes, one-way ball-valve mechanism due to a tissue flap.

An external CSF leak may occur through:
1. the skin incision
2. via the eustachian tube; see possible routes of egress following suboccipital vestibular schwannoma removal (p.683):
   a) through the nose (CSF rhinorrhea)
   b) down the back of the throat
3. the ear (CSF otorrhea) in cases with perforated TM

Treatment:
Initial treatment measures to temporize in the hope that CSF hydrodynamics will normalize and/or that the leak site will scar closed within a few days:
1. elevate the HOB
2. lumbar subarachnoid drainage
3. If the leak occurs through the skin incision:
   a) reinforce the incision with sutures, e.g. running locked 3–0 nylon after preparation of the skin
      with antimicrobial and local anesthetic
   b) alternatively, the incision may be painted with several coats of collodion

If persistent, a CSF fistula requires surgical correction, see CSF fistula (cranial), for general information
(p.384), see CSF fistula following suboccipital removal of vestibular schwannoma (p.684).

Fifth or seventh nerve injuries
Causes diminished corneal reflex with potential corneal ulceration; initially managed with isotonic
eye drops (e.g. Natural Tears®) q 2–4 hrs & PRN, or with a moisturizing insert (e.g. Lacricert®) q day,
and at night with an eye patch or taping eyelid shut.

Miscellaneous
Supratentorial intracerebral hemorrhage has been described, and may result from transient
hypertension.

94.2 Pterional craniotomy
94.2.1 Indications
1. aneurysms
   a) all aneurysms of anterior circulation
   b) basilar tip aneurysms
2. direct surgical approach to cavernous sinus
3. suprasellar tumors
   a) pituitary adenoma (when there is a large suprasellar component)
   b) craniopharyngioma

94.2.2 Technique
Position, skin incision, craniectomy, approach...
1. supine, ipsilateral shoulder roll if head turned >30° (see below)
2. elevate thorax 10–15°: reduces venous distension
3. flex knees
4. Mayfield 3 pin head-holder: applied between true AP and true lateral (so that it is horizontal
   when head is rotated to the necessary position, see Fig. 94.5)
5. neck extended 15°: allows gravity to retract frontal lobe away from skull base
6. head rotated from vertical as shown in Fig. 94.5

Room arrangement
1. microscope: observer tube to operator’s right for either right or left pterional craniotomy

Skin incision
See Fig. 94.6. From zygomatic arch 1 cm in front of tragus (to avoid frontalis branch of facial nerve
and frontal branch of superficial temporal artery), curving slightly anteriorly, staying behind hairline
to widow’s peak, optional additional curve beyond midline to aid in skin retraction. Over temporalis
muscle, incise skin down to but not through temporalis fascia.

The temporalis muscle may be incised caudal to the skin incision (i.e. closer to zygomatic arch): this
minimizes the muscle mass that needs to be retracted inferiorly and yet keeps the scar behind
hairline (note: there is an increased risk of frontalis weakness with this technique than if the tempora-
ralis muscle is incised in-line with the skin incision).

Craniotomy
There are numerous ways to cross the pterion (the lesser wing of the sphenoid makes this difficult).
One method is outlined here, Fig. 94.7.
Burr holes

Two burr holes are sufficient; made as far caudally as possible to minimize the amount of bone to be rongeured off to gain access to the floor of the middle cranial fossa. One burr hole is made at the posterior insertion of the zygomatic arch (“A” in Fig. 94.7); this burr hole may be placed slightly forward when exposure is centered over structures around the ACoA (e.g. suprasellar tumor). The second burr hole (“Z”) is made at the intersection of the zygomatic bone (near the frontozygomatic suture), the superior temporal line and the supraorbital ridge. The hole should be as low as possible on the orbit; aim the drill slightly superiority to avoid actually entering the orbit. The dura is dissected off the inner table with a Penfield #3 dissector.

Fig. 94.5 Head position for pterional craniotomy depending on exposure required. The blue line indicates the approximate centerline.
Craniotomy

The resulting bone flap is centered over the depression of the sphenoid ridge. Approximately 33% of the craniotomy is anterior to the anterior margin of temporalis muscle insertion, ≈ 66% is posterior.

With the craniotome, starting at the frontal burr hole the craniotomy is taken anteriorly across the anterior margin of the superior temporal line staying as low as possible on the orbit (to obviate having to rongeure bone, which is unsightly on the forehead). The distance “B” from the medial extent of the craniotomy to the frontal burr hole is 3 cm for anterior circulation aneurysms. For the approaches to skull base (e.g. Dolenc approach), distance “B” is larger and takes the opening to ≈ the mid orbit. Then from point “B”, a sharp superior turn is made and the opening is taken back to point “A.” The height (“H”) of the craniotomy needs to be only ≈ 3 cm for aneurysms of the Circle of Willis, and slightly larger (≈ 5 cm) for middle cerebral artery aneurysms. Minimal exposure of temporal cortex is necessary for aneurysms of the skull base region. For large flaps (e.g. for tumors), “H” is made larger to expose more temporal lobe.

From the frontal burr hole, the craniotomy is then taken posteriorly towards the depression corresponding to the sphenoid wing until the drill hangs up.

The craniotomy from the posterior burr hole is taken forward towards the depression corresponding to the sphenoid wing until the drill hangs up.

The bone between the two points where the drill hangs up is scored with the craniotome, and then the bone is fractured at this point. A rongeure is used to remove as much sphenoid wing as possible.

Fig. 94.6 Skin incision for pterional craniotomy
Dural flap
Curvilinear, centered over sphenoid wing, retracted inferiorly with dural stitch.

Dissection
For some anterior circulation aneurysms (e.g. MCA aneurysms) and for the Yasargil approach to basilar tip aneurysms, the sylvian fissure needs to be split. This can be accomplished by working from the lateral aspect of the fissure medially, or, by starting at the point where the carotid artery penetrates the fissure and working laterally. The latter method may be easier when prolific veins overly the junction of the frontal and temporal lobe. There are no arteries that cross the sylvian fissure, and so if the correct plane is maintained, no arteries need to be sacrificed.

Fig. 94.8 shows a theoretical exposure of the circle of Willis possible through a pterional craniotomy. This diagram is semi-schematic, and in reality dissection would be directed either anteriorly (e.g. to expose ACoA) or posteriorly (e.g. for basilar tip aneurysms) but not both.

94.3 Temporal craniotomy
94.3.1 Indications
1. temporal lobe biopsy: herpes simplex encephalitis
2. temporal lobectomy: for resection of seizure focus, decompression post-trauma...
3. hematoma (epidural or subdural) overlying temporal lobe
4. tumors of the temporal lobe
5. small, laterally located vestibular schwannomas
6. access to the floor of the middle cranial fossa (including foramen ovale/Meckel’s cave, the labyrinthine and upper tympanic portion of the facial nerve)
7. access to medial temporal lobe e.g. for amygdalo-hippocampectomy (p.1556) or for mesial temporal sclerosis (p.441)

94.3.2 Technique

See Fig. 94.9. Two basic methods for temporal craniotomy:
1. small craniotomy or craniectomy through a linear skin incision: good for cortical biopsy or draining chronic subdural hematoma. Also permits access to floor of middle fossa. Simple quick closure
2. question-mark skin incision with standard craniotomy flap: useful for temporal lobe exposure for tumor or acute hematoma

94.3.3 Position, skin incision, craniectomy, approach...

1. patient supine with shoulder roll (to assist in rotating neck to get head almost horizontal)
2. elevate thorax 10–15°: reduces venous distension
3. flex knees slightly
4. Mayfield 3 pin head-holder: true AP with single pin anteriorly
5. head rotated almost horizontal to floor: avoid over-extending to prevent kinking neck veins
94.3.4 Craniotomies

Small craniectomy

Linear skin incision completely within the extent of the temporalis muscle. To access the temporal tip: place the incision midway between the lateral canthus and external auditory canal (EAC); extend it from the zygomatic arch upward for \( \approx 6 \) cm. For small, laterally located vestibular schwannomas, the incision is made 0.5 cm anterior to the EAC extending \( \approx 7-8 \) cm above the zygomatic arch.\(^{26}\) To drain a subdural, place the incision just anterior to the tragus and start it 1–2 cm above the zygomatic arch for \( \approx 6 \) cm (modified based on the location of the epicenter of the subdural). Take the incision down to temporalis fascia with the knife, and incise the fascia and muscle with Bovie cautery. Spread with self-retaining retractors, and make a burr hole. Enlarge with rongeurs and/or Kerrison punches.

Standard craniotomy

Question-mark skin incision

See Fig. 94.9. Used for access to the temporal lobe including tip (a reverse question mark incision may be used to gain access to the middle and posterior temporal lobe).

1. the pinna is either sutured inferiorly out of the way before draping, or it can be folded under the drapes which may be stapled to the skin
2. the lower limb extends from the zygomatic arch just anterior to the tragus (to avoid the superficial temporal artery)
3. curve as far posteriorly as \( \approx 6-7 \) cm on the non-dominant side, or \( \approx 8-9 \) cm on the dominant side at the level of the top of the pinna (these dimensions allow access to the “safe” area of temporal tip for lobectomy)
4. then superiorly to the level of the superior temporal line
5. then anteriorly towards the forehead, stopping at the hair line

Fig. 94.9 Temporal craniotomy (exposing entire temporal lobe)
Burr hole placement
1. at the posterior insertion of the zygomatic arch
2. at upper anterior junction of zygomatic arch
3. one or two burr holes along posterior and superior aspect of the skin incision

Craniotomy
Connect the burr holes with the craniotome, keeping as low as possible in the middle fossa to minimize the amount of bone that must be rongeured. The remaining bone is rongeured down to the floor of the middle fossa (cross-hatched area in Fig. 94.9).

Temporal lobectomy
Danger points:
1. dominant hemisphere: Wernicke’s speech area. Although variable (see Temporal lobectomy (p.1556)), one can usually safely resect up to 4–5 cm from temporal tip without use of mapping techniques to localize speech
2. non-dominant hemisphere: one can resect up to 6–7 cm before running the risk of injuring the optic radiation
3. sylvian fissure (middle cerebral artery): it is best to amputate the temporal lobe backward from the tip for the extent of the desired resection, and then work deep
4. medially, the incisura should be identified to avoid injury to the brain stem which lies just medial to this

94.4 Frontal craniotomy

94.4.1 Indications
1. access to frontal lobe: e.g. for infiltrating tumor
2. approach to third ventricle or to sellar region tumors in some situations, including craniopharyngiomas, planum sphenoidale meningiomas
3. repair of ethmoidal CSF fistula

94.4.2 Danger points
1. anterior cerebral arteries in the midline (deep)
2. superior sagittal sinus (SSS) in the midline (note: the SSS may be sacrificed in its anterior third without engendering venous infarction in most cases, whereas venous infarction will almost always occur with division of the SSS posterior to that)
3. avoid inadvertently crossing the midline into the contralateral hemisphere through the corpus callosum
4. dominant hemisphere: Broca’s (motor speech) area is located in the inferior frontal gyrus

94.4.3 Technique

Craniotomy options
Two basic choices for craniotomy:
1. unilateral craniotomy through a curved skin incision taken anteriorly up to the hairline: used when one does not need to be low in the frontal fossa in the midline (otherwise the skin incision would have to be taken far into forehead) and when there is no need to cross the midline
2. large bifrontal skin incision from “ear-to-ear” (souttar skin incision27) allowing low approach to one or both frontal fossa

Unilateral frontal craniotomy
Fig. 94.10. Skin incision starts <1 cm anterior to the tragus, and does not need to go all the way down to the zygomatic arch. It curves superiorly and slightly posteriorly before being taken to the midline frontally.

Burr holes
1. at the junction of the superior temporal line and the orbital rim
2. just posterior to the depression of the sphenoid wing (behind the pterion)
3. anteriorly just behind the hairline to avoid having a burr hole under the forehead (which causes an unsightly depression)
4. superiorly

**Bilateral frontal craniotomy**

1. “ear-to-ear” or souttar skin incision  
   a) just behind hairline with a slight widow’s peak at the front  
   b) does not need to go all the way to the zygomatic arch, it just needs to be ≈ as low as the orbital roof  
   c) unlike pterional craniotomy, usually do not need to incise the temporalis muscle and fascia. Dissect the flap off the muscle/fascia  
   d) if a periosteal flap is likely to be needed, it sometimes helps not to incise the periosteum at the same time as the skin incision. Then, the periosteum can be incised behind the skin incision to yield a longer periosteal graft than would have otherwise been obtained  

2. burr holes: to avoid burr hole defects on the forehead, the bone flap can be created with two burr holes straddling the superior sagittal sinus (SSS) close to the skin incision, and two burr holes laterally  
3. the SSS may be divided low, near the orbital roof, with little risk  
4. if the frontal sinus is entered, it is dealt with as outlined under Frontal sinus fractures (p.886)

**94.5 Petrosal craniotomy**

**94.5.1 Indications**

1. lesions of the petrous apex (e.g. petroclival meningiomas)  
2. lesions of the clivus (e.g. chordomas) with both posterior fossa and supratentorial components

**94.5.2 Advantages**

Spares sinus and otologic apparatuses. Minimizes cerebellar and temporal lobe retraction.

**94.5.3 Technique**

See reference.28
Position

1. patient supine, ipsilateral shoulder roll
2. elevate thorax 10°: reduces venous distension
3. flex knees
4. Mayfield 3 pin head-holder: close to true AP with single pin on forehead
5. head positioned to place petrous base at highest point of field:
   a) head rotated 40–60° from vertical
   b) head abducted towards contralateral shoulder
   c) neck extended 15°: allows gravity to retract frontal lobe away from skull base

Skin incision

Reverse question mark starting from zygomatic arch 1 cm anterior to tragus, arcing posteriorly over ear, descending to 0.5–1 cm medial to mastoid notch.

Temporalis muscle and periosteum reflected anteriorly and inferiorly.

Craniotomy

Four burr holes are utilized, two on each side of the sinuses (near the junction of the transverse and sigmoid sinuses).

94.6 Approaches to the lateral ventricle

Surgical approaches to the trigone – Contemporary Neurosurgery Vol. 27 No.529

Classic review18(p 561–74) summarized:

1. atrium (AKA trigone): numerous approaches include29:
   a) middle temporal gyrus: through the dilated temporal horn
   b) lateral temporal parietal
   c) superior parietal occipital
   d) transcallosal (see below)
   e) transtemporal horn: access to temporal horn is via lobectomy of the temporal tip
   f) occipital lobe incision or occipital lobectomy: recommended only if patient has homonymous hemianopsia pre-op
2. frontal horn
   a) middle frontal gyrus
3. midventricular body
   a) transcallosal
   b) middle frontal gyrus: usually prevents access to vascular supply until most of the tumor is removed (especially for tumors supplied primarily by posterior choroidal artery)
4. temporal horn
   a) middle temporal gyrus
   b) transtemporal horn

94.7 Approaches to the third ventricle

94.7.1 General information

Classic references review the microsurgical anatomy30 and surgical approaches,31 and are briefly summarized below.

Alternative approaches for lesions of the anterior third ventricle32:

1. transcortical: approach is through the lateral ventricle and is feasible only in the presence of hydrocephalus; especially useful if the tumor extends from the third ventricle into one of the lateral ventricles. Risk of seizures is 5% (higher then with transcallosal) (p.1466).
2. transcallosal: may be preferable in the absence of hydrocephalus (see below)
   a) anterior transcallosal: good visualization of both walls of third ventricle; risk of bilateral fornical damage
   b) posterior transcallosal: allows approach to quadrigeminal plate or pineal region; risk of damage to deep veins
3. subfrontal: allows four different approaches
   a) subchiasmatic: between optic nerve and optic chiasm
   b) optico-carotid: through the triangular space bordered by optic nerve medially, carotid artery laterally, and ACA posteriorly
c) lamina terminalis: above the optic chiasm

d) transsphenoidal: requires removal of tuberculum sellae, planum sphenoidale, and anterior wall of the sella turcica

4. transsphenoidal
5. subtemporal
6. stereotactic: may be useful for aspiration of colloid cysts; see Stereotactic drainage of colloid cysts (p.759)

94.7.2 General principles of tumor removal
Summarized. During the approach, deep veins should be preserved at all costs, even if it means stretching them to the point that they may rupture.

It is helpful to place a suture through the tumor capsule to act as a tether.

The tumor should first be removed from within the capsule; techniques include aspiration, and then opening the capsule and debulking from within. The capsule may then be collapsed and dissected from adherent structures. If the capsule adhesions seem unyielding, the most likely cause is incomplete intracapsular evacuation.

Vessels on the surface of the tumor should be presumed to be supplying normal brain, and should be dissected off the capsule once it is completely emptied.

94.7.3 Transcallosal approach to lateral or third ventricle

General information
Performed through an interhemispheric approach to the corpus callosum (CC) via a parietal craniotomy, usually right sided in a left-hemisphere dominant patient.

Indications
Primarily for tumors or lesions of the lateral or third ventricle, including:
1. colloid cysts
2. craniopharyngiomas
3. cysticercosis cysts
4. thalamic glioma
5. AVM

Booking the case: Transcallosal surgery

Also see defaults & disclaimers (p.27).
1. position: supine with pin headholder
2. equipment:
   a) microscope
   b) image guided navigation system
3. post-op: ICU
4. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: operation between the two halves of the brain to remove lesion
   b) alternatives: non-surgical management, surgery through the surface of the brain (transcoritcal), radiation therapy for some diagnoses
   c) complications: stroke, “disconnection syndrome” (uncommon) (p.1556), hydrocephalus with possible need for a shunt, memory deficits

Technique
See references.

General information
Fig. 94.11. Image-guided navigation is very helpful in ascertaining the correct trajectory which permits minimizing the size of the callosotomy, and helps distinguish the corpus callosum from the cingulate gyri.
Position
Supine with neck flexed. Thorax elevated 20°. Spinal drain not used. Keep the head perfectly vertical to minimize disorientation that can easily occur with this approach. Alternatively, gravity retraction may be employed either by tilting the head slightly to the right (causing the right hemisphere to fall away) or by using the lateral position.

Skin incision
Either of the following may be used:
1. inverted “U” with the top just left of midline, extending from 6 cm anterior to the coronal suture to 2 cm behind the coronal suture, taking the sides for 7–8 cm
2. soultar skin incision
**Craniotomy**

Pre-op angiography is recommended to plan the position of the flap to avoid sacrificing large cortical veins. MRI may also suffice for this. There tends to be fewer veins bridging from the cortex to the superior sagittal sinus anterior to the coronal suture, therefore this is often a good location to enter the interhemispheric fissure. The bone flap is either trapezoidal or triangular in shape, for adequate exposure it is critical to go all the way to the superior sagittal sinus (SSS). Several techniques may be used. NB: the SSS is often to the right of the sagittal suture (p.61).

1. to expose the SSS, straddle the SSS with paired burr holes anteriorly and posteriorly, dissect the dura from the inner table between pairs, and make the longitudinal cut on the left of midline. Disadvantage: removing the midline bone puts the SSS at greater risk of injury and makes it more difficult to control lacerations
2. one can make the long cut well to the right of midline, and then under direct vision rongeur off the bone to the SSS. Safe, but leaves a large bone gap that may need to be filled (e.g. with methyl methacrylate) and is time consuming
3. most risky for causing a sagittal sinus laceration is to make the long cut just right of the midline (over the edge of the SSS, which may lacerate it)

To stay away from the motor strip and to keep the sagittal sinus exposure as anterior as possible, 2/3 of the opening should lie anterior to coronal suture, 1/3 posterior (generally: 6 cm total with 4 cm anterior and 2 cm posterior). The craniotomy extends laterally to 3–4 cm to right of midline. The last cut with the craniotome should connect the burr holes along the sinus (midline); leaving this cut for last permits rapid access to the sinus in case it is torn. The dural flap is based towards the sagittal sinus.

**Approach to corpus callosum**

None, or at most, only one bridging vein from the cortex to the sagittal sinus may be sacrificed (and then, only if it is not a large draining vein). Gently retract the right hemisphere. Avoid retractors on the sagittal sinus to prevent injury to the SSS which may lead to sinus thrombosis (once CSF is released (with the callosotomy) retraction will be easier). Enter the interhemispheric fissure and follow the falx deep. Open the arachnoid membrane beyond the deep edge of the falx.

The two cingulate gyri may be adherent in the midline, and can easily be mistaken for the corpus callosum (CC). This error may be compounded by mistaking the callosomarginal arteries for the pericallosal arteries. To differentiate: the CC is a pure white structure, is usually deeper than one anticipates, and is appreciated beneath the paired pericallosal arteries. Image guided surgery or measuring the depth to the CC on the pre-op MRI may help.

**Callosotomy**

The callosotomy is usually performed between the two pericallosal arteries. Some arterial branches may cross the midline, occasionally it is necessary to sacrifice some. Trajectory: a line drawn from the coronal suture (in the midline) to the external auditory canal (the foramen of Monro lies along this line); this helps avoid the tendency to tunnel posteriorly through the CC. Either the bipolar cautery, suction and sharp knife, or the laser is used to make the callosotomy. In hydrocephalus, the callosum will be thin. Entering the lateral ventricle releases CSF which aids retraction. When the foramen of Monro is occluded (e.g. with colloid cyst), it helps to fenestrate the septum pellucidum to prevent it from bulging into the ventricle in which one is operating (otherwise, as CSF is aspirated from the ipsilateral lateral ventricle, it cannot escape from the other).

Disconnection syndrome (p.1556): more common with posterior callosotomy (near the splenium) where more visual information crosses. The risk is reduced by creating a callosotomy <2.5 cm in length extending posteriorly from a point 1–2 cm behind the tip of the genu. For an interfornicial approach, the callosotomy must be perfectly midline.

**Approach to third ventricle**

Usually, the callosotomy will not be exactly midline, and one of the lateral ventricles will be entered. Great care must be taken to correctly identify which lateral ventricle has been entered, another potentially disorienting pitfall. For orientation (Fig. 94.12), the choroid plexus passes forward in the choroidal fissure to the foramen of Monro (which is medial) where it converges with the thalamostriate vein approaching from a more lateral position in the groove between the thalamus and caudate. The septal and caudate veins approach the foramen from anterior. With colloid cysts, the
foramen of Monro may be hard to recognize initially as it will be plugged with the cyst which can resemble the ependymal lining of the ventricle, but on close inspection is usually slightly grayer (the choroid plexus enters the posterior aspect of the foramen).

Another possible pitfall upon incising the CC is entering a cavum septum pellucidum (p.1375). The give-away here is that no landmarks will be visible.

Alternative approaches to third ventricle
1. interfornicial: go above body of fornix, approaches roof of third ventricle. Well suited for lesions of the mid and posterior third ventricle. Callosotomy should be as close to midline as possible
2. from lateral ventricle through the foramen of Monro: with hydrocephalus, the foramen of Monro is usually dilated. If the foramen is too small for adequate access to the third ventricle, one can:
   a) return to the interfornicial approach (see above) or
   b) enlarge the foramen of Monro only if absolutely necessary. Either by:
      • opening the foramen laterally
      • the “subchoroidal” approach, making the incision posteriorly (sacrificing the thalamostriate vein) which is reportedly well tolerated
      • last resort: incising the antero-superior margin of the foramen through the column of one fornix. Caution: if the other fornix is non-functional for any reason, this would produce a bilateral fornicical lesion and may (but not definitely) result in loss of short term memory and ability for new learning

Colloid cyst removal
It is critical to debulk and empty a cystic lesion, such as a colloid cyst, before delivering it from the third ventricle through the foramen of Monro. This will minimize the retraction and manipulation of the fornix. Inserting a needle and aspirating may work. The partially emptied cyst is grasped with a micro-pituitary and is delivered into the lateral ventricle through the foramen of Monro. One should only attempt to deliver the empty capsule through the foramen of Monro (p.1462). There is usually a stalk attaching the lesion to the roof of the third ventricle, this is coagulated with bipolar cautery and divided.

For other tumors, if the tumor is too large to fit through the foramen of Monro, it should be gutted from within.
Complications

1. venous infarction, may be due to:
   a) sacrifice of critical cortical draining veins: plan the flap to avoid this with preoperative angiography, or with sagittal T2WI MRI images. 
   b) superior sagittal sinus (SSS) thrombosis. Factors that may contribute to sinus injury include:
      - injury from retractor: avoid placing retractor on sinus (deformation of midline should not exceed 5 mm)
      - over-retraction of the dural sinus flap or on SSS itself (lateral deformation should be <2 cm)
      - injury during the opening of the bone in the region of the sinus
      - over-use of bipolar coagulation in the region of the SSS
      - hypercoagulable state of the patient, including dehydration

2. transient mutism as a result of bilateral cingulate gyrus retraction or thalamic injury in conjunction with section of the midportion of the callosum

94.7.4 Transcortical approach to lateral or third ventricle

Indications

In the absence of hydrocephalus, it is difficult to navigate through the ventricular system. Thus, with normal sized ventricles, the third ventricle and region of the foramen of Monro are better approached transcallosally (p.1462).
1. tumors of the atrium of the lateral ventricle
2. tumors of the roof of the third ventricle
3. third ventricular tumors with significant extension into one lateral ventricle

Approaches

1. posterior parietal
2. middle temporal gyrus: useful when temporal horn of lateral ventricle is dilated due to hydrocephalus caused by the tumor; access is through the temporal horn
3. middle frontal gyrus approach: a 4 cm incision is made parallel to the axis of the middle frontal gyrus, above and anterior to the expressive speech center (Broca's area) and anterior to the motor strip; about the same point as used for frontal ventriculostomy, see Kocher's point (p.1512)

94.8 Interhemispheric approach

94.8.1 Indications

For lesions abutting on midline, deep to surface, but superficial to corpus callosum (lesions that can “fall away” from midline). Similar to transcallosal approach above, except that the pathology can be placed on the down side, which allows gravity to retract the hemisphere and thus minimizes pressure necrosis injury from mechanical retractors.

94.8.2 Technique

Position

True lateral (prevents getting lost from unusual angles). Head tilted slightly up.

Approach

Similar to transcallosal (p.1462). Need to be sure that lateral portion of craniotomy extends at least 4 cm from midline to minimize the necessity of retraction of brain against bone.

94.9 Occipital craniotomy

94.9.1 Indications

Occipital lobe tumors including posterior falk meningiomas or tentorial meningiomas with only supratentorial component. Occipital lobe intracerebral hemorrhages.
94.9.2 Positions

Supine

Shoulder roll on affected side; elevate thorax 15°. Mayfield 3 pin headholder with single pin in forehead off to the side of the crani, double pin just over midline on opposite side.

Lateral oblique

1. Affected side up, can operate either
   a) from behind patient similar to p-fossa crani for CPA lesion
   OR
   b) from top of table
2. Alternative approach: affected side down. Useful in lesions adjacent to the falx; see Interhemispheric approach (p.1466)

94.10 Decompressive craniectomy

94.10.1 Indications

Indications (controversial) include:

1. Malignant middle cerebral artery occlusion syndrome (p.1303) primarily for nondominant hemisphere. Use on dominant side is more controversial
2. Traumatic intracranial hypertension
   a) as an adjunct for persistent intracranial hypertension when other ICP control measures fail (p.914)
   b) Early in the management: may be considered for patients undergoing emergent surgery (for fracture, EDH, SDH…)
3. Uncontrollable brain swelling during craniotomy (p.1429)
4. Reported in children with refractory nontraumatic intracranial hypertension (e.g. infection, infarction, Reye’s syndrome…)

94.10.2 Potential complications

1. Bleeding
2. Herniation of the brain through the opening, compressing and lacerating the brain on the bone edges (risk may be reduced by making generous craniectomy)
3. Post-op injury to the brain from inadvertent external pressure applied to the now relatively less protected brain
4. Post-op fluid collections: hygromas or hematomas at the operative site, on the contralateral side, or interhemispheric

94.10.3 Techniques

General considerations

1. It is necessary to open the dura
2. Options for the removed bone flap
   a) Discard it: this may be the best option when the bone flap has been contaminated as a result of an open traumatic scalp laceration
   b) Place it in a separate subcutaneous pouch in the patient’s abdomen for later retrieval and re-implantation into the skull. This is especially helpful if the patient’s own skull is preferred and the patient does not live in the area where he/she is having the surgery
   c) Store it for future implantation: saturate with sterile solution (e.g. RPMI medium 1640 www.invitrogen.com/GIBCO) and then place within sterile storage (e.g. intestinal bags which are then placed in a sterile plastic container) and store in a bone freezer at -80°C
   d) For non-contaminated situations (e.g. stroke): re-implantation can be considered after 6–12 weeks
3. Bone openings need to be large (e.g. >12 cm diameter, often >15 cm)

Hemicraniectomy

1. Some prefer use of a Mayfield headholder placed low (Fig. 94.13) to give greater access (not feasible with severe comminuted skull fractures)
2. AP axis of head is placed horizontal to floor (unless C-spine not cleared or if neck too immobile – one may compensate for this by rotating table)

3. skin incision: two options
   a) Fig. 94.14A starts at widow’s peak, similar to trauma flap (p. 837), but with increased exposure by taking it posteriorly close to the inion then turning sharply anteriorly and hugging the ear to preserve blood supply
   b) Fig. 94.14B “T” incision. Less risk of flap ischemia. The “T” joins the midline incision behind the coronal suture to preserve the STA
   c) burr holes (Fig. 94.15): a burr hole is made just above the posterior root of the zygomatic arch, a second one may be made just behind the frontal insertion of the zygomatic arch, inferior to the superior temporal line
   d) bone flap: proceed posteriorly from the posterior zygomatic arch using the footplated craniotome. Posteriorly, stay \( \approx 1 \) cm superior to asterion to avoid the transverse sinus. The flap is taken 1 cm beyond the lambdoid suture, and then up towards the sagittal suture, crossing the lambdoid suture again (this leaves a small amount of bone posteriorly on which the head can rest post-op). An anterior turn is made 1 cm short of the sagittal suture to avoid the superior sagittal sinus, and the sagittal suture is paralleled. The coronal suture is crossed and the drill is taken as low as possible in the frontal fossa near the midline. Staying as low as possible, the orbital roof is followed posteriorly towards the second burr hole. The burr holes are then connected
   e) some bone may need to be rongeured to expose the floor of the middle fossa (stippled area in Fig. 94.15)
   f) dural opening: based inferiorly, taken to 1 cm short of the craniotomy edge. Dural releasing incisions may be made at intervals up to the bone margin to avoid strangulation of the brain on the dural edge
   g) duraplasty
      • onlay: 2 cm wide strips of dural substitute can then be placed partway under the dural edge around the periphery to isolate the brain from the undersurface of the skin flap where there will be a gap in the dura
      • some authors suture a dural draft in place
   h) the dural flap is then replaced on top of the brain and dural substitute strips, and is not sutured

Bilateral craniectomy

The above procedure can be performed bilaterally, however, it is difficult to position the head to do this. Alternatively, a bifrontal craniectomy can be performed.

1. skin incision: bicoronal, posterior to the coronal suture (Fig. 94.16)
2. burr holes: may use the same ones as for hemicraniectomy (see above) bilaterally. Addition burr holes to straddle the superior sagittal sinus may be made if a large single bone flap is planned
3. bone flap (Fig. 94.17): two options, both are taken back to the coronal suture
   a) a single large bone flap extending back to the coronal sutures, or
   b) two frontal flaps leaving a thin strip of bone in the midline overlying the superior sagittal sinus (if this strip is too wide, it can damage the brain)
4. dural opening: bilateral, based against the midline (superior sagittal sinus)
Posterior fossa decompressive craniectomy

1. skin incision: midline skin incision from above inion to \( \approx \) C2 spinous process
2. bone opening: laterally to sigmoid sinuses, superiorly to transverse sinus. C1 laminectomy is typically performed as well\(^{42}\)
3. dural opening: “Y” shaped incision

---

Fig. 94.17 Bilateral craniectomy skull flap. Shown with 2 separate frontal flaps (the preserved midline bone strip over the superior sagittal sinus is optional)
95 Spine, Cervical

95.1 Anterior approaches to the cervical spine

1. anterior odontoid screw (p. 1476)
2. C1–3 (upper cervical spine):
   a) transoral approach: including odontoidectomy (p. 1472)
   b) extrapharyngeal approaches: use nasotracheal intubation (so that the mandible can be completely closed) through the contralateral nares. The head is slightly extended and is rotated 15° to the contralateral side. Avoid any oral tubes
      • medial extrapharyngeal approach: medial to carotid sheath. Provides a more anterior position than the lateral retropharyngeal approach. Structures encountered: branches of external carotid artery, upper laryngeal nerves, hypoglossal nerve
      • lateral retropharyngeal approach: only the spinal accessory nerve is encountered
3. C3–C7: standard anterior cervical discectomy approach
   a) For 1 or 2 level ACDF or 1 level corpectomy, a horizontal incision is usually employed
   b) For more levels, a vertically oriented incision may be preferred to facilitate access

95.2 Transoral approach to anterior craniocervical junction

95.2.1 General information
Primarily useful for midline extradural lesions (approach to intradural lesions has been described, but the use has been extremely limited because of difficulties obtaining watertight closure and increased risk of meningitis). Refinements in techniques and equipment (e.g. flexible reinforced oral endotracheal tube, McGarver or Crockard retractor, operating microscope, and suturing transnasal red-rubber catheters to the uvula to aid in retraction) allows access from as high as the inferior third of the clivus to as low as C3 (and sometimes C4) vertebral body without need for tracheostomy or splitting of the tongue. Additional access can be achieved with use of extended techniques including splitting of the hard & soft palate, tongue splitting, and transmandibular approach.

95.2.2 Transoral odontoidectomy

Indications
Anterior extradural compression of the cervicomedullary junction as with pannus from rheumatoid arthritis, irreducible basilar invagination, tumors of C2, infection.

Stabilization
75% of patients undergoing transoral removal of the odontoid process required posterior fusion afterwards due to ligamentous instability. While the stabilization intuitively seems like it should be done first, it is often done following the decompression at the same sitting or at a soon to follow date. Some reasons for decompressing before stabilization:
1. positioning the patient for fusion may cause neurologic compromise if there is cord compression
2. a post-op MRI can be done to determine if enough decompression was achieved from the odontoidecotomy. If not, a laminectomy can be done at the same time as the posterior stabilization
3. the amount of destabilization may not be known until after the odontoidecotomy - in some cases a C1–2 fusion may suffice

Stabilization usually entails posterior occipitocervical fusion. Occasionally fusion may be limited to C1–2 or C1–3 without the occiput. It is also possible to place an anterior strut between the body of C2 and the clivus, or between C2 and C1. Fibula is recommended. Metal instrumentation should be avoided.

Pre-op preparation
1. make sure that the patient can open the mouth at least 25 mm. If not, then other approaches such as translabiomandibular should be considered
2. for conditions resulting in malalignment or basilar invagination, cervical traction for 1 or more days is sometimes required
3. radiographic evaluation
   a) cervical MRI without and with contrast to define the soft tissue pathology
   b) CT of the craniocervical junction with sagittal and coronal reconstruction
   c) CTA to assess the position and involvement of the vertebral arteries. Measuring the distance between the VAs provides useful information

**Booking the case: Transoral approach**

Also see defaults & disclaimers (p. 27).

1. position: supine with pin headholder
2. equipment
   a) microscope
   b) high-speed drill with long bits
   c) C-arm
   d) image guided navigation system (if used)
3. instruments
   a) transoral set (usually includes oral retractor such as Crockard, Dingman, Dickman-Sonntag…)
   b) long instruments: microdiscectomy instruments often work
4. anesthesia: awake, fiberoptic endotracheal intubation
5. some surgeons use ENT to perform the approach and closure and for follow-up
6. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: transoral resection of odontoid, placement of halo-vest immobilization, MEP monitoring (MEP should be consented specifically due to risk of seizures). Need for posterior stabilization at the same setting or in the immediate future
   b) alternatives: nonsurgical management, radiation therapy for some diagnoses
   c) complications: CSF leak with possible meningitis, spinal cord injury, wound breakdown, swallowing difficulties (may require PEG tube), breathing problems (may require tracheostomy), seizures with MEP

**Technical considerations**

For details, see references. Some key points:

- Awake fiberoptic orotracheal intubation is employed. Nasotracheal (NT) is used by some, but at the narrow upper part of the exposure the NT tube tends to get in the way.
- SSEP and MEP monitoring are used in appropriate cases.
- Positioning: 3-point fixation with a Mayfield headholder is typically used. The patient is supine with no neck rotation (distorts the anatomical relationships and may bring one VA closer to the midline). Tilt the whole patient or the table towards the surgeon. 10–15° neck extension improves the exposure. Alternatively, the surgeon can stand above the patient who is kept perfectly supine.
- A specialized retractor (e.g. Crockard transoral retractor) or a conventional Dingman retractor is placed. Verify that the tongue is not being compressed against the teeth.
- Landmark: the tubercle of the atlas can be palpated through the posterior pharynx to locate the midline and for cranio-caudal orientation.
- The mucosa of the posterior pharynx is infiltrated with 1% lidocaine with epinephrine. Some authors culture the oropharynx to obtain drug sensitivities of organisms for use in the event of infection. Some advocate liberal topical use of 1% hydrocortisone ointment to the mucosa of the oropharynx and posterior tongue at the beginning and also during the operation to reduce intra-op and post-op swelling. Others feel it has no effect, and IV Decadron is used by some.
- A 3 cm long vertical midline incision is made.
- To reduce the risk of C1 spreading and allowing basilar invagination, C1 ring-sparing surgery may be attempted by removing only the inferior half to two-thirds of the anterior C1. When C1 ring-sparing is not done, the central 3 cm of the atlas is removed with a high-speed drill.
- There is ≈ about 20–25 mm working distance between the two vertebral arteries at their point of closest approximation where they enter the foramen transversarium at the inferior aspect of the lateral mass of C2.
- The odontoid is hollowed out “like a canoe”) using a high-speed drill, checking progress on lateral fluoro at frequent intervals. Once the bone has been reduced to a thin shell, it can be fractured in
towards the hollowed out portion using curettes. The superior tip of the odontoid is particularly challenging due to the apical ligament.

Closure: a two layer closure is preferred by some. Others recommend a single layer closure incorporating deep muscle, superficial muscle, and mucosa. If the dura has been violated, a fascial patch is secured with tissue adhesive and a lumbar subarachnoid drain is placed in the O.R. and maintained at low pressure for 3–4 days. An NG tube is placed under direct visualization to avoid injury or penetration of the mucosal closure.

**Posterior stabilization**

Transoral odontoidectomy produces instability in most cases (sometimes delayed). For basilar invagination or occipitocervical instability, an occipitocervical fusion is recommended (p.1474).

For Cl–2 instability alone, a posterior Cl–2 arthrodesis may be performed (p.1479).

**Possible complications**

1. dural tear with CSF leak and risk of meningitis
2. vertebral artery injury
3. spinal cord injury

**Post-op care**

1. NG feeding or IV hyperalimentation is used initially (in anticipation of oropharyngeal swelling (lasts 2–3 days) and to avoid disruption of the mucosal closure)
2. intubation is maintained until the swelling subsides. Initial removal of the endotracheal tube over a tube changer facilitates reintubation if needed; the tube changer can be removed if no problem develops after 1 hour
3. if the NG tube comes out, it should only be replaced under direct vision (usually by ENT physician) to avoid injury/penetration of the mucosal incision
4. halo-vest immobilization is maintained until the posterior fusion is performed
5. for staged procedures when the fusion is being done at a later date, a post-op MRI should be done to assess the degree of decompression. If further decompression is needed, then a laminectomy can be added to the posterior fusion

95.3 Occipitocervical fusion

The patient will lose about 30% of neck flexion mobility with an occipital to Cl fusion.

Indications for occipitocervical fusion: 1. traumatic occipitoatlantal dislocation 2. absence of a complete arch of Cl. Note: Alternatively, Cl–2 lateral mass fusion (with or without lateral mass screws) (p.1479) may be used in cases b and c if only the posterior arch of Cl is compromised a) congenital b) post-traumatic c) posttraumatic; “bursting” Cl fracture (bilateral or multiple Cl ring fractures). NB: some feel that this may be satisfactorily treated with halo immobilization until the atlas fracture heals (as they almost all do) followed by Cl to C2 wiring/fusion.

3. congenital anomalies of the occipitocervical joints
4. upward migration of the odontoid into the foramen magnum
5. marked irreducible shifts of Cl or C2

Disadvantages of occipitocervical fusion:

1. loss of movement at the occipitoatlantal junction further reduces the range of motion as follows:
   a) flexion/extension: reduced by ≈ 30% (13° occurs at occiput-Cl junction)
   b) lateral rotation: 10° is lost
   c) lateral bending: 8° is lost
2. non-union rate is higher than with Cl–2 fusion alone
Options:
1. keel plate (placed centrally over the thickest portion of the occipital bone) connected via rods to cervical screws (C2 pedicle screws and C3 lateral mass screws): reduced range of motion (ROM) to 17% of normal in a cadaver study\textsuperscript{11} (for technique, see below)
2. occipital condyle (OC)-C1 polyaxial screws\textsuperscript{12}: see below
3. occipital-C1 (AKA atlantooccipital) transarticular screws (see below)
4. looped rod wired to the occiput via wire cables placed through holes drilled in the occiput. Reduced ROM only to 31% of normal\textsuperscript{11}

95.3.1 Keel plate occipital-cervical fusion

Pre-op planning:
1. CT scan through C2
   a) to rule-out aberrant position of foramen transversarium
   b) to measure diameter of pedicles (may be best done on coronal sections due to the fact that the axial images are not usually oriented along path of pedicle) and estimate length of screws to be used
   c) to verify trajectory of screws
2. measure thickness of occipital bone to determine screw-length for occipital screws

Technique:
1. occipital keel screws/plate
   a) a drill, tap and screwdriver with flexible shafts or universal joints are usually needed because of interference from patient’s skin
   b) midline holes are preferred since occipital bone is thickest here
   c) drill with drill guide to 8 mm, check depth with probe, if the inner cortex has not been breached, drill to 10 mm, check depth again, keep drilling 2 mm at a time until the inner cortex is breached, use that screw length
   d) SCREWS 4.5 diameter blunt screws, 8–12 mm length
2. C2 pedicle screws (p.1485)
3. C3 lateral mass screws (p.1485) (if used)

95.3.2 Occipital condyle to C1 polyaxial screw fusion

See references\textsuperscript{12,13} Utilizes polyaxial screws placed in the occipital condyles that are then connected to screws placed at lower levels (see below) via connecting rods.

1. PROS compared to occipital plate/keel instrumentation:
   a) circumvents problem of poor occipital bone purchase which may occur with keel plates
   b) can be used even following posterior fossa craniectomy
   c) greater surface area for fusion
   d) avoids risk of intracranial injury from occipital screws

2. CONS: due to condylar variability, not all patients are candidates

3. biomechanics: compared to occipital plate, similar stiffness in flexion-extension and axial rotation, increased stiffness to lateral bending\textsuperscript{14}

4. clinical: 1 patient, 2 years F/U with solid OC fusion\textsuperscript{15}

Pre-op planning: CT scan occiput through C2.

Technique:
Structures to avoid include: hypoglossal nerve in hypoglossal canal (just above the occipital condyles (OC)), carotid and vertebral arteries, jugular bulb. IG may be helpful

1. occipital condyle screws
   a) ENTRY 4–5 mm lateral to the foramen magnum, 1–2 mm rostral to the atlanto-occipital joint (do not need to or want to expose the entire condyle – there is an emissary vein laterally which is best left alone)
   b) TRAJ 12–22° medial (mean: 17°), 5° maximal superior angulation
   c) SCREWS 3.5 mm diameter polyaxial screws; bicortical purchase obtained using 20–24 mm length (mean: 22 mm)

2. condyle screws are connected with 3 mm diameter rods to either:
   a) screws in C1 lateral mass and C2 pedicles (p.1483), or
   b) C1–2 transarticular screws (p.1480)
95.3.3 Occipital-C1 (AKA atlantooccipital) transarticular screws

See references.16,17
1. PROS: no compromise of C1–2 joint
2. CONS: steep trajectory requires additional incision at level of C-T junction
3. ENTRY midpoint of posterior C1 lateral mass
4. TRAJ 10–20° medially, aiming cranially to TARGET middle of occipital condyle
5. SCREWS 28–32 mm cannulated lag screws
6. biomechanics: ≈ equal to occipital plate-C1 lateral mass fusion18
7. clinical data: 2 cases reported, 2 year F/U, no complication

95.3.4 Post-op immobilization/bracing
1. for severe C1 fractures, or those with impaired bone healing capacity (elderly or unreliable patients, smokers…) a halo-vest is recommended × 8–12 weeks
2. otherwise, if C1 is not badly damaged, a collar that limits flexion (e.g. Miami-J collar) suffices × 8–12 weeks

95.4 Anterior odontoid screw fixation

95.4.1 Introduction
50% of axial rotation of the head occurs at the C1-C2 complex. Treatment of odontoid fractures by C1–2 fusion significantly reduces this mobility (although subaxial articulations will compensate to some degree over time). Odontoid screw fixation (OSF) attempts to treat odontoid fractures by restoring the structural integrity of the odontoid process (osteosynthesis) without sacrificing the normal mobility.

Stability of the C1–2 joint depends primarily on the integrity of the odontoid process and the atlantal transverse ligament (p.70) (which is the most important structure holding the odontoid process in position against the anterior arch of C1).

95.4.2 Evaluation
A full set of C-spine x-rays is needed, including an open-mouth odontoid view. MRI is recommended to rule-out disruption of atlantal transverse ligament. Cervical axial CT with coronal and sagittal reconstructions are also recommended to demonstrate the orientation of the fracture path and to verify the integrity of the posterior elements. Complex motion polytomography may be used if the CT findings are unclear.

95.4.3 Indications
Reducible odontoid Type II fracture (and Type III fractures where the fracture line is in the cephalad portion of the body of C2 in an elderly patient who may not fuse as well with immobilization as a younger patient19). The transverse ligament must be intact.

95.4.4 Contraindications
1. fractures of the C2 vertebral body (except cephalad Type III fracture)
2. disruption of atlantal transverse ligament: see Transverse atlantal ligament (TAL) injuries (p.1479). May be directly demonstrated on MRL. Indirect evidence: if the sum of the overhang of the lateral masses of C1 on C2 exceeds 7 mm (rule of Spence (p.970))
3. large odontoid fracture gap
4. irreducible fracture
5. age of fracture: controversial. Fusion rates in fracture > 18 months old was 25%20 Fracture < 6 months old have ≈ 90%fusion rate20
6. patients with short, thick necks and/or barrel chest: makes it difficult to achieve the proper angle. May be circumvented by the instrumentation distributed by Richard-Nephew which utilize a cannulated flexible drill, tap and screwdriver
7. pathologic odontoid fracture
8. fracture line in oblique orientation to frontal plane (shearing forces can cause malalignment during screw tightening)
Booking the case: Odontoid screw fixation

See defaults & disclaimers (p. 27).
1. position: supine head on horseshoe headrest, halter traction
2. anesthesia: awake fiberoptic or nasotracheal intubation. Do NOT use a wire reinforced endotracheal tube
3. equipment: 2 C-arms for biplane fluoro, or O-arm image guidance
4. instrumentation:
   a) ACF surgical set
   b) tube retractor (e.g. METRx® by Medtronic)
   c) some surgeons use specialized instrumentation (e.g. Apfelbaum set)
5. implants: cannulated screw set
6. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery to place screw(s) from the front of the neck across the fractured odontoid bone. Possible posterior approach in case the anterior approach cannot be completed
   b) alternatives: nonsurgical management in a collar, fusion
   c) complications: screw breakage/pullout, failure to fuse which might require addition surgery (which will reduce neck motion)

95.4.5 Technique summary

Preparation

Various instrumentation systems have been developed to facilitate the procedure. The following describes some of the basic elements that are not specific to any one instrumentation (see reference by Apfelbaum21 for details of his instrumentation distributed by Aesculap Instrument Corporation, South San Francisco, CA).

Two C-arm fluoroscopy machines are mandatory for bi-plane imaging (simultaneous AP and lateral views). Some surgeons prefer placing 2 screws if there is enough bone to accommodate them, however, this may also reduce the amount of bone surface that can heal and the fusion rate appears to be the same.22

Anesthetic considerations

The anesthesiologist is positioned at the foot of the table. Awake fiberoptic or nasotracheal intubation is recommended, especially for easily dislocatable fractures. Do NOT use a wire reinforced endotracheal tube since the wire interferes with the AP imaging.

Position

Supine. The neck is placed in extension (critical to performing the procedure) either with Holter traction and a small shoulder roll with the head on a doughnut (a strip of tape across the forehead stabilizes the head), or a radiolucent head holder may be used. Place the lateral fluoro unit first, then the AP unit slides into the “C” of the lateral unit. Lateral fluoroscopy is used to assess reduction of the fracture fragment, and the head is repositioned to try and achieve reduction. If there is retrolisthesis of the odontoid, the neck may need to be slightly less extended. A radiolucent mouth gag is placed to hold the mouth open for AP transoral imaging (a small tape roll works well). Abort the procedure if AP and lateral fluoroscopic views do not adequately image the odontoid.

Approach

A Cloward-type of horizontal skin incision at \( \approx C5–6 \) (the entry site can be localized by placing a guidewire adjacent to the patient’s neck and taking a lateral fluoro) and approach identical to anterior cervical discectomy is used (all the way to exposing the longus coli muscles (p. 1073)). A Kittner is used to dissect superiorly anterior to the longus coli muscles in the loose areolar tissue up to C2. A self-retaining retractor (e.g. Caspar retractor – not distractor) with a superior retractor blade is attached (or a hand-held retractor, preferably radiolucent, may be used). Alternatively, a retractor tube system23 (e.g. METRx® by Medtronic) may be used. The bovie is used to remove the soft tissue over the inferior front of C2.
Procedure

Localization: lateral fluoroscopy is used to place the tip of an awl as far anteriorly as possible on the inferior endplate of C2 (Fig. 95.1; a common error is to go too far back along the inferior margin of C2, then the guidewire end up towards the back of the dens). AP fluoroscopy is used to place the awl in the exact center of the C2 body in the lateral dimension. The awl is used to make a pilot hole at this location.

Guidewire placement, drilling, tapping and ultimately screw placement are performed while monitoring the progress on frequent fluoroscopy images, aiming for the exact middle of the dens on AP fluoroscopy, and aiming towards the apex of the odontoid fracture fragment (skimming just within the anterior part of the C2 vertebral body) on lateral fluoroscopy. Drilling is performed under fluoroscopy all the way through the apical cortex of the dens to avoid cracking the dens with the screw (the area just distal to the apex of the dens is safe).

A titanium partially threaded (lag) screw is placed. If an appropriately sized lag screw is not available, one can overdrill the part of the path through the body of C2 up to the fracture. In this way, a fully threaded screws can be used which will slip through the overdrilled hole and still have a lag effect on the fracture fragment. If a second side-by-side screw is used, it may be fully threaded. In chronic nonunion cases, prior to advancing the screw a bifaced curette may be inserted within the fracture space to freshen the fracture site. The screw(s) should be drawn up tightly to the inferior edge of C2. Fig. 95.1 shows the final position of an anterior odontoid screw.

At the end of the procedure confirm integrity of the transverse ligament by carefully flexing the neck under lateral fluoroscopy.

---

Fig. 95.1 Final position of anterior odontoid screw
Postoperative immobilization

The immediate post-op strength of the odontoid + screw is only \( \approx 50\% \) of the normal odontoid. Therefore, a cervical brace is recommended for 6 weeks\(^9\) (although some authors don’t use one\(^{21}\)). If the patient has significant osteoporosis, a halo brace is recommended.

Results

Healing takes \( \approx 3 \) months (or longer with chronic nonunion). With fractures <6 months old, the union rate was 95% Chronic nonunions >6 months old have a significant risk of hardware failure (screw breakage or pull-out), with a bony union rate of 31% and 38% rate of presumed fibrous union.\(^{21}\) Thus, in cases of chronic nonunion >6 months old, C1–2 arthrodesis is probably a better choice unless the need to maintain motion is worth the risk of needing a second operation if this one fails.

The average technical complication rate is \( \approx 6\% \)(2% screw malposition, 1.5% screw breakout).

95.5 Atlantoaxial fusion (C1–2 arthrodesis)

95.5.1 Indications

NB: The patient will lose \( \approx 50\% \) of head rotation with C1–2 fusion.

Instability of the C1–2 joints, including:

1. atlantoaxial dislocation due to incompetence of the transverse atlantal ligament (TAL):
   a) rheumatoid arthritis (p.1136): symptomatic patients, or asymptomatic patients with subluxation \( \geq 8 \) mm
   b) local infection
   c) trauma
   d) Down syndrome (p.1138): due to laxity of the TAL

2. incompetence of the odontoid process
   a) odontoid fractures meeting surgical criteria, including
      • Type II fractures with >6 mm displacement
      • instability at the fracture site in halo-vest traction
      • chronic nonunion of odontoid fractures
      • disruption of the transverse ligament
   b) following transoral odontoidectomy
   c) tumors destroying the odontoid process

Vertebrobasilar insufficiency with head turning (p.1307) (bow hunter’s sign)

95.5.2 Technical considerations

Some cases require incorporation of the occiput in addition to C1–2.

Surgical options include:

Rigid instrumentation:

1. C1–C2 fusion using polyaxial screws connected by rods:
   a) C1: screws placed in lateral masses. May be used in cases where the posterior arch of C1 is compromised
   b) C2 screw options:
      • screws may be placed in pedicles (pars)
      • screws may be placed in lateral masses
      • crossed C2 laminar screws

2. C1–2 posterior transarticular facet screws (TAS)\(^{22,26,27}\)

Posterior cervical wiring and fusion. With the development of rigid fixation, these techniques are used less frequently. While they are poor in limiting rotation, they are effective in limiting flexion. And since the Dickman & Sonntag technique is effective in limiting extension, it has recently been used to offload C1 lateral mass screws which have a tendency to break at the point of entry to the bone of C1

1. interspinous fusion technique of Dickman and Sonntag (p.1483)
2. not presented here
95.5.3 Techniques of atlantoaxial fusion

Positioning

The patient is placed in a halo ring (with a gap in the back and secured to the table using a Mayfield adapter) or Mayfield pin fixation and is then placed prone on the O.R. table on chest rolls. The table will usually need to be positioned in a maximal reverse-Trendelenburg position to bring up the surgical area. The patient’s feet are allowed to rest on a padded footplate on the table to prevent the patient from sliding down. Lateral intraoperative x-rays are taken after patient positioning.

Incision and approach

A midline skin incision is made from just below the inion to the spinous process of C5 or C6.

C1–2 transarticular facet screws (TAS)

May be used as an adjunct to posterior C1–2 wiring and bone graft – e.g. technique of Dickman and Sonntag (p. 1483) – to achieve immediate stabilization without the need for postoperative external orthosis, or in cases where the posterior arch of C1 is fractured or absent. A major risk of the procedure is vertebral artery (VA) injury. Therefore many practitioners have adopted C1 lateral mass screws (p. 1481).

Selection of candidates

May be appropriate in elderly patients or those with rheumatoid arthritis, in whom there may be slow fusion, or for those who have failed a previous attempt at C1–2 wiring/fusion. Also in young individuals who have ligamentous laxity.

All patients must have thin cut CT scans from the occipital condyles through C3 with sagittal reconstruction through the C1–2 facet on both sides to look for the presence of a vertebral artery in the intended path of the screw. Also, risk of VA injury can be reduced using CT scans reconstructed along the planned trajectory of the screw (aiming from a point 4 mm above the inferior C2 facet to a point in the anterior C1 button on CT).

Technique summary

A number of instrumentation sets are available for the procedure, and each has its own nuances. The following is intended to primarily cover the basic procedure common to most or all (see reference by Apfelbaum for details with that system).

Position:

Patient supine, with the head clamped in a Mayfield head-holder with a slight military tuck of the chin. Lateral C-arm fluoroscopy is used for the procedure, and some have advocated biplane fluoro.

Approach:

Utilize a standard midline posterior laminectomy approach from occiput to the C3 spinous process. The lamina of C2 and the posterior arch of C1 are exposed to the lateral aspect of the C2 inferior articular facet. The lateral extent of the spinal canal is defined using a small angled curette. The C1–2 facet is curetted to facilitate arthrodesis and permits observation of the drill as it crosses the joint.
ENTRY 1–2 mm superior to the C2–3 facet on the midline axis of the pars interarticularis. The trajectory is determined fluoroscopically using a K-wire placed on the side of the neck as a guide, aiming it through the C2 inferior articular process, pars interarticularis, superior articular process and across the C1–2 articulation into the lateral mass of C1. This helps establish the appropriate entry site for the drill guide through a separate stab wound, usually around the T1–2 level, 2–3 cm off the midline.

TRAJ A pilot hole is then drilled using visual guidance to maintain a straight parasagittal course (it helps to stand on 1 or 2 footstools to eliminate some of the parallax error) and fluoroscopic guidance to maintain the trajectory towards the C1 lateral mass. An assistant can reduce any atlanto-axial translational malalignment using a towel clip on C1 or C2 just prior to the drill crossing the C1–2 facet joint. To minimize the risk of VA injury, keep the drill as far dorsally as possible within the pars interarticularis. The pilot hole is then tapped and a fully threaded titanium screw is placed. If brisk arterial bleeding (not bone bleeding) occurs after drilling or tapping the first side, the VA may have been injured. The screw may still be placed but the contralateral hole and screw should not be placed. A post-op arteriogram is then performed to assess for propagating thrombus or dissection. Barring any contraindications, the procedure is repeated on the contralateral side. After screw placement, then posterior arthrodesis – e.g. technique of Dickman and Sonntag (p. 1483) – is performed. External immobilization is usually not employed post-op (the screws are considered to supply adequate internal immobilization).

Results
A fusion rate of up to 99% with no complications has been reported. Injury to the vertebral artery is the main potential complication.

C1–2 lateral mass screws
Placement of polyaxial mini screws in C1 lateral mass and C2 pedicle with rod fixation. Originated by Goel and Laheri in 1994 and promulgated in 2001 by Harms and Melcher.

Advantages over C1–2 transarticular screws (see above):
1. the more superior and medial trajectory should reduce the risk of VA injury
2. may be used in the presence of C1–2 subluxation
3. may be usable in certain cases of aberrant VA course
4. in selected cases, this can be used for temporary fixation without fusion (since joint spaces remain intact) and the hardware may be removed after an appropriate time to reclaim motion in the C1–2 articulation

Booking the case: C1–2 lateral mass fusion
Also see defaults & disclaimers (p. 27) and pre-op assessment (see below).
1. position: prone, pin headholder
2. anesthesia: awake fiberoptic or nasotracheal intubation
3. equipment: C-arm or O-arm image guidance
4. implants:
   a) mini-polyaxial screws (smooth shank screws needed for C1)
   b) cable required for interspinous graft (optional, but recommended)
   c) have rep bring in occipital plates and instrumentation in case of inability to place C1 screws therefore enabling occipital-cervical fusion as a bail-out option
5. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery to place screws & rods from the back of the neck to stabilize, and usually to fuse the top 2 bones of the neck
   b) alternatives: nonsurgical management in a collar, in some cases screws may be temporary and no fusion would be done
   c) complications: screw breakage/pullout, failure to fuse which might require addition surgery, loss of some neck bending motion is expected (≈ 20% is typical)

Surgical technique (excerpted highlights)
See references
NB: if fusion is to accompany screw placement (i.e. permanent screw placement), strong consideration should be given to supplemental interspinous fusion, if not contraindicated (p. 1483) to prevent fatigue breakage of C1 screws.

Applied anatomy: there is no true neural foramen at C1–2, the C2 nerve root lies on the posterior surface of the capsule of the C1–2 articular joint.

Pre-op assessment
It is mandatory to know the position of the VA on both sides (and in particular, the location of both foramina transversarium of C1), and the following bony information (requires thin-cut CT scan):

1. cranio-caudal thickness (height) of the posterior arch of C1 (in case the arch needs to be drilled to facilitate screw placement)
2. to determine screw length: distance from the planned entry point (see below) to the planned exit target (midposition of the anterior part of the superior C1 VB)
3. to estimate medio-lateral angle for screws

Approach
Completely expose the C1–C2 complex. Dissect over the superior surface of the C2 pars interarticularis to expose the C1–C2 joint to accurately locate the entry point for the C1 lateral mass screws. Bleeding is controlled with bipolar cautery and/or Gelfoam-thrombin. Complete exposure of the posterior face of the inferior C1 facet also mobilizes the C2 root from the underlying attachments and facilitates its inferior mobilization.

1. C1 lateral mass screws: ENTRY visualization commonly requires caudal retraction of the C2 dorsal root ganglion (occasionally this may not be feasible\(^3\); sacrificing the C2 root may be required but this can lead to post-op pain and numbness\(^3\); technique is to divide the preganglionic nerve fibers and to close the dural defect\(^1\)). The screw entry point is the midpoint of the inferior part of the C1 lateral mass (for both mediolateral and cranio-caudal directions). An awl or a 1- to 2-mm high-speed drill is used to mark the position to prevent slippage while drilling the hole. Drilling a portion of the inferior arch of C1 is sometimes needed to allow screw placement (caution: the thickness of the arch in the cranio-caudal dimension varies widely, and the horizontal segment of the VA lies immediately above – use pre-op CT for planning)
2. C1 screw TRAJ averages ≈17° medially, ≈22° rostrally, TARGET the superior aspect of the anterior tubercle of C1 on lateral fluoro (see Fig. 95.2)
3. C1 SCREWS 3.5 or 4 mm diameter, length is determined from pre-op fine-cut CT to obtain bicortical purchase (CAUTION: the ICA may be as close as 1 mm to the ideal exit site of the screw\(^3\); some authors use only unicortical purchase). The screw needs to be proud to bring it up to the level of the C2 screw (it may actually be necessary to have the C1 screw protruding 1–2 mm more than the C2 screw in order to allow rod attachment\(^3\)), and it should have an ≈8 mm unthreaded superficial portion to minimize irritation of the C2 nerve which could produce occipital neuralgia
4. C2 pedicle (pars) screws, see description of placement (p.1483)
5. if a fusion is to be performed: the posterior arch of C1 and the C2 lamina are decorticated with a drill. Onlay fusion substrate is then placed, taking care not to compress the dura. Optional adjunct: intra-articular decortication and packing bone within the C1–2 joint

**Fig. 95.2 Screw entry point and trajectory for C1 lateral mass screws**
Post-op care
A cervical collar (soft or rigid, as preferred) for 4–6 weeks suffices.

Interspinous fusion technique of Dickman and Sonntag
A single bicortical graft is used, with multistranded cable passed sublaminar to C1 only. The bone graft is wedged between C1 and C2 (trapping it between loops of cable).\textsuperscript{39,40} see Fig. 95.3. Currently, this technique is infrequently used as the primary fixation for C1–2 fusion (unless technical difficulties prevent e.g. C1–2 lateral mass fusion). However, it may be most useful for limiting extension to offload C1 lateral mass screws to reduce the risk of screw breakage.\textsuperscript{41}

Cannot be used if the posterior ring of C1 or C2 is fractured.

Bone graft
Autologous bone is preferred. Bone is often taken from the posterior iliac crest (p. 1440). A tricortical graft of \( \approx 4 \text{ cm length} \times >1 \text{ cm height} \) is obtained. The top edge is removed to create a bicortical graft of \( \approx 1 \text{ cm height} \).

95.6 C2 screws
95.6.1 Options
1. pedicle screws (pars interarticularis screws): directed medially (see below)
2. lateral mass screws: directed laterally. Length is sized to fall short of foramen transversarium
3. C1–2 transarticular screws (p. 1480): associated with more risk of VA injury
4. translaminar screws\textsuperscript{42,43}: 1 year stability appears to be less than C2 pedicle screws when used for subaxial fusions, but was \( \approx \) as effective for axial fusions (C1–2 or C1–3).\textsuperscript{44} May be useful as a “bailout” for subaxial fusions when the C2 pars diameter is too small for pedicle screws\textsuperscript{45}

95.6.2 C2 pedicle (pars) screws
Check CT scan or MRI to rule-out aberrant location of vertebral artery or unusual location of foramen transversarium before placing C2 pedicle screws. Some find image guided navigation systems to be helpful.
Technique:
1. **ENTRY** palpate the medial and superior aspect of the pars with a Penfield 4 dissector (Fig. 95.4). Enter at the estimated center of the surface projection of the C2 pars at the midpoint medio-laterally in the supero-medial quadrant of the surface of the C2 isthmus.

2. **TRAJ** 20–30° medially (through the central axis of the C2 pedicle), 25° superiorly (on lateral fluoroscopy, place the screw parallel to the pars) (Fig. 95.5). To assist with trajectory, expose the proximal upper and medial border of the C2 pars interarticularis, and use a Penfield 4 to palpate during drilling (Fig. 95.4).

3. Drill a shallow entry point, then drill with drill-stop set at 12 mm, monitoring progress at intervals under fluoro and palpating with probe, and if no breakout, then complete drilling by gradually increasing drilling depth by 2 mm increments either up to 15-20 mm to stay in the pedicles, or up to ≈30 mm depth to perform osteosynthesis for a hangman’s fracture. If withdrawal of the drill is followed by brisk bleeding, the screw should be inserted immediately to stop the bleeding. This bleeding may be from the vertebral artery; however, it is usually due to injury to the venous plexuses, and will not have any ill effects. In such cases it is best to not place the contralateral screw and to obtain an angiogram very soon post-op.

4. **SCREWS** 3.5 mm dia. Screw length is not critical except when attempting to bridge a fracture gap (osteosynthesis) e.g. with a hangman’s fracture in which case screws of 20–30 mm length are placed to avoid penetrating anterior C2 cortex (lag screws are used for this, or the proximal bone can be overdrilled); for most purposes screw lengths of 15–20 mm length are used. Shorter screws (15-16 mm length) can still grip the pedicle with lower risk of VA injury.

---

Fig. 95.4 Entry point for C2 pedicle screw placement (posterior view)

Fig. 95.5 Screw trajectory for C2 pedicle screws
95.6.3 C3–6 fixation

Lateral mass screws
Generally applicable to C3–6. The lateral masses of the thoracic spine are usually too small and not strong enough for these screws. C7 is a transitional level, and lateral mass screws may sometimes be used. Occasionally even T1 may be amenable (see below).

Technique:
A number of methods have been promulgated with various screw entry points and trajectories (some are shown in Table 95.1). Comparing 3 techniques there was a lower risk of nerve injury with the following (method of An):

1. ENTRY1 mm medial to the midpoint of the lateral mass (Fig. 95.6). In the cranial-caudal direction, the midpoint is used. A Penfield 4 may be used to palpate the medial wall of the pars to help determine entry point and trajectory

2. TRAJ30° laterally, 15° cephalad (editor’s note: for upper cervical levels more cephalad trajectory is used, for caudal cervical levels 15° or less may be closer) (Fig. 95.6). To get the lateral angulation, the holes are best drilled from the contralateral side of the patient, holding the drill shaft almost up against the spinous processes (if they are still present)
   a) SCREWS 3.5 mm diameter, 14–16 mm length (for C3–6)
   b) rod size: 3.5 mm diameter rods are usually used, and can be placed as far caudally as T3 as long as there is not gross instability (below T3, 5.5 mm diameter rods are used either via transitional rods or with rod connectors, e.g. “domino” connector)

Spinous process wiring may be used with intact spinous processes to help secure the bone graft.47

Transarticular screw fixation
An alternative to lateral mass fusion. First described in 1972 by Roy Camille. May be used alone or as an anchor point.

*angle can be determined by inserting probe into the joint

Fig. 95.6 Screw entry point and trajectory for C3–6 lateral mass screws (method of An)
1. **PROS:**
   a) screws cross 4 cortical surfaces for better purchase
   b) compresses across the joint to promote fusion
   c) useful at cervico-thoracic junction where trajectory preserves facet capsule
   d) lower implant profile
2. **CONS:** cannot correct deformity
3. **ENTRY** midpoint of lateral mass
4. **TRAJ** perpendicular to joint, neutral to 5° lateral (to avoid VA and exiting root)
5. biomechanics: stability equivalent to lateral mass screws
6. clinical: 25 patients (81 screws), 71 anchor, 10 fixation, 3.5 years F/U: solid fusion, no complications

**Translaminar cervical screw fixation**

May be used in cervical or thoracic spine.

1. indications: salvage technique when anatomy precludes pedicle screws
2. **PR O S:**
   a) avoids complications related to pedicle screws
   b) no need for fluoroscopy (reduces radiation exposure)
3. **CONS:** requires intact posterior elements (cannot do with laminectomy)
4. **ENTRY** contralateral spinolaminar junction (at base of spinous process)
5. **TARGET** junction of the transverse process and the superior facet contralateral to the entry point
6. **SCREWS** 3.5–4.5 mm × 26 mm polyaxial screw
7. biomechanics: no data
8. clinical: 7 patients (C-T fixation), 14 months F/U, no hardware complications. Inconsequential ventral penetration in 5%

**C7 screws**

C7 is a transitional level, and as a result either the lateral masses or the pedicles or both may be relatively small.

Screw fixation options:
1. pedicle screws (p.1489): recommended especially when the C7 lateral mass is of inadequate size for lateral mass screws. Placement with fluoroscopy may be difficult due to shoulder artifact on lateral fluoro, and direct visualization of the medial wall of the pedicle may be required as in the thoracic spine
2. lateral mass screws:
   a) **ENTRY** as for C3–6 (see above)
   b) **TRA J** compared to C3–6 screws, slightly less lateral at ≈ 15° and a little less cephalad at ≈ 10°
   c) **SCREWS** 3.5 mm diameter, 14 mm length
   d) biomechanics: lab studies indicate that C7 lateral mass screws are biomechanically equivalent to C7 pedicle screws in constructs extending down to C7
3. **C7 transfacet screw**:
   a) **PR O S:** reduced risk to spinal cord and nerve roots
   b) **CONS:** disrupts C7-T1 facet capsule, so T1 must be included in fusion. Short screws result in low pullout strength may be best used as an intermediate anchor point and not an construct endpoint
   c) **ENTRY** 1–2 mm medial and superior to center of facet
   d) **TRA J** 30° inferiorly and 20° laterally, **TARGET** goal is bicortical purchase
   e) **SCREWS** 3.5 mm diameter × 8–10 mm polyaxial screws
   f) biomechanics: equivalent to C7-T1 pedicle screws
   g) clinical: 10 patients, long cervico-thoracic fixation, 6 months F/U, 3 patients with solid fusion

**Anterior vertebral body screw-plate fixation**

Plate should be contoured to directly contact the front of the VBs being instrumented.

Typically, fixed screws are used in the lowest level, and variable screws are used at levels above. However, practices vary.

For the most rostral and most cranial screw holes, the plate should be sized such that the edge of the VB would just be visible when looking through the hole.

Screw length: Typical lengths vary from 12 mm (usually in women) to 16 mm. As a guide, if Caspar pins are used during the operation, most have 14 mm of threads in the VB, the screw length can
be chosen based on how close these Caspar pins come to the posterior VB. The screws in the plate are usually angled, so an additional 1–2 mm can be accommodated beyond this length.

95.8 Zero profile interbody devices

These devices incorporate holders for screw placement into an interbody cage without need for a separate anterior plate. Most often used in cervical spine.

1. PROS:
   a) Are often easier to place adjacent to a previously placed anterior plate (because the plate will often cover too much of the VB to provide enough room for another plate on the same VB)
   b) Avoids plates that are not parallel to the long axis of the spine
   c) Posterior migration of the cage is prevented once the screws are placed

2. CONS: Biomechanical stability is less than that with a plate (4-screw devices are more stable than 3 screw devices)

References

96 Spine, Thoracic and Lumbar

96.1 Anterior access to the cervico-thoracic junction/upper thoracic spine

96.1.1 Sternal splitting procedure

Permits access down to T3 (occasionally as far as T5) from an anterior midline approach (access to this region with a lateral (transthoracic) approach is poor due to the small volume of the pulmonary apices).

The neck and thorax are prepped down to the umbilicus. A hockey stick incision may be used, the horizontal portion is the usual for an ACDF. The vertical limb is centered over the sternum. In most cases, the services of a CV surgeon are employed to split the sternum and divide the sternocleido-mastoid. This approach does not violate the pericardium or pleura, and a chest tube is not required (but is often used as a large bore drain to prevent hemomediastinum, and also as a precaution in case the parietal pleura is cut during the exposure). Because of the depth of the approach, longer instruments than the routine 7 inch length instruments used for an ACDF are required.

The exposed edges of the sternum may also be used to obtain cancellous bone for the graft.

96.2 Anterior access to mid and lower thoracic spine

96.2.1 Transthoracic approach

Position: lateral position on a bean-bag on the O.R. table with the break in the table under the level of pathology (remember to unbreak the table prior to instrumenting). Stabilize the patient using adhesive tape over surgical towels. An axillary roll is placed. A double-lumen endotracheal tube is used to permit deflating the lung on the side of the thoracotomy. If the patient does not tolerate completely deflating one lung, it is often adequate to just partially deflate the lung.

To increase the exposure, a rib may be resected. Generally, the level opened and the rib removed are one or two levels above the level of pathology (e.g. for T7 VB tumor, the T6 or T5 rib are removed).

If a compression plate is going to be used, the goal is to be lateral on the VB, to achieve this try to position it as far posterior as possible (rongeur off a little bit of the rib heads to facilitate this).

96.2.2 Anterior access to mid thoracic spine

Laterality of approach: if the pathology does not dictate use of one side over another:
1. advantages of right-sided thoracotomy: the heart, mediastinum and brachiocephalic vein do not impede access
2. advantages of left-sided thoracotomy: aorta is easier to mobilize and retract

Determining the level in the upper T-spine can be quite difficult intraoperatively. Counting up from the sacrum on an AP view using live fluoro sometimes will work when lateral spine x-rays cannot penetrate the lower c-spine due to the shoulders.

96.2.3 Anterior access to lower thoracic spine

Unless pathology is predominantly right-sided, a left-sided thoracotomy is preferred (easier to mobilize aorta than vena cava).

At about T10 and below, the attachment of the diaphragm increases the difficulty of the approach. In this area, a retrocoelomic approach (outside the pleural cavity) can facilitate surgery.

96.3 Thoracic pedicle screws

96.3.1 General information

Preferable to lateral mass screws because the transverse processes (which are analogous to the lateral masses in the cervical spine) of most thoracic vertebrae are not as strong. Thoracic pedicles are
usually very narrow in the lateral dimension (the width is a little larger at the cranial end) and are very tall in cranio-rostral direction. Image guidance systems may also be helpful.

Accurate placement of thoracic pedicle screws is generally more challenging than the lumbar spine. There are at least 4 methods to place these screws, and a combination of methods may be used.

1. Intra-operative fluoro: for parts of the thoracic spine, biplane fluoro may be used as in the lumbar spine (see above)
   a) **PROS:**
      - Allows percutaneous screw placement
      - generally good accuracy in screw placement
   b) **CONS:**
      - due to the dense bone of the shoulders, the thoracic spine is usually difficult to image from T1 to about T4 on lateral fluoroscopy. For non-percutaneous cases, Steinman pins may be placed at the estimated entry points for the screws, and AP fluoro is used to fine-tune the position so that the screw enters the pedicle at the desired location
      - may increase radiation exposure to surgery team and patient

2. “Free hand” placement based on anatomic landmarks. X-rays are usually still obtained at the end, and any screws with unsatisfactory placement must be revised
   a) **PROS:**
      - As the number of levels (and therefore, screws) placed in a patient increases, may save time over other methods
      - The small facetectomies that are needed to visualize the facet joint of the level below can facilitate correction of spinal curves and provide a good fusion surface
      - likely reduces radiation to the surgical team and the patient
   b) **CONS:** Steep learning curve: this method probably takes the most practice to perfect

3. Performing small laminotomies at each level where pedicles are not exposed by a laminectomy, and use position of pedicle either by visualization or by palpate of the medial and superior aspect of the pedicles with a dissector to get an approximation of the entry point and pedicle trajectory
   a) **PROS:** can permit accurate placement at essentially any level with potentially less radiation (depending on how often the surgeon checks screw position)
   b) **CONS:** takes a little time at each level, but is over all comparable to other methods

4. Image guidance using instruments that are fitted with specialized markers that are tracked real-time by “cameras” that project the drill and/or screw location on a CT or x-ray image viewed in the OR.
   a) **PROS:**
      - reduces intra-operative radiation to surgical team, and to a lesser extent to the patient
      - Allows percutaneous screw placement
   b) **CONS:** accuracy may be compromised by movement of spinal segments relative to the registration array, or by technical errors. The surgeon must be vigilant for screw placement that does not look appropriate based on the anatomy

96.3.2 Fluoro and laminotomy thoracic pedicle screw placement technique:

1. **ENTRY:** See Freehand thoracic pedicle screw placement technique (p.1491) for entry points using landmarks. Alternatives: making a small laminotomy to palpate the medial and cephalad edges of the pedicle with a Penfield #4 dissector, using Steinman pins at estimated entry points and taking AP fluoro to fine tune (see Fig. 96.1).

2. **TRAJ**
   a) below T1: 5–10° medially and 10–20° caudal (Fig. 96.2). A thoracic Lenke probe may be used as a pedicle finder.
   b) T1: if a lateral mass screw is placed at T1 (instead of a pedicle screw), aim almost straight down at the floor (with patient positioned horizontally, i.e. without Trendelenberg or reverse-Trendelenberg)

3. **SCREW** Smaller pedicles (usually T1–4, especially in females) usually require the smallest screw diameter (typically 4.5 mm). Others may accommodate 5.5 mm. Typical length: 20–25 mm

4. Rod size: when connecting to a cervical rod, down to ~T3 you can use a 3.5 mm diameter cervical rod throughout (here, the stiffer cobalt-chrome rod may be advantageous over titanium) with some systems (e.g. Mountaineer by DePuy using a 4.35 diameter screw). Below T3, ~5.5 mm diameter rods (or 6.35 mm for scoliosis surgery) are usually used either via a transitional rod or using a domino connector to mate the two rods
96.3.3 Freehand thoracic pedicle screw placement technique

Advantages and disadvantages

Possible advantages
- May speed up surgery especially when instrumenting a large number of levels
- Reduces the amount of x-rays/fluoroscopy needed during surgery
- Avoids the challenges of getting fluoro aligned for each level in a scoliotic spine especially when a rotational component is present
- Not impeded in areas that are difficult to image on fluoroscopy (typically upper thoracic spine)
- Accuracy as good or better than other techniques
- Obtains bone for use in graft (from facetectomies)
- Exposes bone (of facet joints) to assist in fusion
- Releases joints which facilitates reduction of scoliosis

Possible disadvantages
- Cannot be used if anatomy distorted by previous fusions, congenital anomalies…
- Steep learning curve: requires learning new aspects of anatomy, necessitates performing numerous screw placements, usually with a mentor, to become proficient
- Possible increased blood loss from increased exposure and facetectomies
Procedure

The details of the procedure are beyond the scope of this book. A summary of key points/information:

- Complete exposure of entire posterior elements (lamina, pars interarticularis, facets, transverse process (tp)…) at every level is mandatory
- Intraoperative electrophysiologic monitoring: SSEP, MEP, triggered EMG
- Facetectomies: performed bilaterally at every level except the most superior (that one is not being fused to the level above). Make 2 cuts: 1st is parallel to canal. Caution: spinal cord is at risk on side of concavity
- It is essential to develop a series of steps that are repeated without deviation with every screw placement:
  - make pilot hole at entry point (as indicated below)
  - insert curved pedicle finder with the tip directed laterally until 2 cm deep (do not force)
  - completely remove the pedicle finder and rotate it 180° and re-insert it with the curve directed medially
  - palpate all 4 walls and the deep end with a ball probe, push it gently through the cancellous bone until the tip strikes the cortical bone of the anterior vertebral body (sound and feel). Place a clamp where the probe enters the bone and...
  - measure the depth that the probe was inserted to determine maximum screw length; if the length is much shorter than expected, the probe may be hitting the lateral VB wall and consideration should be given to redirecting the screw more medially
  - tap the pedicle (i.e. cut the threads for the screw using a tap)
  - probe 2nd time with ball probe
  - place screw
  - run a set of motor evoked potentials on electrophysiologic monitoring
  - after all screws are placed, stimulate each screw with triggered EMG: stimulation at <6 mA (some surgeons use cutoff of 8 mA instead) or a threshold that is 65% or more decreased from the average of the other screws indicates a possible medial pedicle breach and should prompt a re-evaluation of the screw (remove screw & re-probe the hole or obtain a fluoro image)

Entry points

- Cranio-caudal (Fig. 96.3)
  - T1, 2, 3 & 12: even with the middle of the transverse process (mnemonic: T1–2-3 “mid tp”) same for T12 (like lumbar spine below it)
  - T7, 8 & 9: even with the top of the transverse process (mnemonic: T7–8-9 “top of the line”)
  - For levels in between these 2 groups (T4, 5 & 6), gradually move slightly superior from mid tp at T1–2-3 to the top of the tp at T7–8-9
- Mediolateral (Fig. 96.3)
  - T1, 2 & 3: even with the lateral edge of the pars
  - T7, 8 & 9: just lateral to midposition of the base of the superior articular facet (the most medial starting points)
  - T11, 12: at or just medial to lateral edge of pars
  - Levels in between these groups: gradually transition the position

Trajectories

- Trajectories using landmarks
  - Practitioners of freehand screw placement use landmarks more than angles. The advantage is that angles are difficult to estimate, and using landmarks allows screws to be placed even in rotated, scoliotic spines.
  - The screw is inserted perpendicular to the surface of the superior articular facet (that is exposed during the facetectomies) while also “aiming” at the contralateral pedicle.
- Trajectories using angles: may be helpful to conceptualize
  - Cranio-caudal angle (Fig. 96.2 – B): either of 2 trajectories are used:
    - Straightforward screw placement: 0° to horizontal (parallel to the superior endplate – allows fixed-head screws for spine derotation)
    - Anatomic screw placement: 10–15° caudal (parallel to the pedicle – provides a longer path for screw contact with bone but requires a multiaxial screw head)
  - Mediolateral trajectory (Fig. 96.2 – A)
    - the angle gradually becomes more medial as you progress from
    - T12 where the angle is slightly lateral (≈ −5°) to
Screw size
- Length: the depth to the anterior cortex varies from 40–45 mm when measured along axis of pedicle (or 30–42 mm when measured parallel to sagittal plane). Typical thoracic screw length is 35–40 mm.
- Diameter: the narrowest pedicles in the mediolateral dimension are typically T4–7. Screw diameter should be approximately 80% of the pedicle diameter.

96.4 Anterior access to thoracolumbar junction

96.4.1 Retroperitoneal approach

Unless the pathology is predominantly left-sided, a left-sided approach is preferred because the spleen is easier to retract than the liver, and the aorta is easier to mobilize than the inferior vena cava. It is important to flex the ipsilateral leg to relax the psoas muscle, permitting safer retraction of the ipsilateral lumbosacral plexus.

96.5 Anterior access to the lumbar spine

96.5.1 Anterior lumbar interbody fusion (ALIF)

Retroperitoneal usually through a Pfannenstiel’s abdominal incision. Relatively contraindicated in males because of risk of retrograde ejaculation in 1–2% (as high as 45% in some reviews). Other risks: injury to great vessels, especially with calcified arteries, especially at L4–5.

Bowel prep the day before surgery for complex cases.

Position: Trendelenburg position, place the level of the iliac crests over the kidney rest or use a sacral bump to increase lordosis.

As a result of the bifurcation of the great vessels (aorta and inferior vena cava) which ranges from just above to just below the L4–5 disc space, this approach is best suited for access to L5-S1.

At L5-S1, the anterior sacral artery runs down the midline of the VB and has to be sacrificed to do an ALIF.
96.6 Instrumentation/fusion pearls for the lumbar and lumbo-sacral spine

1. a lumbar fusion that includes L1 should not be terminated at L1 or T12
2. the taller the disc space the less likely that interbody grafts are well suited:
   a) the disc may not be significantly degenerated to require discectomy
   b) tall disc space means larger interbody implants which requires more retraction of nerve to
      insert (using a PLIF technique)
3. a long fusion should not be terminated at or near a vertebral level that is at the apex of
   scoliosis
4. laminectomy without fusion should be avoided at the apex of scoliosis
5. posterior midline fusion: early experience with midline fusions resulted in lumbar spinal stenosis
   as a late complication. Therefore, current fusion techniques include postero-lateral fusion, inter-
   body fusion (from anterior or posterior approach), facet fusion...

96.7 Lumbosacral pedicle screws

96.7.1 General information

Pedicle screw pull out strength is determined in part by the major screw diameter which should be
70–80% of pedicle diameter (larger screws can break through the pedicle wall or can burst the
pedicle). The minor diameter determines the strength of the screw and should be ≥5.5 mm in the
adult lumbar spine. The length should allow penetration of 70–80% of the VB. Bicortical purchase or
anterior VB penetration should be avoided to reduce the risk of injury to great vessels or abdominal
viscera.

96.7.2 Placement techniques

There are at least 4 screw placement techniques
1. Intra-operative fluoro: biplane fluoro facilitates this technique
   a) PROS:
      • allows percutaneous screw placement
      • generally good accuracy in screw placement
   b) CONS:
      • imaging may be difficult in some parts of the lumbar spine, especially in larger patients. In
        these cases, the Steinman pin method below can be used to supplement
      • may increase radiation exposure to surgery team and patient
2. Steinman pin method: Steinman pins are placed at the estimated entry points for the screws, and
   AP and lateral fluoro is used to fine-tune the position so that the screw enters the pedicle at the
   desired location
3. Freehand placement based on anatomic landmarks. Usually with X-ray assistance. Greatly facil-
   itated at levels where a laminectomy has been performed since the medial pedicle is exposed and
   is easily palpated
   a) PROS: likely reduces radiation to the surgical team and the patient
   b) CONS: requires somewhat more experience than the other methods
4. Image guidance using instruments that are fitted with specialized markers that are tracked real-
   time by “cameras” that project the drill and/or screw location on a CT or x-ray image viewed in
   the O.R.
   a) PROS:
      • reduces intra-operative radiation to surgical team, and to a lesser extent to the patient
      • allows percutaneous screw placement
   b) CONS: accuracy may be compromised by movement of spinal segments relative to the regis-
      tration array, or by technical errors. The surgeon must be vigilant for screw placement that
      does not look appropriate based on the anatomy

96.7.3 Open lumbar pedicle screw technique (see below for percuta-
aneous placement)

1. ENTRY at the base of the transverse process, at the intersection of the center of the transverse
   process (in the rostral-caudal direction) and the sagittal plane through the lateral aspect of the
superior facet. If a laminectomy has been performed at that level, the location of the pedicle is then verified by palpation using a probe within the spinal canal, otherwise fluoroscopy is used.

2. TRAJ
   a) the approximate mediolateral trajectory is shown in Table 96.1, and equals the lumbar vertebral number multiplied by 5° for each level from L1 to L5. The angle of the screw in the rostral-caudal direction is determined by fluoroscopy, maintaining a course that is parallel to the vertebral end plate. A frameless stereotactic navigation system may help orient screw trajectory.
   b) S2 screws are oriented laterally and superiorly and can be as long as 60 mm.

3. SCREWS goal is for screw to cross \( \approx \frac{2}{3} \) of the VB (typical screw lengths: 40-55 mm except for S1 which are usually only 35-40 mm long).

4. Rod diameter: typically 5–6.5 mm.

X-ray verification once pedicle screws are placed: on AP view if the screw tip crosses the midline to the contralateral side, there is likely to be a breach of the medial pedicle (sensitivity 0.87, specificity 0.97, accuracy 0.98), and if the screw does not pass medial to the medial pedicle wall there is likely to be lateral pedicle/VB violation (sensitivity 0.94, specificity 0.90, accuracy 0.96).

96.7.4 Percutaneous pedicle screws

The principles here are also employed in accessing the pedicles for e.g. vertebroplasty/kypheoplasty, percutaneous biopsy of pathology in the pedicle and/or vertebral body.

Basic principles:

1. requires AP and lateral fluoroscopy, or “O-arm” imaging (essentially an image guided intra-operative CT scan). With fluoroscopy, biplane fluoro (1 C-arm dedicated for AP view, another for lateral) greatly expedites the procedure.

2. this method can be employed essentially from T1 through S1 as long as adequate AP & lateral imaging of the involved level is possible. Using fluoro for upper thoracic placement (e.g. above \( \approx T5 \)) is challenging (small pedicles, and the shoulders interfere with lateral x-ray).

3. the skin entry site is lateral to the lateral edge of the pedicle. This permits the needle to pass through the pedicle in a medial direction into the VB. The degree of angulation and therefore the distance off the midline for the entry site depends on the vertebral level being accessed (thoracic pedicles are oriented in a more AP direction, lumbar pedicles angulate medially inward) as well as the amount of overlying muscle/fat.

Procedure:

1. a needle, typically a Jamshidi needle, is placed such that the tip is just short of entering the pedicle on the lateral fluoro (on left in Fig. 96.4).

2. at this point, on the AP view the needle tip should be at or just barely lateral to the lateral edge of the pedicle near the equator of the pedicle (on the right side, this would be at the “3:00” position, on the left side this would be at the “9:00” position).

3. the needle is advanced to just enter the pedicle on lateral fluoro, at this point it should be just within the pedicle margin at the 3:00 or 9:00 position on the AP view (as shown on the right in Fig. 96.4).

| Table 96.1 Medial angles for lumbar pedicle screw |
|---|---|
| Level | Medial angle |
| L1 | \( 5° \) medially |
| L2 | \( 10° \) medially |
| L3 | \( 15° \) medially |
| L4 | \( 20° \) medially |
| L5 & S1 | \( 25° \) medially |
| S2 | \( 40–45° \) laterally |

\( ^a \) aim for sacral promontory.
4. continue advancing the needle into the pedicle. Intermediate fluoro images can be obtained (e.g., to monitor trajectory on the lateral fluoro), but the next critical landmark is when the needle tip is just traversing the junction of the pedicle and the VB on the lateral fluoro (i.e., just entering the VB, as shown on the left in Fig. 96.5). It should be close to but never more medial than the medial border of the pedicle on the AP view (as shown on right in Fig. 96.5). If this criteria is maintained, the needle cannot breach the medial wall of the pedicle where it can threaten neural structures or compromise the purchase of the pedicle screw.

5. subsequent steps differ for various procedures and manufacturers.

96.7.5 Pedicle-screw rod diameters

Approximate weight guidelines for pedicle-screw rod diameters are shown in Table 96.2.

96.7.6 Lumbar lateral mass screw fixation

Trademarked names for equipment related to this procedure include “Cortical Screws.”

These screws enter the bone of the lumbar spine near the infero-medial border, and are directed superiorly and laterally, thereby passing close to 3 cortical margins, which provides a pull-out strength close to (but probably slightly less) than pedicle screws.

1. PROS: placement through a midline incision is somewhat easier than trying to get a more laterally situate entry point for a pedicle screw, and the supero-lateral trajectory does not require fighting the paraspinal muscles as occurs in trying to get a medial trajectory with pedicle screws.

2. CONS:
   a) pull-out strength slightly less than pedicle screws
   b) the bone that has to be left unviolated at the screw entry site may interfere with some of the decompression

96.7.7 Translaminar lumbar screw fixation

1. indications:
   a) short segment lumbar fusion
   b) posterior component in a 360° fixation combined with interbody fusion

2. PROS:
   a) small incision, minimal soft tissue disruption
   b) decreased cost (fewer screws implanted)
   c) decreased blood loss
   d) adjacent facet joint spared
### Table 96.2 Minimum recommended titanium rod diameter for lumbar pedicle-screw fixation

<table>
<thead>
<tr>
<th>Patient weight (lbs)</th>
<th>Rod diameter (mm)</th>
</tr>
</thead>
<tbody>
<tr>
<td>30–90</td>
<td>12–40</td>
</tr>
<tr>
<td>90–225</td>
<td>40–100</td>
</tr>
<tr>
<td>&gt;225</td>
<td>&gt;100</td>
</tr>
</tbody>
</table>

3. **CONS:**
   a) requires intact posterior elements (cannot use with laminectomy)
   b) cannot reduce

4. **ENTRY** skin incision 5–7 off midline, screw entry into bone in contralateral spinous process. Can be placed bilaterally

5. drill between the tables of the lamina across the center of the facet joint, terminating at the base of the transverse process

6. **SCREWS** 4.5 mm diameter fully threaded screws (no polyaxial head)

7. biomechanics: equivalent to bilateral pedicle screws. Limited in extension

8. clinical: 476 patients, 10 years mean F/U, 74% good outcomes

### 96.7.8 Posterior lumbar interbody fusion (PLIF and TLIF)

Originally developed by Cloward in 1943. Bilateral laminectomy and aggressive discectomy followed by the placement of bone grafts into the decorticated disc space. It has been advocated to reduce the movement in an abnormal “motion segment” (defined as the area between two vertebrae). Relatively contraindicated with well preserved disc-space height.

Many PLIFs when studied ≈1 year later show re-collapse of the disc space, which raises the question as to whether the PLIF has any benefit over simple discectomy. Areas of concern include: concerns regarding injury to nerves at the time of surgery or later due to retropulsion of bone graft.

Transforaminal lumbar interbody fusion (TLIF): a variation on a PLIF where the graft is placed from one side (via the “neural foramen”) after complete removal of the facet joint on that side. Requires much less nerve root retraction than PLIF, and is often advantageous for re-operations with primarily unilateral pathology where going through the foramen avoids the scar tissue.

Stand-alone PLIFs or TLIFs may be associated with progressive spondylolisthesis at that level and are usually supplemented with pedicle screws/rods.
96.8 Minimally invasive lateral retroperitoneal transpsoas interbody fusion

96.8.1 General information

First introduced by Luiz Pimenta in 2001 as an adaptation of an endoscopic lateral transpsoas approach to lumbar fusion described by Bergey et al. Trademarked names include “extreme-lateral” (XLIF™, NuVasive, San Diego, CA) or “direct-lateral” lumbar interbody fusion (DLIF™, Medtronic, Memphis, TN); the generic term lateral lumbar interbody fusion (LLIF) will be used here. Variants to the approach include the oblique lumbar interbody fusion (OLIIF™, Medtronic, Memphis, TN) which utilizes a pre-psoas approach (at L5-S1 the OLIF is halfway between an ALIF and a LLIF). A retroperitoneal approach. Indirectly decompresses nerves by distracting the disc space and fuses the spine with an interbody cage having a large cross-sectional area. Access is best from L1–5. For L1–2, one can retract the 12th rib, or go between 11th & 12th rib, or excise the 12th rib. Iliac crest prevents access to L5-S1 (axial-LIF may be used here) and occasionally to L4–5 (see below). A similar retropleural approach may be employed in the thoracic spine up to T4.

With thoracic lateral interbody fusions, DO NOT penetrate the contralateral anulus. Intra-operative EMG monitoring is critical, so the anesthesiologist needs to use only short-acting neuromuscular blockade at beginning of case. In males, implants are typically 55-60mm in length (oriented along patient’s lateral axis) if placed in the midposition of the VB, or 45 mm in the anterior portion (lengths are 10% shorter in females).

Potential advantages include less tissue trauma, minimal blood loss, shorter operation time, less wound issues, placement of a larger cage, early patient mobilization, no risk of durotomy with CSF leak.

96.8.2 Indications

- central lumbar spinal stenosis (mild to moderate only) with neurogenic claudication
- foraminal stenosis (indirect decompression)
- spondylolisthesis grade 1 or 2
- axial low back pain associated with degenerative disc disease
- total disc replacement
- for correction of sagittal or coronal imbalance
- adjacent segment failure: LLIF is particularly attractive here because it obviates dealing with scar tissue and (often) hardware from previous surgery and which also reduces risk of durotomy
- burst fractures and tumors in the thoracolumbar area (corpectomy)
- to retrieve damaged or malpositioned lumbar disc replacement devices
- adult spinal deformity: can be used to correct scoliosis and to increase lumbar lordosis especially when combined with release of the anterior longitudinal ligament (ALL release)

96.8.3 Contraindications

1. cases requiring direct decompression: includes
   a) pathology within the spinal canal e.g. herniated disc, synovial cyst, where simply distracting the disc space is less likely to correct the pathology
   b) somewhat imprecisely defined “pinpoint” central canal stenosis (some cases may still respond)
2. tall disc spaces: disc space height >12 mm usually implies that further distraction may be difficult to achieve. However, the interbody cage can still prevent compression at these levels when the patient stands up
3. prior retroperitoneal surgery on the planned side of LLIF (can still be done on contralateral side, sometimes may still be feasible on ipsilateral side)
4. pathology at L5-S1: the technique cannot reliably access L5-S1 due to the interference from the ilium of the pelvis
5. may not be able to access L4–5 if the iliac crest extends more than halfway up the L4 VB. Sometimes it is necessary to position the patient on the O.R. table with the table flexed and a bump under the hip to see if the space will “open up” and permit access. Angled instruments can usually permit acceptable access to the space of the lumbar plexus is not located too far forward on the VB
6. anomalous vascular anatomy interfering with approach: check position of great vessels on pre
7. relative contraindications:
   a) osteoporosis: may also be contraindication to lateral plates
   b) active infection (relatively contraindicated with any fusion technique)
96.8.4 Surgical Technique (MIS retroperitoneal transposas approach)

1. Position
   a) lateral decubitus position with the top of the iliac crest just superior to the table break
   b) choice of side: If there is no reason not to do so, the left side is usually up. Factors that might influence which side is to be up:
      - right side up if access is needed to L4-5 and the iliac crest is higher on left and would interfere (use AP x-rays, lateral x-rays and/or lumbar CT to evaluate)
      - previous retroperitoneal surgery would cause one to consider placing the contralateral side up
      - if scoliosis is present and the intent is to correct this, the concave side is usually up: this usually provides better access to L4/5 if it is an operative level. Also usually allows access to multiple levels through potentially fewer and smaller incisions because the corridors to each disc space tend to converge
      - if ACR is planned, a posterior location of the great vessels and especially the lack of any soft tissue between the vertebral body/osteophyte and the vessel would speak for using the contralateral side if that is more favorable (if not, ACR may not be advisable)
   c) true orthogonal position: the c-arm fluoroscopy is placed horizontal with 0° tilt, the patient position is then find-tuned until the spinous process is exactly in the center between the pedicles on the AP view. If this is not possible due to rotation between levels, a relatively neutral level is chosen to start, and the OR table will need to be rotated slightly for each level as it is being worked on in order to make that level true lateral (centering spinous process). Adhesive tape is applied to maintain the patient in this position

2. lateral fluoroscopy is used to mark the index disc space transversely and the posterior third of the disc space vertically. An exception is at L4/5, where the vertical mark is at the middle of the disc space based on the anatomic safe zones

3. retroperitoneal access through a single lateral skin incision and blunt dissection through abdominal muscles and fascia (external oblique, internal oblique, transversalis)

4. transposas approach and retractor placement is achieved using sequential tubular dilators that are placed under the guidance of fluoroscopic imaging (or navigation) and using directional EMG monitoring (Neurovision™, NuVasive, San Diego, CA) allowing the dilator placed anterior to the main lumbar plexus

5. discectomy and preparation of the disc space without violation of the endplates (to reduce the risk of subsidence) are performed. Work straight up-and-down in the ventral-dorsal plane (to avoid injuring the ALL anteriorly or entering the spinal canal posteriorly)

6. interbody spacer is placed usually with the posterior edge in the posterior third of the disc space (as the EMG monitoring allows)

7. for anterior column release (MIS-ACR), additional steps have to be performed after diskectomy, which include dissection/section of the ALL, and placement of hyperlordotic cages (20 or 30 degrees) usually more anteriorly in the disc space than a routine cage. This is a technique for the advanced lateral access surgeon

96.8.5 Instrumented augmentation (pedicle screws or lateral plate)

Standalone cage

May be feasible in the following circumstances:
- no osteoporosis
- no instability on pre-op lateral flexion/extension x-rays
- the ALL was not disrupted during LLIF surgery
- a cage width of at least 22 mm (26 mm or larger is optimal) has been placed: the large surface area reduces the risk of subsidence

When these conditions are not met, additional instrumentation should be considered.

Lateral plate and screws

May be applied through the same exposure. May not be optimal in patients with osteoporosis or age >55 due to increased risk of subsidence from weaker bone. Not as practical for multilevel LLIFs.
Posterior instrumentation
For cases with instability, posterior instrumentation (e.g. pedicle screws, including percutaneously placement) may be superior. Also, may be indicated if laminectomy is needed for direct decompression.

96.8.6 Complications
1. thigh numbness: incidence is ≈ 10-12\%\textsuperscript{16,19} Due to injury to the genitofemoral nerve. Risk of direct injury in the quadrant anterior to the midline at L2-3 and in the anterior quadrant at L3-4 and L4-5.\textsuperscript{18} A sensory nerve – cannot be monitored with EMG. Usually transient, resolves in ≈ 2 weeks
2. thigh flexion weakness: due to psoas injury. Risk increases if>2 levels are done. Usually transient, resolves in 1–8 weeks
3. femoral nerve injury with quadriceps weakness: due to nerve root/plexus injury\textsuperscript{20} (probably from psoas retraction – shorter operations may have lower risk) or psoas hematoma. Onset may be delayed 1–2 d post-op. Incidence ≈1\% May improve slowly over a long time (>9 months)
4. lumbar plexus injuries: the risk of direct injury to the lumbar plexus is reduced by staying at or anterior to “safe” working zones defined by Uribe et al.\textsuperscript{18} as follows (NB: it is often possible to work posterior to these zones using EMG monitoring to ascertain the proximity of the plexus, and conversely injuries can occur even in these safe zones):
   - L1-2 through L3-4: middle of the posterior quarter of the VB
   - L4-5: midpoint of the VB
5. contralateral femoral nerve injury
6. genitofemoral neuralgia
7. abdominal viscera perforation
8. vascular injury\textsuperscript{21} including common iliac artery (at the L4-5 level) or aortic injury (above L4-5), common iliac vein or inferior vena cava
9. kidney-ureter injury
10. graft subsidence
11. unintended rupture of anterior longitudinal ligament
12. psoas/retroperitoneal hematoma ipsilateral/contralateral
13. abdominal wall paresis or hernia\textsuperscript{22}
14. rhabdomyolysis
15. retrograde ejaculation (primarily with ACR and pre-psoas approaches)

96.8.7 Postoperative care
- for single-level lumbar LLIF: mobilize the patient in the immediate post-op period without a brace
- hip flexion pain on the approach side is anticipated during the immediate postoperative period
- transient hip flexion weakness related to psoas muscle manipulation is usually self-limited and improves by 8 weeks post-op
- in case of significant leg weakness (femoral nerve injury), a lumbar CT or MRI is indicated to rule out compression by a psoas hematoma, disc extrusion or malposition of cage or screw. If compression is ruled out, patients can be followed by postoperative EMG at 6 weeks to define extent of injury (neuropraxia, axonotomesis, neuronotomesis), again at 3 months to evaluate if the expected interval improvement from neuropraxia has occurred and 5 months to follow up axonal growth\textsuperscript{20}

96.8.8 Outcomes
- fusion rates range from 91-100\%\textsuperscript{23}
- outcomes scales (ODI and VAS leg and back) are significantly improved at follow up\textsuperscript{24}
96.9 Transfacet pedicle screws

96.9.1 General information

Screws placed directly across the lumbar facet joint into the pedicle of the level below. No rod is needed. Immobilizes only, does not provide any decompression, distraction or fusion. Therefore not intended for use as a standalone. Can be placed percutaneously.

96.9.2 Indications

Placement is optimal for L3–4, L4–5 or L5-S1. Difficulty increases in upper lumbar levels. May be used as adjunct to:

1. ALIF
2. LLIF (when lateral plate not used)
3. contralateral to TLIF (pedicle screws could be used on the side of the TLIF, or a spinous process clamp could be used)
4. axial-LIF (Ax-LIF)

96.9.3 Contraindications

A transfacet pedicle screw cannot be used where the facet has been removed (e.g. for a TLIF) or with a pars defect in the upper of the two levels to be fused.

96.9.4 Technique

1. placed percutaneously or via an open procedure usually in the prone position
2. approximate skin incision site: a single midline ≈ 1.5 cm vertical incision is used
   a) for L5-S1 or L4–5: incision at L3 spinous process
   b) for L3–4: incision at L2 spinous process
3. Use AP & lateral fluoro to guide trajectory
   a) AP fluoro: Lay a guidewire on the patient’s back and orient it to pass through the desired
      pedicle. Use a skin marker on the patient’s back to mark the guidewire’s trajectory
   b) lateral fluoro: Initial bony target is the midpoint of the inferior facet of the upper level. The
      tip of the guidewire should contact the bone directly posterior to the inferior endplate of the
      upper level

96.10 Facet fusion

A bone dowel (e.g. TruFUSE® by MinSurg) is placed into a predrilled opening in the facet joint to
promote fusion across the joint. Marketed as a possible standalone.

96.11 S2 screws

May be directed medially (analogous to pedicle screws), or more commonly, directed laterally and
superiorly into the ala. In either case, bicortical purchase is necessary.
   The main structure to avoid is penetrating the sacroiliac (SI) joint with the screw.

96.12 Iliac screws

Wide exposure is needed. On the initial few cases, the surgeon may be better served by exposing all
the way to the posterosuperior aspect of the sciatic notch so that the screw trajectory can be aimed
using a palpating finger.
   A small amount of bone is removed just below and medial to the posterior superior iliac spine.
   This prevents the head of the screw from being too superficial which may cause discomfort or skin
   breakdown. The screw trajectory aims towards the acetabulum to pass approximately 1 cm superior
to the sciatic notch on AP fluoro. Avoid penetrating the cortex, especially in the sciatic notch.
   An offset adapter is usually required to connect to rods passing through pedicle screws in the lev-
   els above.
   SCREWS Length 50–70 mm (the screw should end just above midpoint of the sciatic notch, or
      slightly medial to that). Diameter: 6–8 mm.

96.13 Post-op clinic visits – lumbar and/or thoracic spine fusion

96.13.1 Visit schedule

Patients are seen in the clinic at intervals depending on the preference of the surgeon. A typical fol-
low-up schedule with studies routinely performed is shown in Table 96.3. For specific problems,
additional investigations are usually needed.

<table>
<thead>
<tr>
<th>Time post-op</th>
<th>Agenda</th>
</tr>

<td>• release patient if they are doing well</td>
</tr>
</tbody>
</table>

*the same schedule can be used for thoracic fusions with the difference that standing AP & lateral x-rays are done in place of flexion/extension views
96.13.2 Post-op x-rays

Items to check on post-op x-rays include:

1. alignment
2. position of grafts if used (e.g. interbody grafts)
3. integrity of hardware (look for screw or rod breakage, screw pullout, rod disconnection)
4. luencies around screws which may indicate motion and implies nonunion
5. any evidence of fusion (may be difficult, e.g. with synthetic interbody cages)
6. on flexion/extension films: look for motion across fused segments (sometimes absence of motion may be the only evidence of fusion on plain x-rays) and the development of abnormal motion at adjacent segments.

References

97 Miscellaneous Surgical Procedures

97.1 Percutaneous ventricular puncture

97.1.1 Indications
In pediatrics, may be used to remove hemorrhagic ventricular fluid following intraventricular hemorrhage, or to obtain CSF specimen in cases of suspected ventriculitis. May be used emergently in pediatrics or adult as a temporizing measure in patient herniating from obstructive hydrocephalus.

97.1.2 Peds
Shave hair. 5 minute Betadine® prep.

The right side is preferred. Enter through coronal suture just lateral to anterior fontanelle (AF) using a 20–22 Ga. spinal needle. If a CT scan has been done, it may be used to help judge angulation (usually varies between contra- and ipsi-lateral medial canthus and intersection with EAM).

97.1.3 Adult
See reference. Only used emergently. Takes advantage of thin orbital roof in adult.

Prep conjunctiva and skin with antiseptic (e.g. ophthalmic betadine). Elevate the eyelid and depress the globe. Using a 16–18 Ga. spinal needle, penetrate the anterior third of orbital roof (1–2 cm behind orbital rim) with firm pressure (may need gentle tapping). Aim at coronal suture in the midline. The frontal horn should be about 3–4 cm deep.

97.2 Percutaneous subdural tap

97.2.1 Indications
Utilized in pediatrics. Used to be done for diagnostic purposes, but this has been supplanted by CT, MRI & ultrasound. Currently, this procedure may be used emergently for decompression, to drain subdural collections and to obtain fluid for diagnostic tests, such as culture (repeat taps may be used, but surgery should be considered after ≈ 5–6).

97.2.2 Technique
Shave hair. Prep 5 minutes with povidone iodine (Betadine®). Using a short 20–21 Ga. spinal needle (spinal needle is recommended because the stylet may reduce the risk of implanting epidermal cells into the CNS), penetrate the lateral margin of the anterior fontanelle (AF) or coronal suture at least 2 cm off midline. Remove the stylet and aspirate. With bilateral fluid collections, bilateral taps should be done.

97.3 Lumbar puncture

97.3.1 Contraindications
1. risk of tonsillar herniation (see below)
   a) known or suspected intracranial mass
   b) non-communicating hydrocephalus
2. infection in region desired for puncture: choose another site if possible
3. coagulopathy
   a) platelet count should be >50,000/mm³ (p.154)
   b) patient should not be on anticoagulants because of risk of epidural hematoma (p.1131) or subarachnoid hemorrhage with secondary cord compression
4. use caution in suspected aneurysmal SAH: excessive lowering of the CSF pressure increases the transmural pressure (pressure across the aneurysm wall) and may precipitate rerupture
5. caution in patients with complete spinal block: 14% will deteriorate after LP
6. relative contraindication: Chiari malformation. There is some evidence that draining CSF may precipitate herniation. This is less of a concern with successfully surgically treated Chiari malformation.

Elevated ICP and/or papilledema by themselves are NOT contraindications (e.g. LP is actually used diagnostically and as a treatment in idiopathic intracranial hypertension, see below).

97.3.2 Technique

Background and anatomy

The spinal cord and column are the same length in a 3-month fetus. After that, the spinal column grows faster than the cord. As a result, the conus medullaris is located rostral to the termination of the thecal sac in the adult, situated between the middle thirds of the vertebral bodies of L1 and L2 in 51–68% of adults (the most common location), T12-L1 in ≈ 30% and L2–3 in ≈ 10% (with 94% of cords terminating within the territory of L1 and L2 vertebral bodies). The thecal sac ends ≈ S2. The tips of the spinous processes as palpated on the surface are located caudal to the corresponding VB. The intercristal line (connecting the superior border of the iliac crests) crosses the spine at the L4 spinous process or between the L4 and L5 spinous processes in most adults.

Procedure

Position: the procedure is usually performed in the lateral decubitus position. As the needle is advanced, it is helpful to have the patient bring the knees up and to flex the neck in order to open up the spaces between the posterior elements of the spine.

For diagnostic LP, a 20 Ga spinal needle is often selected. Larger needles (e.g. 18 Ga) may be used e.g. with pseudotumor cerebri to encourage post-procedure drainage of CSF into the soft tissues of the back.

The back is prepped and draped to create a sterile working area.

Entry point: in an adult, use the L4–5 interspace in most cases (located at or just below the intercristal line) or 1 level higher (L3–4). Peds: L4–5 is preferred over L3–4.

The needle is always advanced with the stylet in place at least through the skin and some subcutaneous tissue to avoid introducing epidermal cells which may cause iatrogenic epidermoid tumors; see Complications following LP (p.1507). The needle is aimed slightly cranially (to parallel the spinous processes) and usually a little down towards the bed (aiming towards the umbilicus). If a Quincke LP (standard) needle is used, the bevel is turned parallel to the length of the spinal column to reduce the risk of post-LP H/A (p.1509). In general, if bone is encountered it is more often due to deviation from a true midline trajectory rather than a failure to aim correctly in the rostral-caudal direction. The needle should be withdrawn to just below the skin surface before attempting a new trajectory.

If during insertion of the needle the patient experiences pain radiating down one LE, this usually indicates that a nerve root has been encountered. The needle should be withdrawn immediately and reinserted aiming more towards the side contralateral to the extremity that experienced the pain. The stylet is removed at intervals during the insertion to look for CSF (a distinct pop is sometimes felt as the needle penetrates the dura).

Once CSF flows, the needle is connected to a manometer through a 3-way stopcock, the pressure is measured and recorded (see below), and CSF is drained into sterile tubes (1–2 ml for each tube) for laboratory analysis (see below). The practitioner should also note the color of the fluid (clear, blood tinged, xanthochromic... and the clarity (clear, cloudy, purulent...).

At the end of the procedure, the stylet should be replaced before the needle is withdrawn (to reduce post-LP H/A, see below).

Opening pressure: The opening pressure (OP) should be measured and recorded for every LP. To be meaningful, the patient should be lying down and as relaxed as possible (should not be in forced fetal position), with the bed flat. The variation of pressure with respirations is usually a good indication of a communicating fluid column (the fluctuation is in-phase with the respiratory pressures in the inferior vena cava, rising with inspiration and falling with expiration). Normal values: in the left lateral decubitus position, average OP= 12.2 ± 3.4 cm H2O (8.8 ± 0.9 mm Hg). Also, see Table 23.1 for peds.

Queneke's test: if a subarachnoid block is suspected (e.g. from spinal tumor), compress the jugular vein (JV) first on one side then on both (do not compress carotid arteries). If there is no block, the pressure will rise to 10–20 cm of fluid, and will drop to the original level within 10 seconds of release of the JV. Do not do JV compression if intracranial disease is suspected.
97.3.3 Laboratory analysis

 Routinely, three tubes are sent for analysis as shown in Table 97.1. See Table 23.4 for interpreting the results of the laboratory analysis.

 If the tap is possibly traumatic (i.e. bloody), or if having an accurate cell count is essential (e.g. to R/O SAH) then 4 tubes are collected, and the first and last are sent for cell counts and are compared; see Traumatic tap (p. 1506).

 If special cultures are required (e.g. acid fast, fungal, viral) they are also specified on the tube for culture & sensitivity (C & S).

 If CSF for cytology is desired (e.g. to R/O carcinomatous meningitis or CNS lymphoma), then at least 10 ml of CSF must be sent in one tube to pathology (where it is spun down, and examined for cells).

97.3.4 Mining useful data with a traumatic tap

 General information

 A traumatic tap (TT) occurs when the spinal needle damages a blood vessel with the result that (usually venous) blood either alone or admixed with CSF will be obtained.

 Estimating true WBC count in CSF with a traumatic tap

 When many RBCs and WBCs are present in the CSF due to a traumatic tap (TT), it is difficult to know if there is a true leukocytosis on the CSF. It may help to determine if the WBCs are elevated or if they are present in the same ratio as in the peripheral blood. In non-anemic patients, there should be ≈ 1–2 WBCs for every 1000 RBCs (as a correction\(^8(p 176)\): subtract 1 WBC for every 700 RBCs\(^8(p 176)\)). In the presence of anemia or peripheral leukocytosis, use Fishman’s formula\(^8(p 176)\) shown in Eq (97.1) to estimate the original WBC count in the CSF before the TT,

 \[
 \frac{\text{WBC}_{\text{CSF Original}}}{\text{WBC}_{\text{CSF}}} = \frac{\text{WBC}_{\text{Blood}} - \text{RBC}_{\text{CSF}}}{\text{RBC}_{\text{Blood}}} \tag{97.1}
 \]

 where WBC_{CSF Original}=WBC count in the CSF before the TT, WBC_{CSF} & RBC_{CSF}=WBC & RBC counts measured in the CSF, and WBC_{Blood} & RBC_{Blood}=WBC & RBC per mm\(^3\) in the peripheral blood.

 Estimating true total CSF protein content with a traumatic tap

 If the hemogram and peripheral protein are normal, then have the cell count and protein content run on the same tube, and the correction is\(^8(p 176):\)

 • subtract 1 mg per 100 ml of protein for every 1000 RBC per mm\(^3\)

 Differentiating SAH from traumatic tap

 See typical findings in SAH (p. 1160). Some features helpful in differentiating SAH from TT are shown in Table 97.2.

### 97.3.5 Complications following LP

#### General information

The overall risk of disabling or persistent symptoms (defined as severe H/A lasting >7 days, cranial nerve palsies, major exacerbation of pre-existing neurological disease, prolonged back pain, aseptic meningitis, and nerve root or peripheral nerve injuries) has been estimated at 0.1–0.5%. Severe side effects, which include brainstem herniation, infection, subdural hematoma or effusion, and SAH, are rare.\(^{10}\)\(^{p171–2}\)

#### Possible complications

1. **Tonsillar herniation**
   - a) acute herniation in the presence of mass lesion (see below)
   - b) chronic tonsillar herniation (acquired Chiari I malformation): this has been reported after multiple traumatic LPs with presumed post-LP CSF leak\(^{11}\)
2. **Infection** (spinal meningitis)
3. **“Spinal headache”:** usually positional (diminishes with recumbency) (see below)
4. **Spinal epidural hematoma** (p. 1131): usually seen only with coagulopathy
5. **Spinal epidural CSF collection:** may be fairly common in patients with post-LP H/A. Usually resolves spontaneously
6. **Epidermoid tumor:** risk may be increased by advancing LP needle without stylet (transplanting a core of epidermal tissue)\(^{12,13,14}\)
7. **Impinging nerve root with needle:** usually causes transient radicular pain, may cause permanent radiculopathy in some
8. **Intracranial subdural hygroma or hematoma**\(^{15,16}\) (rare)
9. **Vestibulocochlear dysfunction**\(^{17}\):
   - a) subclinical (demonstrated on audiogram) or moderate reduction in hearing may occur, and seems to correlate with post-procedure CSF leakage. Most studies show reduction is at frequencies <1000 Hz
   - b) sudden hearing loss may occur. Perform audiogram to quantify loss. Treat with bedrest for several days, prednisone 60 mg/d tapered over 2–3 weeks
   - c) pathogenesis: reduced CSF pressure may reduce perilymph pressure through the cochlear aqueduct (may be especially pronounced with a patent aqueduct),\(^{19}\) producing endolymphatic hydrops
10. **Ocular abnormalities**
    - a) abducens palsy: almost invariably unilateral. Often delayed 5–14 days post-LP, usually recovers after 4–6 wks\(^{19}\)
11. **Dural sinus thrombosis**\(^{20}\) (usually with underlying thrombophilia)

---

\(\ast\) Other conditions can cause xanthochromia
Risk of acute tonsillar herniation following lumbar puncture

The question of when to do LP first (to save time) and when to obtain CT scan first to R/O intracranial mass (for safety) before performing an LP is controversial.

Issues
The time delay to initiating antibiotics is the most important variable in the outcome of meningitis. Time may be more crucial in community acquired meningitis, where a virulent organism infects a sometimes immune compromised host (e.g. children or the elderly), than in post-op neurosurgical meningitis (usually a low virulence organism, e.g. Staph. aureus, in an immune intact host where the BBB has been disrupted).

The theoretical risk in performing an LP with an intracranial mass is that the resultant shift in pressure may precipitate tonsillar herniation.

Starting antibiotics without first having a CSF specimen from an LP may prevent cultures from growing in the lab which then risks the difficulties inherent in managing partially treated meningitis, or a suboptimal choice of antibiotic medication.

Clinical evaluation for possible contraindication to LP is unreliable. Papilledema is one possible indication of increased ICP. Papilledema takes a minimum of 6 hrs to develop after the onset of increased ICP, and in most cases it requires up to 24 hrs to develop. Therefore, its absence does not insure normal intracranial pressure. Furthermore, papilledema may be seen in conditions where there is not a contraindication to LP, e.g. idiopathic intracranial hypertension, where LP is one of the accepted treatments (p.766).

The ready availability of CT scans, often within the emergency department itself, may involve a delay of only a few minutes, if qualified personnel to interpret the study are also immediately available. However, in a busy E/R, there may be delays related to other patients also requiring emergency CT, the need to transmit scans to an off-site radiologist...

Historical information
Herniation following LP was more common prior to ≈ 1950, long before CT scans were available, where the procedure was performed even when some patients had clear evidence of ↑ ICP, large bore spinal needles (12–16 gauge) were more commonly employed, and large quantities of CSF were removed for therapeutic purposes. In a 1969 report of 30 patients who deteriorated after LP, 73% had localizing signs (hemiparesis, anisocoria...) and 30% had papilledema. None of 5 patients with cerebral abscess deteriorated after the first of multiple LPs.

In a series of 129 patients with ↑ ICP, the complication rate reported was 6% however, some of these complications were probably unrelated to LP, and many of these patients were in extremis. In 7 series totalling 418 patients, a complication rate of 1.2%was calculated.

Post LP (myelogram) H/A
General information
AKA “postspinal headache” or “spinal headache.” May also follow procedures other than LP/myelogram, such as dural opening (p.1055). Can also occur with spontaneous intracranial hypotension (p.389) and following decompressive craniectomy.

Clinical features
Important distinctive characteristic: H/A occurs when patient is erect, and is completely or partially (but significantly) relieved when recumbent. May be associated with nausea, vomiting, dizziness, or visual disturbances.
Time course. Most post-LP headaches (PLPHA) have a delayed onset 24–48 hrs after the LP, and although they may occur weeks post-LP, most also develop within 3 days. The duration of PLPHA varies, with a mean of 4 days, and reports of duration of months and even >1 year.

Pathophysiology
Thought to be due to continued CSF leakage through the hole in the dura, which reduces the CSF "cushion" of the brain. In the upright position, the pull of gravity on the brain produces traction on the blood vessels and any structures tethering the brain to the pain-sensitive dura. CSF may sometimes be demonstrable in the epidural space.

Epidemiology following LP
Reported incidence range is 2–40% (typically ≈ 20%), higher after diagnostic LP than for epidural anesthesia.

See also variables in LP that impact upon the risk of PLPHA (p. 1508) (e.g. incidence is lower with smaller gauge spinal needle).

1. Risk factors for post-LP H/A outside the control of the physician:
   a) age: incidence ↑ in younger patients
   b) sex: incidence ↑ in females
   c) prior headache history (including previous PLPHA)
   d) body size: ↑ with small body mass index = weight/height²
   e) pregnancy

2. Variables that have been shown to influence the incidence of PLPHA:
   a) needle size: larger needles carry increased risk
   b) bevel orientation: orienting the bevel parallel to the longitudinally running fibers of the dura reduces the risk of PLPHA
   c) replacing the stylet prior to needle removal lowers the incidence
   d) the number of dural punctures (may not be totally under the physician’s control)

3. Variables that may or may not influence the incidence of PLPHA: needle type
   a) Quincke needle: bevelled edge with cutting tip (the standard LP needle). Incidence of PLPHA with 20 and 22 gauge Quincke needles: 36% (1)
   b) atraumatic needles: a number of types are available (Sprotte, Whitacre…). Most are "pencil pointed" and may produce a hole with a lower incidence of transdural leak. Unproven

4. Factors found not to affect the incidence of PLPHA:
   a) the position of the patient after LP (does not seem to prevent PLPHA, but may delay the onset of symptoms)
   b) volume of fluid removed at the time of LP
   c) hydration following LP

Treatment for H/A following LP
Initial “conservative” measures include:
1. flat in bed for at least 24 hrs
2. hydration (PO or IV)
3. analgesics for H/A
4. tight abdominal binder
5. desoxycortisone acetate 5 mg IM q 8 hrs
6. caffeine sodium benzoate 500 mg in 2 cc IV q 8 hrs up to 3 d max (70% of patients had relief with 1 or 2 injections)
7. high-dose steroids: report of success in a case of intracranial hypotension associated with spontaneous slit ventricles tapering down from a starting dose of dexamethasone 20 mg/day
8. blood patch if refractory

Epidural blood patch. For refractory post-lumbar puncture or post-myelogram H/A. Works in one application in over 90% of cases, may be repeated if ineffective. Theoretical risks: infection, cauda equina compression, failure to relieve H/A.

Technique. Summary: 10 ml of non-heparinized autologous blood injected into epidural space.
resistance) while advancing, when the epidural space is entered, resistance to injection disappears, but CSF cannot be aspirated.

A venipuncture site is prepared aseptically. 10 ml of the patient’s blood is withdrawn. After verifying CSF cannot be aspirated through the spinal needle, the blood is injected into the epidural space. After 30 minutes supine, patient may ambulate ad lib.

97.4 Lumbar catheter CSF drainage

97.4.1 General information

Insertion of a catheter into the lumbar subarachnoid space for the purpose of draining CSF. Usually connected to a closed drainage system similar to that for an EVD. Generally used for periods of only a few days or so.

97.4.2 Indications

1. to reduce CSF pressure on a site of CSF leak/fistula. Example situations:
   a) dural breach during spine surgery or craniotomy (especially posterior fossa)
   b) for spontaneous CSF fistula (rare) (p.386)
2. to reduce intracranial pressure in cases of communicating hydrocephalus: e.g. drain test for NPH, or when an infected shunt has been removed
3. to reduce CSF pressure to attempt to increase perfusion of the spinal cord: e.g. during surgery for abdominal aortic aneurysm, or following spinal cord injury

97.4.3 Contraindications

As with lumbar puncture (see above).

97.4.4 Insertion technique

Positioning, entry site, and trajectory are all similar to lumbar puncture (see above). Instead of a spinal needle, a Tuohy needle is used. The bevel is inserted parallel to the fibers of the dura (rostro-caudal). The needle is then rotated 90° (usually pointing rostrally) and the catheter is threaded into the needle. If the catheter does not thread, the needle must be withdrawn together with the catheter – attempting to withdraw the catheter through the needle will shear off the catheter at the tip of the needle.

97.4.5 Management

The orders for the nursing staff to maintain the catheter include:
1. instructions as to how to regulate the CSF drainage. Most commonly one of:
   a) by pressure: accomplished by specifying a height of the drip chamber, usually at the level of the tragus or shoulder
   b) by withdrawing a specified amount of CSF per hour: usually 10–20 cc. This method reduces the risk of overdrainage if the drip chamber is too low
2. instructions for the exit site: usually treated as an arterial-line

97.4.6 Complications

1. infection
2. overdrainage: usually as a result of the drainage bag being too low when using the pressure drainage method described above (either from falling to the floor, or not being raised when the patient sits or stands up) or from catheter disconnection. Can cause:
   a) subdural hematoma from tearing of bridging veins from downward displacement of the brain
   b) headache
3. pneumocephalus: usually from placing the drain height below the site of a fistula, and air is drawn in through the fistula tract
   a) tension pneumocephalus: usually with a ball-valve effect at the fistula site
4. catheter pull out: frequently occurs simply as a result of patient movement in bed or with patient transfers
97.5 Cl–2 puncture and cisternal tap

97.5.1 Indications

Situations where CSF specimen is required but access via LP is difficult or contraindicated (lumbar arachnoiditis, superficial infection, marked obesity, patients who cannot be turned on their sides...), or to instill contrast to demonstrate the rostral extent of a block documented by dye injected via LP. Spinal headache is less common with these procedures than with LP. Cl–2 puncture is safer than cisternal tap.

Contraindicated: in patient with Chiari malformation (often present in myelomeningocele) due to low lying cerebellar tonsils and medullary kink.

Normal CSF values for glucose and protein differ only slightly from CSF obtained by lumbar puncture. Opening pressures averaged 18 cm of fluid with lateral puncture.

97.5.2 Cl–2 puncture

AKA lateral cervical puncture. Equipment: LP tray (useful for the specimen tubes, extension tube for contrast injection under fluoroscopy, lidocaine, and spinal needle) with a standard 20 Ga spinal needle, contrast if needed (e.g. Iohexol®). It is preferred to perform the procedure under fluoro, however it has also been described without fluoroscopic guidance with a completely cooperative patient.37

Patient position: supine in bed without a pillow, with the head straight up. Avoid any head rotation which may bring the vertebral artery (VA) into the needle path.38 Place head within lateral fluoroscopy unit (since this is rarely available, a C-arm fluoro positioned horizontally may be used).

If iodinated dye is being injected for myelography, the head should be elevated to prevent contrast from running into posterior fossa; in cases with cervical spine injury, one can put the entire bed in reverse Trendelenburg.

Entry point: 1 cm caudal and 1 cm posterior (dorsal) to the tip of the mastoid process. Needle insertion: use a 25 Ga. needle to anesthetize the skin at the entry point. Under fluoro, advance a larger needle (e.g. 21 Ga.) towards the Cl–2 interspace while injecting local anesthetic: aim for a target in the middle of the posterior third of the bony spinal canal (or, alternatively, 2–3 mm anterior to the posterior margin of the bony canal) (“X” in Fig. 97.1). Leave this needle in as a marker. Insert the 20 Ga. spinal needle parallel to the marker needle. Verify the course with fluoro. If fluoro is not used, insert the spinal needle at the entry point, and advance it parallel to the plane of the bed, perpendicular to the neck.37 If the needle penetrates deeply without encountering bone or CSF, it is most likely that the tip is too far posterior. If bone is encountered, redirect the needle in the rostrocaudal plane.

Several “pops” may be felt, and the stylet should be removed after each to check for CSF return. The subarachnoid space is ≈5–6 cm deep to the skin surface in most adults.39 The needle must be supported more than with a lumbar puncture.

To inject iodinated contrast, use e.g. ≈5 ml of 180 mg% Iohexol® for cervical myelogram, watch dye on fluor (should be able to see it in subarachnoid space).

Risks

Case report of a death from subdural hematoma due to puncture of an anomalous vertebral artery40 (found in ≈0.4% of population). If the VA is penetrated, the needle is withdrawn and local pressure is applied. Penetration of the upper spinal cord/lower medulla (risk of serious neurologic sequelae, even from this, is small). Herniation (as with LP) when there is increased ICP.

97.5.3 Cisternal tap

Suboccipital access to the cisterna magna. Usually done with patient sitting, with neck slightly flexed.41 Overlying hair should be shaved. Local anesthetic is infiltrated. A 22 gauge spinal needle is inserted exactly in the midline between the inion and the C2 spinous process, directed superiority towards the glabella until the needle strikes the occiput or enters the cisterna magna. If the occiput is encountered, the needle is withdrawn slightly and reinserted directed slightly inferiorly, the process is repeated (“walking down the occiput”) until the cisterna magna is entered (a “pop” will be felt).

The distance from the skin surface to the cisterna magna is 4–6 cm, and from the dura to the medulla is ≈2.5 cm. However, due to tenting of the dura, the needle may be very close to the medulla before entering the subarachnoid space.
Risks
1. hemorrhage in the cisterna magna: may be due to perforation of a large vessel
2. piercing the medulla oblongata: may cause vomiting, respiratory arrest...
3. positioning may compromise blood flow in the vertebral artery in elderly patients

97.6 CSF diversionary procedures
97.6.1 Ventricular catheterization

Most common insertion sites:\(^{42}(p. 151–3);\)

1. Kocher’s point (coronal): localizes an entry point into the frontal horn of the lateral ventricle that passes anterior to the motor strip. The right side is usually used. Often employed for ICP monitors, EVDs, shunts, ventriculoscopes.... Originally described as, “about 2 cm from the central line and 3 cm from the precentral fissure.”\(^{43}\) A number of surface landmarks have been described to locate a point anterior to the motor strip that is in this general vicinity, and the author will often refer to the position as “Kocher’s point.” Commonly cited landmarks:
   a) entry site: 2–3 cm from midline which is approximately the mid-pupillary line with forward gaze, 1 cm anterior to coronal suture which is approximately 11 cm up from the nasion (to avoid the motor strip)
   b) trajectory: direct catheter perpendicular to surface of brain, which can be approximated by aiming in coronal plane towards medial canthus of ipsilateral eye and in AP plane towards EAM
   c) insertion length: advance catheter with stylet until CSF is obtained (should be <5–7 cm depth; this may be 3–4 cm with markedly dilated ventricles). Advance catheter without stylet 1 cm deeper. CAUTION: if CSF is not obtained until very long insertion length (e.g. ≥8 cm) the tip is probably in a cistern (e.g. prepontine cistern) which is undesirable
2. occipital-parietal region: commonly used for CSF shunt
   a) entry site: a number of means have been described, including:
      • Frazier burr hole: placed prophylactically before p-fossa crani for emergency ventriculostomy in event of post-op swelling. Location: 3–4 cm from midline, 6–7 cm above inion \( \text{rFVIIa} \) (caution: an error in locating the inion could put the catheter in an undesirable location if this method alone is used)
      • parietal boss: flat portion of parietal bone
      • follow point from mid-pupillary line parallel to sagittal suture until it intersects line extending posteriorly from the top of the pinna
      • \( \approx 3 \) cm above and \( \approx 3 \) cm posterior to top of pinna
   b) trajectory: insert the catheter parallel to skull base:
      • initially aim for middle of forehead
      • if this fails, aim for ipsilateral medial canthus
   c) insertion length: ideally, the tip should be just anterior to the foramen of Monro in the frontal horn. Ventriculoscopic guidance (if available) increases the accuracy to a significant degree. In the absence of this:
      • intracranial length should be \( \approx \) two-thirds of the length of the skull (this is short enough to prevent penetration of frontal brain parenchyma, but long enough to take tip beyond the foramen of Monro to prevent catheter from ending up in the temporal horn where choroidplexus increases the chance of obstruction)
      • in adults without macrocrania the inserted length is usually \( \approx 12 \) cm when the burr hole is in line with the axis of the lateral ventricle \((\text{lengths} > 12 \text{ cm are rarely required})\). In hydrocephalic infants usually \( \approx 7–8 \) cm is required
      • use the stylet for the initial \( \approx 6 \) cm of insertion, then remove it and insert the remaining length (keeps the catheter straight during penetration of occipital parenchyma and prevents the tip from dropping into the temporal horn where there is choroidalplexus, also the temporal horn may collapse and occlude the catheter when the HCP is resolved)

3. Keen’s point (posterior parietal): (placement in trigone) 2.5–3 cm posterior and 2.5–3 cm superior to pinna (was the usual site of occurrence of cerebral abscesses arising from otitis media, and was often used to tap these)

4. Dandy’s point: 2 cm from midline, 3 cm above inion (may be more prone to damage visual pathways than above)

97.6.2 Ventriculostomy/ICP monitor

General information

AKA intraventricular catheter (IVC) or external ventricular drainage (EVD).

Elevated INR: for patients with an elevated INR (such as patients on warfarin), it has generally been recommended that placement of intraparenchymal catheters be delayed until the INR be \( \leq 1.6 \) in order to reduce the risk of hemorrhage to an acceptable level. However, intraparenchymal ICP monitors were placed without hemorrhagic or thrombotic complications in 11 patients with grade III/IV hepatic encephalopathy associated with fulminant hepatic failure who had an average INR of 3 when it was performed within 15–120 minutes after receiving 36.7 micrograms/kg IV of recombinant activated factor VII (rFVIIa).

Insertion technique

Unless contraindicated (e.g., right ventricular bleed), the right (non-dominant) side is preferred. Shave entire ipsilateral hemicanthus and contralateral frontal portion. Clip the hair around the planned incision site and the exit site for the tunneled catheter (avoid shaving which degrades the skin’s barrier function against infection). Prep with any acceptable surgical prep (betadine prep for 5 minutes, Chloroprep, Duraprep...)

Site: approximately Kocher’s point (see above). To avoid motor strip, enter 1–2 cm anterior to coronal suture (estimated position of coronal suture: follow line up midway between lateral canthus and EAM, or measure 11 cm up from the nasion), and to avoid the sagittal sinus, 2–3 cm lateral to midline (2 fingerbreadths or \( \approx 3 \) cm is commonly employed as an approximation). Incision oriented in sagittal plane (in case it needs to be incorporated in flap); elevate periosteum; place self-retaining retractor; make twist drill hole. Bone-wax edges to stop bone bleeding; cauterize dura with bipolar coagulator; incise dura in cruciate fashion with #11 scalpel blade; cauterize incised dural edges and then pia/arachnoid with bipolar.

For ventriculostomy: insert catheter perpendicular to brain surface to a depth of 5–7 cm (most catheters are marked at 5 and 10 cm). With any ventricular enlargement, CSF should flow at least by
3–4 cm depth (with normal ventricles, this may be 4–5 cm). If no CSF is encountered here and the catheter is passed further until CSF is obtained, it is unlikely to be due to catheterization of frontal horn of lateral ventricle (in this case, at ≈ 9–11 cm the tip will often be in the pre-pontine cistern, a subarachnoid space, which is undesirable). If unsuccessful after a maximum of three attempted passes, then place a subarachnoid bolt or intraparenchymal monitor.

For (Richmond) subarachnoid bolt: screw in until tip is flush with inner table.

Removal

Patients receiving anticoagulants need to have normal coagulation and platelet function before discontinuing the catheter to reduce the risk of intracranial hemorrhage. For heparin and LMW heparin, stop the drug 24 hours prior to discontinuing the drain.

“Sump drainage”

The tip of a 25 gauge butterfly may be bent at a 90° angle, and inserted into a subcutaneous reservoir for prolonged ventricular drainage. In one series of 34 patients, this was used for prolonged periods (up to 44 days) with acceptably low infection rate. The use of a one-way valve, continuous antibiotics (ampicillin and cloxacillin) and meticulous technique was credited for the lack of infection.

97.6.3 Ventricular shunts

Booking the case: Ventricular shunt

Also see defaults & disclaimers (p. 27).

1. position: supine with shoulder roll
2. implants: need to specify shunt manufacturer and valve type (e.g. programmable, low profile…)
   - Uncommon components (e.g. ultra-low pressure, tumor filter) may need special order
3. equipment:
   - a) C-arm for ventriculo-atrial shunts
   - b) endoscopic display (e.g. if NeuroPen is used)
   - c) image guided navigation system (infrequently used)
4. consent (in lay terms for the patient – not all-inclusive):
   - a) procedure: surgery to insert a permanent drainage tube from the brain to the abdomen, outside of the lungs, vein near the heart (as appropriate) to drain excess cerebrospinal fluid
   - b) alternatives: nonsurgical management (rarely effective for hydrocephalus), third ventriculostomy (for certain cases)
   - c) complications: infection, suboptimal position which might require re-operation, failure to relieve hydrocephalus/symptoms, subdural hematoma, bleeding in the brain, shunts are mechanical devices and will eventually fail (break, block up, move…) and need repair/replacement (sometimes sooner rather than later). Abdominal shunts: risk of bowel injury (which could require further surgery)

Ventricular catheter

Kocher’s point is currently used in most cases for insertion site of ventricular catheter; see Ventricular catheterization (p. 1512) for technique. An alternative is an occipital burr hole aiming toward the frontal horn of the lateral ventricle.

An inverted “J” shaped incision is used to keep hardware from lying directly under the skin incision (minimizes risk of skin breakdown and also creates additional barrier to infection of subjacent hardware). CSF should be sent for culture at the time of insertion since it has been estimated that in ≈ 3% of patients the CSF is already infected. 4 mg of preservative-free gentamicin may instilled into the ventricular catheter by the technique of barbotage, (a technique to administer a drug while reducing the amount of drug lost in the dead space of the catheter: a portion of the antibiotic solution is injected into the CSF, then a lesser amount of CSF is aspirated, a second portion is then injected and the process is repeated until all of the medication is administered).

If you think the catheter is in the ventricle, but you don’t get CSF flow, it may be due to low pressure, you can compress the jugular veins or lower the head of the bed to try and induce CSF flow.
Connectors

If a connector must be used near the clavicle, place it rostral to (above) the clavicle. Avoid placing it caudal to the clavicle which increases the risk of disconnection.

Distal catheter placement options

All things being equal, the general order of preference for distal catheter placement:

1. peritoneal cavity: see below
2. pleural space (p.416): not for age \( \leq 7 \) years. For technique, see below
3. right atrium or superior vena cava (p.1516)
4. infrequently used distal shunt sites
   a) gall bladder
   b) internal jugular vein (with the catheter pointing “upstream”)
   c) superior sagittal sinus

Ventriculoperitoneal shunt

Peritoneal catheter

For small children, use at least 30 cm length of intraperitoneal tubing to allow for continued growth (120 cm total length of peritoneal tubing was associated with a lower revision rate for growth without significant increase in other complications\(^\text{52}\)). A silver clip is placed at the point where the catheter enters the peritoneum so that the amount of residual intraperitoneal catheter can be determined on later films (more important in growing children).

Distal slits on the peritoneal catheter may increase the risk of distal obstruction,\(^\text{53}\) and some authors recommend that they be trimmed off. Wire reinforced catheters should not be used because of excessively high rate of viscus perforation, and this tubing was designed to prevent kinking which is not a problem with modern shunts.

Open technique

A vertical incision lateral and superior to the umbilicus is one of several choices. The following layers should be identified as they are traversed to avoid confusing preperitoneal fat with omentum and erroneously placing the tip in the preperitoneal space:

1. subcutaneous fat
2. anterior sheath of the abdominis rectus muscle (anterior rectus sheath)
3. abdominis rectus muscle fibers: should be split longitudinally
4. posterior rectus sheath
5. preperitoneal fat (may be very well developed in a few individuals, but is essentially nonexistent in most)
6. peritoneum (usually closely adherent to the posterior rectus sheath)

Trocar technique

1. place a Foley catheter to decompress the bladder
2. 1 cm skin incision above and lateral to the umbilicus
3. pull abdominal skin anteriorly (away from patient)
4. insert trocar aiming toward the ipsilateral iliac crest
5. feel 2 “pops” of penetration: 1 = anterior rectus sheath, 2 = posterior rectus sheath/peritoneum
6. peritoneal catheter should feed easily through trocar
7. contraindications: prior abdominal surgery, extremely overweight patients

VP shunt, post-op orders (adult)

1. flat in bed (to avoid overshunting and possible subdural hematoma) with gradual mobilization
2. if peritoneal end is new or revised, do not feed until bowel sounds resume (usually at least 24 hrs, due to ileus from manipulation of peritoneum)
3. shunt series (AP & lateral skull, and chest/abdominal x-ray) as baseline for future comparison (some surgeons obtain these films immediately post-op in case some immediate revision is indicated, e.g. ventricular catheter tip in temporal horn)

Ventriculopleural shunt insertion

See reference.\(^\text{54}\)
See also more details (p.416). Not for age ≤ 7 years. A 3 cm horizontal incision is made just below the level of the breast either in the midclavicular line or in the anterior axillary line. Divide the subcutaneous tissue, deep fascia, and pectoralis muscle. The external and internal intercostal muscles are divided along the superior margin of the inferior of the two ribs exposed (to avoid the neurovascular bundle running along the inferior margin of each rib). A self retaining retractor between the ribs aids the exposure. The parietal pleura is visualized with the visceral pleura sliding underneath with each respiration. The pleura is not opened until the catheter is brought out subcutaneously at this incision. Have the anesthesiologist hold respirations, and nick the parietal pleura (or use a blunt-tip hemostat to pop through) to admit the catheter. Allow the lung to drop away and insert 20–40 cm of tubing into the pleural cavity. If the pleural opening is lax around the catheter, it can be snugged with a 4–0 absorbable suture. Have the anesthesiologist perform a valsalva maneuver before cinching down the pleural suture, and again before closing the deep muscle layer. A chest tube is usually not required. A maneuver that may sometimes be helpful is to place a red-rubber catheter next to the shunt tube at the same time (to permit the escape of air from the pleural space). Begin closing, but prior to placing the last deep suture, have the anesthesiologist perform a valsalva maneuver and allow air to escape through the red-rubber catheter (you can place the end in saline to see the bubbles). Once the bubbles stop, pull the red-rubber catheter and close the last stitch. If the bubbles don’t stop, there is an air leak in the visceral pleura and a pigtail catheter or a chest tube connected to a Pleur-evac® should be used.

Ventriculo-atrial shunt insertion

Open method

The common facial vein (CFV) is located by making a diagonal cervical incision across the anterior border of the sternocleidomastoid at or just below the level of the angle of the mandible (the CFV may be as far as = 2 cm below this point). The platysma is divided, and the CFV is located as it joins the internal jugular vein (IJV) at the level of the hyoid bone. The CFV is cannulated with the atrial tubing, and is secured with a snug ligature close to the junction with the IJV. If the CFV is not suitable, a purse string suture is placed directly in the IJV, and the IJV is then opened in the center of the purse string and cannulated.

Percutaneous method

May be utilized in adults (and possibly peds). The IJV is catheterized using the Seldinger technique with a guide-wire and needle through a stab wound at the anterior margin of the SCM. Fluoroscopy is used to place the tip of the wire at the desired location (see below). A No. 13 French peel-away introducer and dilator are then inserted over the wire, which is then bent at the skin edge and withdrawn (for a pediatric case: may use a No. 7 French introducer with a 1.5 mm O.D. lumboperitoneal catheter for the distal atrial catheter). The atrial catheter is cut to the length of the wire distal to the bend, and the catheter is then threaded into the introducer. The position of the catheter tip should again be confirmed (e.g. with radio-opaque contrast under fluoroscopy). A short skin incision is then made starting at the point where the catheter penetrates the skin to permit subcutaneous tunneling of the tubing.

Location of distal tip

Placement pointer: if the catheter repeatedly goes down the wrong vessel (e.g. the subclavian vein), a “T” guidewire may help. Also, rotating the head to a more neutral position sometimes works.

The ideal location of the distal tip is in the right atrium (unlike the location for central catheters in the superior vena cava (SVC)) so that the turbulent blood flow will reduce the risk of thrombus formation. The tip may enter the right atrium, but must not penetrate the tricuspid valve. A number of methods for optimal placement of the distal shunt tip may be employed, and include:

1. using an intraoperative chest x-ray to locate the tip between the level of T6-T8 vertebra in an adult. In a growing child, initially insert to = T10 level. This method is subject to error due to malalignment of the x-ray beam (parallax error)
2. locating the tip near the level described above, then inject iodinated contrast, e.g. 20 ml of Omnipaque 180 (iohexol) (p.219) under intraoperative fluoroscopy to locate the tip in SVC
3. fill the catheter with normal or 3% saline and use the catheter as an EKG electrode. The P-wave changes from a downward to a biphasic morphology as the tip enters the atrium. A sharp upward deflection occurs as the tricuspid valve is approached. Some recommend advancing the tip to maximal P-wave amplitude and then backing off a centimeter or two
4. fill the catheter with heparinized saline (1–5 U per cc NS) and measure the pressure as the tip is advanced, leave tip just short of where atrial pressure tracing occurs
5. utilizing intraoperative echocardiography
A growing patient is followed with annual CXRs. When the catheter tip is above \( \approx T4 \), the catheter must be lengthened or converted to a VP shunt.

97.6.4 Third ventriculostomy

General information

See also indications and complications (p. 415).

Older techniques include a subfrontal approach, opening the chiasmatic and lamina terminalis cisterns, and making a 5–10 mm opening in the lamina terminalis. Stereotactic third ventriculostomy (using contrast ventriculography or CT guided) has also been described. Current technique, endoscopic third ventriculostomy (ETV) often with assistance of image-guidance consists of fenestrating the floor of the third ventricle using a ventriculoscope.

Ventriculoscop ic technique

1. equipment: requires a rigid endoscope (does not work well with flexible)
2. image guided stereotactic technology helps immensely with the trajectory, but once you’ve entered the third ventricle, you must navigate by visual landmarks and cannot rely on image guidance because of the limitations of the accuracy
3. burr hole: 2–3 cm lateral to the midline just anterior to the coronal suture (Kocher’s point)
4. pass through the foramen of Monro and fixate the sheath just within the third ventricle
5. the floor of the third ventricle is inspected and must be thin enough and translucent enough to permit visualization of the basilar artery and mammillary bodies. If these structures cannot be visualized then the procedure should be aborted
6. the location of the opening is chosen:
   a) in the midline (avoids p-comm and PCA)
   b) in the region of the tuber cinereum (prominence of the base of the hypothalamus, extending ventrally into the infundibulum and pituitary stalk)
   c) posterior to the infundibular recess
   d) anterior to the mammillary bodies
   e) anterior to the tip of the basilar artery
7. an effective technique consists of “rubbing through” the floor of the third ventricle either with a probe or Decq forceps. Alternatively, hydrodissection or bipolar electrocautery may be used to thin down the lamina. Do not use laser due to possibility of injury to basilar artery!
8. the opening can be enlarged with the Decq forceps, or a 3 french use of a Fogarty balloon or a double balloon (Fogarty or Neuroballoon™ catheter (Integra LifeSciences 7CBD10)). The balloon is inflated distal to the opening in the floor and is then withdrawn through the opening
9. the opening does not need to be large (unlike e.g. fenestrating an arachnoid cyst): \( \approx 4–5 \text{ mm} \) is usually adequate
10. after penetrating through the floor of the third ventricle, make certain that you can see vessels (sometimes the arachnoid is not perforated, or there is a second membrane or webs of membranes that need to be lysed)
11. consider injection of diluted iohexol or other intrathecal contrast agent into the lateral/third ventricle (see ventriculogram) prior to removal of scope. CT head 1 hour after surgery will show diffuse subarachnoid contrast in cisterns and over convexity if ETV successful
12. sagittal T2 weighted, thin-slice sequence will show drop out of T2 signal at stoma of ETV

97.6.5 LP shunt placement

Technique of insertion

See reference.

1. position: lateral decubitus position, both knees flexed (right side up preferred)
2. prep back, flank and abdomen
3. 1 cm skin incision over L4–5 or L5-S1 (in obese patients, use larger skin incision carried down to fascia overlying spinous processes. This may also be superficially incised between spinous processes to aid insertion)
4. tilt table to 30° reverse-Trendelenburg to expand lumbar subarachnoid space
5. insert 14 gauge Tuohy needle into subarachnoid space, with opening directed rostrally (caudal placement also acceptable). Confirm placement by CSF flow
6. remove trocar, insert shunt tubing such that \( \leq 8 \text{ cm} \) of catheter (for L4–5 insertion) lies within spinal canal (minimizes conus medullaris irritation)
7. needle then withdrawn over catheter
8. make flank incision, pass tunneler from flank to back incision. Feed catheter from back to flank. Withdraw tunneler over catheter

9. abdominal placement:
   a) open: incision made through peritoneum. Catgut (or other absorbable suture) purse-string placed in peritoneal opening
   b) trocar

10. pass tunneler from abdominal incision to flank incision. Feed catheter from flank to abdomen. Withdraw tunneler over catheter

11. verify CSF flow. Place catheter inside peritoneum. For open technique: cinch purse-string snugly, but loose enough to allow catheter to slide with gentle pushing

12. snug fitting retaining sleeve placed around catheter at all three incisions, and secured to subcutaneous tissue with non-absorbable suture

Lumbo-peritoneal (LP) shunt evaluation

When problems develop, evaluation of function may be more difficult than with VP shunt. Evaluation may include:

1. abdominal x-rays: AP & lateral x-rays can rule out breakage or migration of a shunt component
2. noncontrast brain CT scan: can rule-out complication such as subdural hematoma
3. LP: perform LP just above or below level of lumbar catheter. The pressure may be 0 or negative, and it may be necessary to aspirate CSF to confirm placement
   a) can give indirect evidence of shunt function by measuring the CSF pressure, which should be low if the shunt is working (only helpful in cases where the shunt was placed for elevated CSF pressure, e.g. pseudotumor cerebri; not helpful in NPH).
   b) "shunt-o-gram": inject contrast into subarachnoid space through LP needle
      • radionuclide (p.421): inject radio-isotope via LP and look for subsequent tracer activity in peritoneal cavity
      • with water-soluble contrast: inject 10 ml of iohexol and monitor the flow of contrast fluoroscopically as the patient is brought vertical. Coughing or valsalva maneuver will accelerate the flow of contrast
4. shunt tap: if an antechamber has been installed, it is accessed after cleaning the skin with antiseptic using a 22 Ga. or smaller needle placed perpendicular to the dome to prevent leakage. If there is no access chamber, it is sometimes possible to tap the tubing itself with a 27 gauge butterfly needle

97.7 Ventricular access device

97.7.1 General information

An indwelling ventricular catheter connected to a reservoir that is situated under the scalp for the purpose of chronic access to the intrathecal space (usually the ventricular system), or sometimes other intracranial compartments such as tumor cysts. Sometimes referred to as an Ommaya® reservoir, this is actually a trade name.

97.7.2 Indications

1. administration of intrathecal (IT) antineoplastic chemotherapy:
   a) for CNS neoplasms, including: carcinomatous meningitis, methotrexate for CNS lymphoma or leukemia (p.713)
   b) IT chemotherapy is often used for the following even in the absence of CNS involvement because of the high relapse rate in the CNS: acute lymphoblastic leukemia, lymphoblastic lymphoma, Burkitt’s lymphoma
2. administration of intrathecal antibiotic for chronic meningitis
3. chronic removal of CSF from infants with intraventricular hemorrhage
4. for fluid aspiration from a chronic tumor cyst that is resistant to therapy (radiation or surgery)
Booking the case: Ventricular access device

1. position: supine
2. equipment
   a) endoscopic display (e.g. if NeuroPen is used)
   b) C-arm (optional) to verify position of ventricular catheter
   c) image guided navigation system (infrequently used)
3. implants: need to specify reservoir manufacturer
4. consent (in lay terms for the patient – not all-inclusive):
   a) procedure: surgery to insert a tube into the fluid space within the brain (ventricle) which is connected to a port under the skin so that fluids can be removed or injected (usually medication)
   b) alternatives: sometimes fluid can be removed and medication can be injected using a lumbar puncture (spinal tap). The effectiveness of this may not be the same as the operation being discussed here
   c) complications: infection, suboptimal position which might require re-operation, subdural hematoma, bleeding in the brain, this is a mechanical device and may eventually fail (break, block up…) and need repair/replacement

97.7.3 Technique of insertion

See reference. Preferably placed in the right frontal region, unless indicated otherwise (e.g. for tumor cyst). Usually placed under endotracheal general anesthesia, although local anesthesia occasionally may be used (e.g. for patients too ill to tolerate general anesthesia).

Patient position: supine, head midline, neck flexed 5°.

Incision: inverted “U”, slightly larger than the reservoir (the original Ommaya® reservoir is 3.4 cm diameter), with the center over the coronal suture approximately 3 cm from midline, roughly centered near Kocher’s point (p. 1512). A circle of pericranium of diameter equal to that of the reservoir is excised and saved. Alternatively, the pericranium may be flapped separately in the opposite direction (i.e. a right-side-up “U”), and closed over the reservoir to help secure it in position.

Make a burr hole over the coronal suture 3 cm off midline. A cruciate incision in the dura is made large enough to visualize the cortical surface, minimal cortical bipolar coagulation is used, and a pial/cortical incision is made to avoid surface vessels.

One may inject 15–20 cc of filtered air into the ventricles with a ventricular needle prior to the catheter insertion to guide the tip of the catheter with intra-operative lateral skull x-rays (intraoperative pneumoencephalogram). The trajectory is towards a point intersecting a plane 2 cm anterior to the EAM aiming minimally towards the midline (1–2°). Alternatively, one may aim perpendicular to the surface of the skull. A total length of ≈ 7.25 cm of catheter is fixed to the base of the reservoir which allows the catheter to lie on the floor of the anterior horn of the lateral ventricle in most adults. This location can be verified with intraoperative pneumoencephalography or with ventriculoscopic techniques.

The excised pericranium is placed over the dura, and the reservoir is sutured to the pericranium. Note: the dome of the original Ommaya® reservoir has a low resistance, and may be easily collapsed if too much tension is placed on the overlying scalp. If early use of the reservoir is desired (i.e. within 48 hrs post-op), the skin closure should be performed with a running nonabsorbable suture (e.g. nylon) and coated with collodion, and the surgical site can then be left without a gauze dressing for easier access to the reservoir. A skin tattoo can be created over the center of the reservoir (to assist in localizing the reservoir for injection) using India ink and a prickig the skin with a sterile needle.

97.7.4 Reservoir puncture

The scalp is prepped with antimicrobial scrub, and using sterile technique, a 25 gauge or smaller butterfly needle is introduced at an oblique angle, preferably with a non-coring needle. The original (Ommaya®) reservoir has firm plastic bottom surface which can be penetrated if too much force is applied.
97.8 Sural nerve biopsy

97.8.1 General information

Although a number of peripheral nerves may be biopsied, the sural nerve fulfills the criteria of being well studied, expendable with minimal deficit, easily accessible, and often involved in the pathologic process in question.

97.8.2 Indications

Nerve biopsy plays a small role in diagnosing peripheral neuropathies, but may be very accurate for vasculitis, amyloidosis, Hansen’s disease, metachromatic and globoid leukodystrophy, neoplastic infiltration of peripheral nerve, and relapsing polyneuritis. May help distinguish the two types of Charcot-Marie-Tooth syndrome. May show demyelination in diabetic amyotrophy (p.545). The yield of sural nerve biopsy may be low if it is normal on nerve conduction testing. Disadvantages of the sural nerve is that it will usually be spared in purely motor neuropathies.

97.8.3 Risks of procedure

1. sensory loss in the sural nerve distribution is expected, but often does not persist for more than several weeks (unless the underlying disease process prevents this)
2. problems with wound healing: the ankle is a notorious region for poor circulation and the loss of sensation (from the disease or biopsy) may render the area subject to repeated trauma without the patient being aware. Furthermore, many patients with an undiagnosed systemic disease requiring a sural nerve biopsy will have poor wound healing (a significant number are also diabetic)
3. failure to make a diagnosis: although biopsy may be able to exclude some contingencies, it often does not make a specific diagnosis

97.8.4 Applied anatomy

The sural nerve is formed by the merging of the distal portion of the medial sural cutaneous nerve (one of the terminal branches of the tibial nerve) and the anastomotic ramus of the common peroneal nerve. It is entirely sensory except for some unmyelinated autonomic fibers. It supplies cutaneous sensation to the posterolateral third of the leg, the lateral heel and foot, and the little toe. At the level of the ankle it lies between the Achilles tendon and the lateral malleolus. This location is constant, superficial, and relatively protected from external trauma which might otherwise confuse the analysis.

97.8.5 Technique

Modified technique Usually done under local anesthesia with sedation. Side to biopsy: if one leg shows more involvement, that is often the preferred side to biopsy.

Position: patient prone. If patient is not under general anesthesia, use 3/4 oblique (not prone) pillow between the legs. The leg to be biopsied is uppermost and is flexed 90° at the knee to relax tension on the nerve, the ankle is slightly everted. Compressing the calf (can be done using a sterile Penrose drain as a temporary tourniquet during surgery) distends the lesser saphenous vein (LSV) at the lateral malleolus (LM), which (when visible) reliably locates the sural nerve usually deep and anterior to the vein.

After prepping, drape the limb with a sterile stockinet or similar drape, infiltrate local anesthetic subcutaneously just posterior to the LM and proximally, paralleling the Achilles tendon for ~10 cm. A 7–10 cm incision is made overlying the course of the LSV beginning usually just posterior to and ~1 cm proximal to the LM. The vein can be seen through the translucent Scarpa’s fascia. The fascia is incised over the vein which is gently retracted to reveal the nerve usually deep to the vein. A common pitfall is to go too deep, the nerve is fairly superficial; it is not necessary to go through the thick fascia. If at any time you see tendons to the toes, you have gone too deep.

To differentiate the sural nerve from the LSV (which may resemble the nerve in some cases): the nerve has many branches at acute angles especially proximal to the LM, vs. the vein which has right angle branches. If in doubt, a frozen section may be helpful to verify that the biopsied structure is a nerve in order to avoid potentially embarrassing explanations and the possible need to repeat the procedure.

After exposing at least 3–5 cm of the nerve, anesthetize the proximal portion with 0.5% lidocaine using a 27 Ga. needle and cut it sharply just distal to the infiltration site (note: sometimes a biopsy
of only a portion of the nerve’s fascicles may suffice: this is accomplished by opening the epineurium for the length of the exposure and teasing out a fascicle with minimal branching. Cut the nerve with slight tension on it to allow the ends to retract deep to the skin incision to prevent the formation of a scar neuroma. Some pathologists request that the proximal end of the nerve be marked, e.g. with a suture. If it is desired to obtain a biopsy of the sural nerve higher up for comparison, it may be accessed in the mid upper calf between the heads of the gastrocnemius muscle. Here it may be as deep as \( \approx 2 \text{ cm} \). Gently tugging on the exposed nerve in the ankle may help in localization. A dissolvable subcuticular closure may be used. Generous padding should be placed over the incision to protect it from bumps (since many patients are numb from the pathology and/or surgery, there is increased risk of inadvertent surgical wound injuries). An elastic pressure dressing is applied after closure.

**97.8.6 Nerve handling**

For light microscopy which suffices in most cases, immerse the nerve in formalin. For electron microscopy, glutaraldehyde is used. For biochemical and immunofluorescence studies, use rapid freezing.

**97.8.7 Post-op care**

Pressure dressing should be worn for protection for two weeks. The patient is allowed to walk but should restrict their activity for 2–3 days. If nonabsorbable sutures are used instead of subcuticular closure, they should be left in place 10–14 days.

**97.9 Nerve blocks**

Also see Occipital nerve block (p. 516).

**97.9.1 Stellate ganglion block**

**General information**

Do not perform stellate ganglion block bilaterally (can cause bilateral laryngeal paralysis \( \rightarrow \) respiratory compromise). Stellate ganglion is actually closer to C7 than C6, but risks at C7 are much higher (closer to pleura \( \rightarrow \) pneumothorax, vertebral artery \( \rightarrow \) arterial injection \( \rightarrow \) seizures and/or hematoma, recurrent laryngeal nerve \( \rightarrow \) unilateral vocal cord paralysis \( \rightarrow \) unilateral hoarseness (common), brachial plexus \( \rightarrow \) UE weakness). Other complications: intradural injection \( \rightarrow \) spinal anesthesia, phrenic nerve block.

**Technique**

Patient supine; interscapular roll; head tilted backward, mouth slightly open to relax strap muscles. Displace SCM and carotid sheath laterally, insert 1.5 inch 22 Ga. needle to contact Chassaignac’s tubercle (anterior tubercle of transverse process of C6) AKA carotid tubercle (the most prominent in the C-spine) usually at the level of the cricoid cartilage, approximately 1.5–2 inches above clavicle.

Withdraw needle 1–2 mm and aspirate (do not inject intravascularly). Inject small test dose, then full 10 ml of 0.5% bupivacaine (Marcaine®) or 20 ml of 1% lidocaine. Remove needle and elevate patient’s head on pillow to facilitate spread.

Verify block by Horner’s syndrome, and anhidrosis and increased warmth of ipsilateral hand.

**97.9.2 Lumbar sympathetic block**

**Technique**

Patient prone on fluoro table. Use local anesthetic to allow insertion of 20–22 gauge spinal needles (10 to 12.5 cm long) at L2, L3 and L4 levels. Needle inserted 4.5–5 cm lateral to spinous process until transverse process contacted, then redirected caudally and inserted to a depth 3.5–4 cm deeper than transverse process. Final needle tip position should be just anterolateral to vertebral bodies. At each level, instill \( \approx 8 \text{ ml} \) of 1% lidocaine local after verifying that nothing can be aspirated.

Keep patient on bed rest for several hours, then ambulate with assist; watch for orthostatic hypotension due to vascular pooling in blocked lower extremity.
97.9.3 Intercostal nerve block

Indications
1. postthoracotomy pain
2. intercostal neuralgia
3. postherpetic neuralgia
4. pain from rib fractures

General principles
In order to obtain good anesthesia, the following should be noted:
1. a good site for injection is in the posterior axillary line (PAL) because
   a) this is proximal to the origin of the lateral cutaneous nerve (which originates ⊥ in the anterior
      axillary line)
   b) this avoids the scapula for nerves above ≈ T7
   c) this reduces the risk of pneumothorax from injecting closer to the spine (the latter requires a
      longer needle path and there is increased difficulty palpating landmarks)
2. due to overlap, at least 3 intercostal nerves usually need to be blocked to achieve at least some
   area of anesthesia; it is usually necessary to block 1–2 intercostal nerves both above and below the
   affected dermatome
3. the intercostal nerves lie on the undersurface of the corresponding rib in close proximity to the
   pleura; the order of structures from top down is: rib, vein, artery, nerve

Technique
1. after raising a skin wheal at the desired level in the PAL, insert a 22 Ga. or smaller needle directly
   against the rib
2. walk the needle down the rib millimeter by millimeter until the needle just slips under the rib;
   to avoid pleural puncture, do not advance the needle more than one-eighth inch deep to the
   anterior surface of the rib
3. aspire to be certain that there is no air (from lung penetration) or blood (from entering the
   intercostal artery or vein)
4. if no air or blood returns, inject 3–5 ml of local anesthetic
5. if there is any question about lung penetration, obtain a portable CXR to R/O pneumothorax

98 Functional Neurosurgery

For functional neurosurgery related to pain, see Pain procedures (p. 1541).

98.1 Deep brain stimulation

A variety of conditions may be treated including:

1. movement disorders
   a) Parkinson’s disease: STN stimulation may be superior to best medical management\(^1,2\) because of similar efficacy to levodopa with fewer side effects (primarily dyskinesias) (see below)
   b) dystonia (p. 1528)
   c) tremor (p. 1537)

2. epilepsy (p. 1554)

3. pain (p. 1550): response is variable, typically only 25–60% respond

4. potential uses
   a) psychiatric disorders: mainly
      - Tourette syndrome: thalamic & pallidal DBS (case reports\(^3,4\))
      - obsessive compulsive disorders: anterior capsule and STN stimulation\(^5\) and, recently, targets more posterior and rostral\(^6\)
      - depression: subgenual cingulate gyrus\(^7\) and anterior capsule stimulation\(^8\)
   b) obesity\(^9\)
   c) drug addiction\(^10\)
   d) hypertension (case report of lowering BP in a patient who was being treated for pain\(^11\))

98.2 Typical targets used in functional brain surgery

Fig. 98.1 depicts relationships of typical targets to other structures and effects of DBS (or lesioning). This figure is intended for illustrative purposes only, and is not presented for purposes of performing surgical procedures.

98.3 Surgical treatment of Parkinson’s disease

98.3.1 Historical background

Prior to the availability of effective medications, surgical procedures were developed to treat Parkinson’s disease. An early procedure was ligation of the anterior choroidal artery. Due to variability in distribution, destruction often extended beyond the desired confines of the pallidum and the results were too unpredictable. Anterodorsal pallidotomy became an accepted procedure in the 1950’s, but long-term improvement was mainly in rigidity, while tremor and bradykinesia did not improve.\(^12\) The ventrolateral thalamus subsequently became the preferred target. Lesions there were most effective in diminishing tremor. In actuality, the tremor was often not the most debilitating symptom, particularly since it is a resting tremor at first (it may become more pervasive later). Bradykinesia and rigidity were frequently more problematic. Furthermore, the procedure only reduces tremor in the contralateral half of the body, and bilateral thalamotomies were not recommended due to an unacceptably high risk of post-op dysarthria and gait disturbance. Use of thalamotomy fell off dramatically in the late 1960’s with the introduction of L-dopa.\(^13\)

98.3.2 Current trends

However, at some point most patients will experience problematic side effects and/or resistance to treatment with antiparkinsonian drugs. This, together with recent refinements in surgical techniques resulting in improved outcomes have produced in a resurgence of interest in the operative treatment of Parkinson’s disease. Tissue transplantation (e.g. with adrenal medullary tissue) appears to have only modest benefits (see below). Lesioning or stimulation techniques have therefore gained in popularity with renewed interest in the posteroverentral pallidum as the target, which was actually pioneered by Leksell around the time that thalamotomy came into vogue.\(^12\)
Tissue transplantation for Parkinson’s disease is generally limited to research centers. The present status of implantation of fetal dopaminergic brain cells into Parkinson’s disease patients is that it may reduce the severity of the illness and increase the effectiveness of levodopa. For ethical reasons, this procedure is rarely performed in the U.S.
Other transplanted tissues include cells from the patient’s own adrenal medulla. After initial enthusiastic results, later studies failed to corroborate the dramatic outcomes, and benefits appear to be modest. A double-blinded, randomized, placebo-controlled trial of 34 subjects with severe PD noted initial improvement at 6 and 9 months, but found no efficacy 2 years after fetal mesencephalic cell transplantation. Of note: immunosuppression was only used for six months. Further research is ongoing.

98.3.4 Ablative surgery and electrical stimulation

General information
Ablative surgery has largely given way to less destructive deep brain stimulation (DBS).

Pallidotomy
See references.

General information
Pallidotomy may work by one of the following mechanisms: directly destroying portions of the internal segment of the globus pallidus internus (GPi), interrupting pallidofugal pathways, or diminishing inputs to the medial pallidum (especially from the subthalamic nucleus; see Pathophysiology (p.177)). Although early methodologies included stereotactic radiosurgery, modern techniques (excluding very select cases) rely primarily on radiofrequency or cryoprobe lesioning after confirming target location by electrical stimulation.

Electrical stimulation
Deep brain stimulation (DBS) in the area of the GPi and subthalamic nucleus (STN) can also relieve parkinsonian symptoms without irreversibly destroying tissue. A randomized study showed similar efficacy between thalamotomy and DBS, but fewer side-effects with DBS. A more recent target of interest for DBS is the pedunculopontine nucleus (PPN).

Indications
1. patients refractory to medical therapy (including multiple agents). However, some investigators feel the response to surgery might be better if done early
2. primary indication (based on an opinion survey): patients with levodopa-induced dyskinesias (especially those with associated painful muscle spasms). Initial results indicate that these are very responsive to pallidotomy
3. gait and postural instability as well as falls and freezing (non-human primate data) may respond to DBS of the pedunculopontine nucleus (PPN)
4. patients primarily with rigidity or bradykinesia (unilateral or bilateral), on-off fluctuations or dystonia. Tremor may be present, but if it is the predominant symptom, then using the ventralis intermedius (VIM) nucleus of the thalamus as the target (for ablation (thalamotomy) or stimulation) is a better procedure. VIM stimulation is also used to treat essential tremor.

Contraindications
1. patients with significant dementia: further cognitive impairment has been noted primarily in patients with cognitive deficits prior to treatment
2. patients with risk of intracerebral hemorrhage: those with coagulopathy, poorly controlled hypertension, those on anti-platelet drugs that cannot be withheld (may consider stereotactic radiosurgery lesions for these rare patients, see below)
3. patients with ipsilateral hemianopsia: due to the risk of post-op contralateral hemianopsia from optic tract injury which would make the patient blind
4. age ≥ 85 yrs
5. patients with secondary Parkinsonism (p.177) i.e. not idiopathic Parkinson’s disease: respond poorly, presumably due to different pathophysiology. Look for:
   a) signs of autonomic nervous system dysfunction (suggests Shy-Drager)
   b) EOM abnormalities (may occur in progressive supranuclear palsy (PSNP))
   c) long-tract signs
   d) cerebellar findings (as in olivo-ponto-cerebellar atrophy (OPCA))
   e) failure to improve with levodopa
f) MRI: lacunar infarcts in basal ganglia (as in arteriosclerotic Parkinsonism), or tumor in region of substantia nigra

g) PET scanning (if available): decreased striatal metabolism detected by deoxyglucose PET scan (suggests striato-nigral degeneration (SND))

Technique

General information

Antiparkinsonian medications are withheld the morning of the procedure to bring out symptoms. A stereotactic frame is applied under local anesthetic parallel to the orbitomeatal line (which aligns with the anterior-posterior commissural (AC-PC) line).

Radiologic target localization

May utilize: MRI, CT, and/or ventriculography. MRI is the most common imaging modality, and may best demonstrate the desired anatomy, but is susceptible to geometric distortion. Therefore many centers also utilize CT and/or ventriculography to supplement MRI. T1WI images are commonly employed, however some feel that optimal MRI imaging may be performed with gadolinium-enhanced axial and coronal projections using 1 mm slice intervals and a STIR or spoiled GRASS volume acquisition protocol.

The posterior commissure is the white-matter band at the level of the pineal that crosses at the posterior third ventricle.

The typical initial target\(^{27}\) is shown in Table 98.1. Avoid encroachment on internal capsule (medial to GPi) and optic tract (inferior to GPi). Lesions of the subthalamic nucleus are associated with hemiballismus. An entry site is chosen from imaging studies, and is usually just anterior to the coronal suture and 15–20 mm lateral to the midline. A 4 mm twist drill hole is used. The trajectory should avoid midline venous structures, arterioles within sulci (therefore enter through a gyrus), and passage through the lateral ventricle.

Electrophysiologic target localization

Stimulation:

The patient must be awake for the procedure. For patients with dyskinesias that occur only following a dose of medication, their normal dose of medicine is given after imaging to bring out the symptoms for the procedure. Stimulation is required to verify the neurophysiologic target which varies between individuals. Macroelectrode stimulation may be done with the lesioning electrode. Impedance typically drops when a white matter tract is encountered. The impedance of the desired target is usually >600 \(\Omega\). Stimulate with square wave at 1, 5, 50 and 100 Hz with voltage range of 0.5–3 volts (NB: above \(\approx\) 2 V you may be seeing wide-field stimulation). Pallidum stimulation usually increases (but occasionally decreases) contralateral muscle tone. Also look for reduction of tremor or dyskinesia. Contralateral weakness or hypotonia indicates proximity to the internal capsule. Visual scotomata suggests stimulation of the optic tract.

Micro-electrode recording:

About half the institutions surveyed perform microelectrode recording, and half the remaining centers were considering starting it.

Lesioning

Kondziolka et al.\(^{22}\) use a 1.1 mm diameter probe with a 3 mm exposed tip. A small lesion is made at 45°C for 30 seconds, before making the definitive lesion at 70–80°C for 60 seconds. The probe is withdrawn 3–4 mm and a second lesion is made. Lesions with cryoprobes may be associated with a higher incidence of intracerebral hemorrhage.

For the very rare patient in whom insertion of an electrode is contraindicated (e.g. refractory coagulopathy), lesioning may be done with stereotactic radiosurgery, however, this eliminates the

\(^{a}\)may be decreased in women (start at \(\approx\) 19 mm), or increased when the 3rd ventricle is dilated
critical ability to verify the site of the planned lesion electrophysiologically before a permanent lesion is made.

Unilateral pallidotomy produces primarily contralateral effects, although some ipsilateral changes occur. Bilateral procedures are usually staged separately with a 3–12 hiatus between sides. Although they can be done in one sitting, bilateral pallidotomies may carry an increased risk of speech difficulties and cognitive decline.

Results

At present, the major focus of therapy has been on improvement of motor symptoms. Although 97% of patients showed at least some improvement (some poor results may derive from inclusion of some patients with secondary Parkinsonism), in 17% the degree of improvement was graded as mild.

Significant reduction of levodopa induced dyskinesias occurred in 90%. Bradykinesia improved in 85% rigidity in 75% and tremor in 57%. Other areas of improvement include: speech, gait, posture, and reduction of on-off phenomenon and freezing. Although symptoms may be ameliorated, overall functional improvement may not be remarkable.

Although dosages of antiparkinsonian medication are often reduced, continued medical therapy is usually required, and no change is made for at least 2 months following pallidotomy.

Indications are that beneficial surgical effects can last ≥5 years, with early failures possibly due to production of too small of a lesion, and late failures possibly due to progression of the disease.

Ongoing studies are investigating longer term results, microelectrode recording, alternate lesioning targets, the role of early surgery… Until more information is available, one cannot make any statements about the optimal target, localizing method, etc.

Complications

Visual field deficit occurs in 2.5% due to proximity of the optic tract to the globus pallidus. Hemiparesis may occur due to the nearby passage of the internal capsule. Intracerebral hemorrhage may also occur. Dysarthria occurs in ≈8% but is usually temporary. Speech difficulties and also cognitive decline may be more risky when bilateral pallidotomies are performed at the same sitting.

Thalamic lesions

Lesioning the thalamic ventralis intermedius nucleus (VIM) nucleus reduces Parkinsonian tremor in >85%. It can also be useful in the treatment of rigidity and drug induced dyskinesias by extending the lesioning anteriorly to include the ventral oralis. However thalamotomy does not improve symptoms of akinesia or bradykinesia and can result in worsening of gait symptoms or speech problems.

Subthalamotomoy

Lesioning the subthalamic nucleus (STN) is classically associated with intractable hemiballism. There are few studies as a result, but the limited data suggests that selective lesioning in this region provides relief on par with pallidotomy. Postoperative hemichorea is a known complication but is generally transitory and mild. DBS in this region may be a better option (p. 1524).

98.4 Dystonia

Pallidal stimulation is the primary surgical treatment for dystonia. Response is better for primary dystonias, e.g. tardive dystonias than for secondary dystonias such as postanoxic, postencephalitic, perinatal and poststroke dystonias (other targets need to be assessed).

For primary dystonias, the globus pallidus internus (GPI) is the most common primary target (Fig. 98.1). Good results have also been reported with STN DBS.

98.5 Spasticity

98.5.1 General information

Results from lesions in upper motor neuron pathway, causing absence of inhibitory influence on alpha motor-neurons (αMN) (alpha spasticity) as well as on gamma motor neurons (intrafusal fibers) (gamma spasticity). Causes uninhibited reflex arc between αMN and Ia afferents from muscle spindles resulting in a hypertonic state of muscles with clonus, and sometimes with involuntary movements. Etiologies include: injury to cerebrum (e.g. stroke) or spinal cord (spasticity is an
expected sequelae of spinal cord injury rostral to the conus medullaris), multiple sclerosis, and congenital abnormalities (e.g. cerebral palsy, spinal dysraphism).

98.5.2 Clinical

General information

Increased resistance to passive movement, hyperactive muscle stretch reflexes, simultaneous activation of antagonistic muscle groups, may occur spontaneously or in response to minimal stimuli. Characteristic postures include scissoring of legs or hyperflexion of thighs. May be painful, or may disrupt patient’s ability to sit in wheelchair, lay in bed, drive modified vehicles, sleep, etc. May also promote development of decubitus ulcers. A spastic bladder will have low capacity and will empty spontaneously.

Spasticity is often exacerbated by same type of stimuli that aggravate autonomic hyperreflexia; see Autonomic hyperreflexia (p.1020).

The onset of spasticity following spinal cord injury may be delayed for several days to months (the latency period is attributed to “spinal shock” (p.931), during which time there is decreased tone and reflexes).35 Onset of spasticity following spinal shock starts with increasing flexor synergistic activity over 3–6 mos, with more gradual increases of extensor synergy which ultimately predominate in most cases.

Some “beneficial” aspects of mild spasticity:
1. maintains muscle tone and therefore bulk: provides support for patient when sitting in wheelchair, helps prevent decubitus ulcers over bony prominences
2. muscle contractions may help prevent DVTs
3. may be useful in bracing

Grading spasticity

Assessment should be performed with patient supine and relaxed. The Ashworth scale (Table 98.2) is commonly used for the clinical grading of the severity of spasticity. Many attempts have been made to quantitate spasticity electrodiagnostically, the most reliable has been H-reflex measurement.

98.5.3 Treatment

General information

Depends on extent of useful function (or potential for same) present in areas at and below the level where spasticity starts (complete spinal cord injuries usually have little function, whereas patients with MS may have significant function).

Medical treatment
1. “prevention”: measures to decrease inciting stimuli (physical therapy to prevent joint damage, good skin & bladder care… see Autonomic hyperreflexia (p.1020))
2. prolonged stretching (more than just range of motion): not only prevents joint and muscle contractures, but modulates spasticity
3. oral medications37; (see Surgical treatment (p.1530) for intrathecal medications: few drugs are effective without significant undesirable side effects

Table 98.2 Ashworth scores36
a) **diazepam** (Valium®): activates GABAA receptors, increases pre-synaptic inhibition of αMN. Most useful in patients with complete spinal cord injuries. Start with 2 mg PO BID-TID, increase by 2 mg per day q 3 days up to a max of 20 mg TID.

**Side effects:** may cause sedation, weakness, decreased stamina (most of which may be minimized by gradual increases in dosage). Abrupt discontinuation may cause depression, seizures, withdrawal syndrome

a) baclofen (Lioresal®): activates presynaptic GABAB receptors of la muscle spindle afferents, causes pre-synaptic inhibition of αMN and decreases nociception. May be most useful in patients with spinal cord lesions (complete or incomplete). Start with 5 mg PO BID-TID, increase in 5 mg increments q 3 days up to max of 20 mg QID. **Side effects:** sedation, lowers seizure threshold. Must be tapered to discontinue (abrupt discontinuation may result in seizures, rebound hyper-spasticity or hallucinations).

b) **dantrolene** (Dantrium®): reduces depolarization induced Ca ++ influx into sarcoplasmic reticulum of skeletal muscle; acts on all skeletal muscle (with no preferential effect on spasmogenic reflex arc). Start with 25 mg PO q d, increase q 4–7 days to BID, TID, then QID, then by 25 mg per day up to max of ≈ 100 mg QID (may take 1 week at new steady state to see effect); **Side effects:** muscle weakness (may make ambulation impossible), sedation, idiosyncratic hepatitis (may be fatal; more common in patients on >300mg/d x>2 mos) that is often preceded by anorexia, abdominal pain, N/V; D/C if no benefit is seen by ≈ 45 days; follow LFTs (SGPT or SGOT)

c) **progabide:** activates both GABAA and GABAB receptors. Useful for patients with severe flexor spasms
d) theoretical benefits may be derived from other agents, but they have not been used for some practical reason in each case (e.g. phenothiazines reduce gamma spasticity, but only at high PO doses or parenterally; clonidine; tetrahydrocannabinol...)

### Surgical treatment

**General information**

Reserved for spasticity refractory to medical treatment, or where side effects of medications are intolerable. Generally either orthopedic (e.g. tendon release operations (tenotomies) of heel cord or hamstrings, iliopsoas myotomies, etc.) or neurosurgical (e.g. nerve blocks, neurectomies, myelotomy, etc.). Herz et al. recommend percutaneous radiofrequency foraminal rhizotomy, usually with percutaneous radiofrequency sciatic neurectomy as the initial ablative procedure (see below).

1. **nonablative procedures**
   a) intrathecal (IT) baclofen (see below)
   b) intrathecal morphine (tolerance and dependence may develop)
   c) electrical stimulation via percutaneously placed epidural electrodes

2. **ablative procedures, with preservation of potential for ambulation**
   a) motor point block (intramuscular phenol neurolysis): preserves sensation and existing voluntary function. Especially useful in patients with incomplete myelopathies; time consuming
   b) phenol nerve block: similar to motor point block, but used when spasticity more severe and complete block of muscle desired. Open phenol block used instead of percutaneous when nerve is mixed and sensory preservation is desired (also reduces post-block dysesthesias)
   c) selective neurectomies
      - sciatic neurectomy (may be done with RF lesion)
      - obturator neurectomy: useful if strong hip adductor spasticity that causes scissoring and wasted energy expenditure in ambulating
      - pudendal neurectomy: useful if excessive detrusor dyssynergy interferes with bladder retraining

3. **percutaneous radiofrequency foraminal rhizotomy:** small unmyelinated sensory fibers are more sensitive to RF lesions than larger myelinated A-alpha fibers of motor units. Technique: start at S1 on one side, and work up to T12, then repeat on other side. At each level: verify needle position by stimulating with 0.1–0.5 V and watch for movement in appropriate myotome (tip should be extradural, avoid subarachnoid placement), ablate with 70–80°C × 2 mins for S1, and 70°C × 2 mins for L5 to T12 (to preserve motor function). If symptoms recur, may repeat with lesions at 90°C × 2 mins

   e) **myelotomies**
      - Bischoff's myelotomy: divides anterior and posterior horns via laterally placed incision, disrupts reflex arc. No effect on α-spasticity
• midline “T” myelotomy: interrupts reflex arc from sensory to motor units without disrupting connections from corticospinal tract to anterior motor neurons. Slightly higher risk of losing motor function.

Technique: laminectomy from T11 to L1. Mobilize midline dorsal longitudinal vein and incise cord in midline from T12 at a depth of 3 mm to S1 at a depth of 4 mm (preserving S2-S4 maintains bladder reflex pathways. Unilateral extension up to conus medullaris reduces bladder spasticity and increases capacity before reflex emptying occurs)

f) selective dorsal rhizotomy\(^{42,43}\): uses intraoperative EMG and electrophysiological stimulation to eliminate sensory rootlets involved in “handicapping spasticity” (leaves rootlets subserving “useful spasticity” intact). Interrupts the afferent limb of pathologic reflex arc. May be temporary, but seems to persist at least \(\approx 5\) yrs. No effect on \(a\)–spasticity. Ambulatory children with cerebral palsy have improved gait, nonambulatory children are improved but are still not able to ambulate afterwards

g) stereotactic thalamotomy or dentatotomy: may be useful in cerebral palsy.\(^{44}\) Useful for unilateral dystonia, but cannot be used for bilateral dystonia as bilateral lesions would be required which jeopardizes speech. Effective only for dystonia distal to shoulders or hips, and should not be used if the condition is rapidly progressive

3. ablative procedures, with sacrifice of potential for ambulation (in complete cord injuries, nonablative procedures are not indicated because there is no motor function to recover). Used after failure of percutaneous rhizotomy (see above) and “T” myelotomy (see above)

a) intrathecal injection of 6 ml of 10% phenol (by weight) in glycerin mixed with 4 ml of iohexol (Omnipaque® 300) (p. 219) for a final concentration of 6% phenol and \(\approx 120\) mg iodine/ml. Administered via LP at L2–3 interspace with patient in lateral decubitus position (most symptomatic side down) under fluoro until T12-S1 nerve root sleeves are filled (sparing S2–4 for bladder function). Patient is maintained in this position \(\times 20–30\) mins and then kept sitting upright \(\times 4\) hrs\(^{45}\) (absolute alcohol provides more permanent blocks, but is hypobaric and more difficult to control)

b) selective anterior rhizotomy: results in flaccid paralysis with denervation atrophy of muscles
c) neurectomies, often combined with tenotomies\(^{38}\)
d) intramuscular neurolysis by phenol injection\(^{38}\)
e) cordectomy\(^{46}\): most drastic measure, reserved for patients who do not respond to any other measure. Results in total flaccidity with loss of benefits from mild spasticity. Converts bladder from UMN to LMN control. Works well for progressive deficit from syringomyelia and for spasticity, but poor for “phantom” leg pain\(^{37}\)
f) cordotomy: rarely used

### Intrathecal baclofen

See references.\(^{48,49,50,51}\)

Selection criteria used in one study\(^{50}\) are shown in Table 98.3. Other indications include: stroke,\(^{52}\) cerebral palsy, TBI, dystonia, stiff-man syndrome.

Test doses: Incremental test doses of 50, 75, and then 100 mcg intrathecal baclofen (ITB) via lumbar puncture or temporary catheter were used,\(^{50}\) randomly alternated with placebo, with dose escalation halted if a response to active drug occurred. The following parameters were evaluated at 0.5, 1, 2, 4, 8 & 24 hrs post injection: pulse and respiratory rate, BP, hypertonia (Ashworth score, Table 98.2), reflexes, spasm score, voluntary muscle movement, and adverse effects (if any, including seizures). Pump implantation was offered if there was a 2 point reduction in the Ashworth score and muscle spasm score for \(\geq 4\) hrs after bolus injection of active drug without intolerable side effects. Usual daily dose for ITB is twice the test dose, typically 200 micrograms/d.

\(^a\)this study used a programmable IT pump
Alternatively, give 25 mcg IT in the O.R., and if the patient improves, insert subcutaneous pump.\textsuperscript{37}

Pump systems: Available programmable systems include N’Vision, manufactured by Medtronic, Inc., Minneapolis, MN.

Insertion technique: IT catheter is typically inserted \( \approx L2-3 \), and is threaded rostrally \( \approx 3 \) levels, but should be no higher than T10 (risk of rostral progression of hypotonia).

Post-op orders: Guidelines for post-operative orders following baclofen pump insertion

1. admit PACU, transfer to:
   a) floor if insertion follows test dosing or if patient has just been transitioned from stable PO dose
   b) ICU if there has been a hiatus in baclofen therapy
2. neuro checks q 2 hrs for 1st 24 hours
3. baclofen:
   a) for patients on oral or IV baclofen: continue baclofen at the previous dose via the same route (oral or IV) until the ITB takes effect (usually 2–4 hrs, full effect is delayed up to 24 hrs). The IV/PO drug is then tapered
   b) if there has been a hiatus in baclofen therapy: baclofen 20 mg PO QID
4. have 2 vials of IV physostigmine available and labeled “FOR EMERGENCY USE ONLY” for possible baclofen overdose

Baclofen overdose:

ABCs (airway/breathing/circulation). Intubate if necessary

1. empty pump reservoir to stop drug flow (record amount withdrawn)
2. administer physostigmine if not contraindicated:
   a) adult: 0.5–1.0 mg IM or IV @ rate \( \leq 1 \) mg/min (may repeat q 10–30 minutes PRN)
   b) ped: 0.02 mg/kg IM or IV @ rate \( \leq 0.5 \) mg/min (may repeat q 5–10 min up to 2 mg max)
3. withdraw 30–40 ml CSF either via LP or through catheter access port
4. notify the pump manufacturer

Complications: Device-related complications are shown in Table 98.4. The frequency of most is \( \approx 1\% \) except catheter-related problems which had a rate of \( \approx 30\% \).\textsuperscript{50}

Complications related to the drug therapy itself include: overdosage problems (rostral progression of hypotonia, respiratory depression, coma, and seizures).

Intrathecal baclofen withdrawal: Interruption of ITB therapy may occur as a result of: empty pump reservoir, pump battery failure, catheter migration/breakage/kinking/disconnection/occlusion, programming error. Steps in assessing the infusion system are shown in Table 98.5.

The severity of withdrawal syndrome depends on dose of drug used (increased with higher dose) and duration of therapy (increased with longer therapy).

Syndromes: with abrupt discontinuation of ITB

\textsuperscript{4}device-related complications requiring a secondary invasive procedure

Table 98.5 Assessing ITB infusion systems

- interrogate the pump (with device programmer)
- refill reservoir with drug if empty (by experienced ITB practitioner)
- obtain AP & lateral x-rays to assess location of catheter tip and to look for breaks, kinks or migration
1. mild withdrawal symptoms: return of spasticity and rigidity, tachycardia, piloerection (goose-bumps) & pruritus
2. more significant withdrawal symptoms: seizures & hallucinations
3. severe withdrawal symptoms (estimated incidence: 3–5%): increased rebound spasticity, rigidity, fever, labile BP, and reduced level of consciousness – resembling but distinct from malignant hyperthermia (p.108) or neuroleptic malignant syndrome. If untreated, the severe syndrome can progress over 24–72 hours to rhabdomyolysis (with elevated creatine kinase (CK) and transaminase), hepatic and renal failure, DIC, and occasionally death

Management of abrupt ITB withdrawal syndrome:
1. ABCs (airway/breathing/circulation). Intubate if necessary
2. primary goal is to reestablish ITB therapy at the same dose as soon as possible
3. assess pump/system as outlined in Table 98.5
4. early use of high-dose oral/enteral baclofen: ≥ 120 mg/d in 6–8 divided doses if the patient’s condition permits (NB: PO baclofen is not reliable as the lone treatment for ITB withdrawal, and safety not established for age <12 yrs)
5. attempt to restore ITB therapy at or near pre-withdrawal dosage by experienced physician by one of the following:
   a) using a programmed bolus through the pump
   b) via the catheter access port
   c) via LP
   d) via new externalized catheter
6. if restoration of ITB therapy is delayed and if symptoms persist
   a) move pt. to ICU if not already there
   b) parenteral benzodiazepine infusion: diazepam or midazolam. Titrate dose to reduce muscle rigidity, hyperthermia, BP lability, seizures
   c) cyproheptadine: a serotonin antagonist. Start with 4 mg po q 6 hrs
   d) diphenhydramine 50 mg PO or IM, may repeat q 6 hrs for pruritis
   e) dantrolene may not be as effective as it is for malignant hyperthermia
   f) rectal baclofen

If it is necessary to electively (or semi-electively) remove a pump system, the optimal scenario is to gradually taper the drug by reprogramming the pump and/or by filling the reservoir with solution of decreased baclofen concentration.

98.6 Torticollis

98.6.1 General information
AKA wry neck. A form of dystonia resulting in a failure to control head position (if shoulders or trunk are also involved, dystonia is a more proper label).

98.6.2 Etiologies
A symptom of diverse causes. Differential diagnosis includes:
1. congenital torticollis (may be the initial presentation of dystonia musculorum deformans)
2. spasmokinetic torticollis, AKA wry neck: a specific subtype of torticollis that is idiopathic by definition. The shortened sternocleidomastoid (SCM) muscle is usually in spasm
3. extrapyramidal lesions (including degenerative): often alleviated by lying down; EMG shows abnormal grouped activity
4. psychogenic (often mentioned, seldom verified)
5. torticollis from atlantoaxial rotatory subluxation (p.968): the elongated SCM may be in spasm (opposite of that in spasmokinetic torticollis)
6. neurovascular compression of the 11th nerve (see below)
7. hemorrhage into sternocleidomastoid muscle (with subsequent contracture)
8. infection of the cervical spine
9. cervical adenitis
10. syringomyelia
11. cerebellar tumors in children
12. bulbar palsies
13. “pseudotorticollis” may develop as an unconscious correction to reduce diplopia that occurs with imbalance of extraocular eye musculature

98.6.3 Non-surgical treatment of torticollis

Should be attempted first, and includes:
1. relaxation training, including biofeedback
2. thorough neuropsychiatric evaluation
3. trans-epidermal neuro-stimulation (TENS) to the neck

98.6.4 Surgical procedures

Reserved for disabling, refractory cases. Includes:
1. dorsal cord stimulation
2. local injection of botulinum toxin: may work for retrocollis, is poor for lateral torticollis (must inject posterior cervicals and both SCM, and may cause temporary pharyngeal muscle dysfunction resulting in dysphagia), and is totally ineffective for anterocollis
3. selective rhizotomy and spinal accessory nerve section

98.6.5 Other treatments for torticollis

Stereotactic electrocoagulation of Forel's H1 field.

98.6.6 Torticollis of 11th nerve origin

1. usually a horizontal type (manifests as horizontal head movement) which may be exacerbated when supine (unlike extrapyramidal torticollis)
2. contraction of SCM is usually accompanied by activity in contralateral agonist muscles
3. may be treated surgically. Procedures include
   a) sectioning of the anastomotic branches between the 11th nerve and the upper cervical posterior root (C1 anastomotic branch is sensory only)
   b) microvascular decompression of the 11th nerve (most cases caused by vertebral artery, but PICA compression is also described). Relief takes several weeks post-op

98.7 Neurovascular compression syndromes

98.7.1 General information

Syndromes due to compression of cranial nerves at the root entry zone (REZ) (or in the case of motor nerves, root exit zone). The REZ (AKA Obersteiner-Redlich zone) is the point where central myelin (from oligodendroglial cells) changes to peripheral myelin (from Schwann cells).

Syndromes include:
1. trigeminal neuralgia, see Trigeminal neuralgia (p.479)
2. hemifacial spasm: see below
3. disabling positional vertigo
4. some forms of torticollis of 11th nerve origin (above)

98.7.2 Hemifacial spasm

General information

Key concepts

- intermittent unilateral painless contractions of facial muscles
- typically caused by compression of VII nerve by AICA
- along with palatal myoclonus: the only movement disorder that persists in sleep
- responds well to microvascular decompression, but risk of hearing loss is $\approx 20\%$
Hemifacial spasm (HFS) is a condition of intermittent, painless, involuntary, spasmoid contractions of muscles innervated by the facial nerve in one side of the face only. May be limited to the upper or lower half of the face only, and excess lacrimation may be present. HFS usually begins with rare contractions of the orbicularis oculi, and slowly progresses to involve the entire half of the face and increases in frequency until the ability to see out of the affected eye is impaired.

HFS may be associated with trigeminal neuralgia, geniculate neuralgia; see Tic convulsif (p.493), or vestibular and/or cochlear nerve dysfunction.

HFS is more common in women, is seen more often on the left, and usually presents after the teenagers. Auditory function testing reveals abnormal acoustic middle ear reflex in almost half of patients, indicating some degree of VIII compromise.

Meige’s syndrome: hemifacial spasm with oral movements.

Note. HFS and palatal myoclonus are the only involuntary movement disorders that persist during sleep.

**Etiologies**

1. vascular compression syndrome (see below): the most common etiology (much more common than with trigeminal neuralgia)
2. idiopathic
3. tumor compressing the nerve
4. can follow some cases of Bell’s palsy
5. conditions that can mimic HFS
   a) blepharospasm (bilateral spasmoid closure of the orbicularis oculi muscles) which is more common in the elderly, and may be associated with organic brain syndrome. Blepharospasm is notorious for disappearing when the patient presents for medical evaluation (an effect of alerting), but may be elicited by asking patient to gently close the eyes and then rapidly open them, following which a blepharospasm may occur. HFS usually involves more than the ocular muscles
   b) facial myokymia: continuous facial spasm which may be a manifestation of an intrinsic brain-stem glioma or of multiple sclerosis. Often associated with other findings

**Vascular compression**

HFS is usually caused by compression of the facial nerve at the root exit zone (REZ) by a vessel, which is most often an artery (most commonly AICA\(^5\) (either pre- or postmeatal\(^5\)), but other vascular possibilities include an elongated PICA, SCA, a tortuous VA, the cochlear artery, a dolichoectatic basilar artery, AICA branches...), aneurysm, a vascular malformation, and rarely, veins have been implicated. In typical HFS (onset in the orbicularis oculi, and progressing downward over the face), the vessel impinges on the antero-caudal aspect of the VII/VIII nerve complex, in atypical HFS (beginning in the buccal muscles and progressing upward over the face) the compression is rostral or posterior to VII.

Vessels contacting the REZ of the vestibular nerve may cause vertigo, whereas tinnitus or hearing loss may result from cochlear nerve REZ compression.

Infrequently, benign tumors or a cyst in the cerebellopontine angle, multiple sclerosis, adhesions, or osseous skull deformities will be the cause of HFS.

Evidence indicates that there is not cross (ephaptic) conduction at the compressed REZ, but that the facial motonucleus is involved secondarily as a result of the REZ compression, via a phenomenon similar to kindling.\(^{61}\) In addition to the spasm, a 2nd electrophysiological phenomenon associated with HFS is synkinesis, where stimulation of one branch of the facial nerve results in delayed discharges through another branch (average latency: 11 mSec\(^62\)).

**Evaluation**

In typical cases of HFS, the diagnostic work-up is negative.

Most patients should have MRI of the posterior fossa (CT scan is less sensitive here) to R/O tumors or AVMs.

Vertebral angiography is usually not performed if imaging is normal. The neurovascular compression responsible for HFS usually cannot be identified on angiography.
Treatment

Medical management

HFS is generally a surgical condition. Early, mild cases may be managed expectantly. Carbamazepine and phenytoin are generally ineffective, unlike the situation with the causally similar condition of trigeminal neuralgia. Local injection of botulinum toxin (Oculinum®) may be effective in treating HFS and/or blepharospasm. Baclofen has been advocated but is not very effective.

Surgical management

General information

Many ablative procedures are effective for HFS (including sectioning of divisions of the facial nerve), however, this leaves the patient with some degree of facial paresis. The current procedure of choice for HFS is microvascular decompression (MVD) wherein the offending vessel is physically moved off of the nerve, and a sponge (e.g. Ivalon®, polyvinyl formyl alcohol foam) is interposed as a cushion. Other cushions may not prove to be as satisfactory (muscle may disappear, and Teflon felt may thin).

Most often, the offending vessel approaches the nerve at a right angle, and causes grooving in the nerve. Compression must occur at the root exit zone; decompression of vessels impinging distal to this area is usually ineffective.

Operative risks: see below.

Post-operatively, there may be episodes of mild HFS, however they usually begin to diminish 2–3 days following MVD. Severe spasm that does not abate suggests failure to achieve adequate decompression, and reoperation should be considered.

Surgical results of MVD depend on the duration of symptoms (shorter duration has better prognosis) as well as on the age of the patient (elderly patients do less well). Complete resolution of HFS occurred in 44 (81%) of 54 patients undergoing MVD, however, 6 of these patients had relapse. 5 patients (9%) had partial improvement, and 5 (9%) had no relief.

Technique of MVD

Intra-operative brainstem auditory evoked potential (BAER), or more applicable, direct V III nerve monitoring may help prevent hearing loss during MVD for 7th or 8th nerve dysfunction. Furthermore, monitoring for the disappearance of the (delayed) synkinetic response may aid in determining when adequate decompression has been achieved (generally reserved for teaching institutions).

For a diagram of the normal anatomy of the CPA, see Fig. 1.9. The facial nerve should not be manipulated, and one should avoid dissection around the VII and VIII nerves near the IAC. Vessels must be preserved, especially the cochlear artery and small perforators.

Place gentle medial traction on the cerebellum (<1 cm is recommended), and incise the arachnoid membrane between the flocculus and the eighth nerve (to avoid tension on nerves that could cause post-op deficit). The IX nerve may be followed medially from the jugular foramen to locate the origin of the VII nerve (the origin of VII is 4 mm cephalad and 2 mm anterior to that of the IX nerve).

Surgical results

Complete resolution of spasm occurs in ≈ 85–93% Spasm is diminished in 9% and unchanged in 6%. Of 29 patients with complete relief, 25 (86%) had immediate post-op resolution, and the remaining 4 patients took from 3 mos to 3 yrs to attain quiescence.

Recurrence

Return of symptoms after a period of complete resolution of HFS occurs in up to 10% of patients, 86% of recurrences happen within 2 yrs of surgery, and the risk of developing recurrence after 2 yrs of post-op relief is only ≈ 1%.

Surgical complications

1. ipsilateral hearing loss: may occur from traction injury or a vasospasm
   a) total hearing loss occurs in ≈ 13% (range: 1.6–15%) (2.8% in one series, 15% in another series)
   b) partial hearing loss: 6%
2. facial weakness
   a) transient: 18%
   b) permanent facial weakness: 6%
3. ataxia in 1–6%
4. other complications that are minor or temporary include:
   a) aseptic meningitis (AKA hemogenic meningitis) in 8.2%
   b) hoarseness or dysphagia in 14%
   c) CSF rhinorrhea in 0.3%
   d) perioral herpes in 3%

98.8 Hyperhidrosis

98.8.1 General information

Either essential (primary, or idiopathic) or secondary (etiologies include: hyperthyroidism, diabetes mellitus, pheochromocytoma, acromegaly, parkinsonism, CNS trauma, syringomyelia, hypothalamic tumors, menopause).75

Due to overactivity of eccrine sweat glands (found over entire body, highest concentration in palms and soles of feet). They produce a hypotonic secretion with saline as the primary constituent. These glands are under control of the sympathetic nervous system, however, the neurotransmitter is paradoxically acetylcholine (i.e. they are cholinergic, unlike most sympathetic end organs which are adrenergic). Most eccrine sweat glands serve a thermoregulatory function, however, those on the palms and soles respond primarily to emotional stress.75

Essential hyperhidrosis is a generalized condition that usually manifests mostly in the palms. The incidence is unknown, although it was ≈ 1% in an Israeli study (probably high).

98.8.2 Treatment

Mild cases are treated medically with:
1. topical agents: astringents (potassium permanganate, tannic acid...) or antiperspirants (contact dermatitis usually limits use of these agents)
2. or systemically with anticholinergics: including atropine, propantheline bromide... (side effects of dry mouth and blurred vision usually limits use of these)
3. tap water iontophoresis: may produce keratinization of palmar epithelium

Severe cases refractory to medical therapy may be candidates for surgical sympathectomy (see below).

98.9 Tremor

Thalamotomy or thalamic stimulation may be useful for tremors that are refractory to medical treatment, including parkinsonian (p. 1526), essential,76,77 cerebellar and post-traumatic.30

98.10 Sympathectomy

98.10.1 Cardiac sympathectomy

With the advances in percutaneous coronary artery techniques, cardiovascular surgery and drugs, cardiac sympathectomy for angina pectoris has found less application. However, it may still be useful in patients who have no further treatment options. Bilateral sympathectomy from the stellate ganglion through the T7 ganglia is required. Newer thoracoscopic techniques may revive some interest in this.

98.10.2 Upper extremity sympathectomy

Various pathologies that may be indications for upper extremity sympathectomy are shown in Table 98.6.

<table>
<thead>
<tr>

</tbody>
</table>
Removal of the only second thoracic ganglion is probably adequate, and avoids a Horner’s syndrome in most. Techniques used include: anterior transthoracic, thoracic endoscopic,78 percutaneous radiofrequency, and supraclavicular. An approach via a midline posterior incision with a T3 costovertebrally allows bilateral access.75,79 The risk of significant complications is < 5% and include pneumothorax, intercostal neuralgia, spinal cord injury, and Horner’s syndrome.

98.10.3 Upper thoracic sympathectomy

Approaches include:
1. posterior paravertebral approach
2. axillary thoracotomy with transthoracic exposure of the sympathetic chain
3. supraclavicular, retropleural exposure
4. percutaneous radiofrequency technique60,81
5. video endoscopic approach82

98.10.4 Lumbar sympathectomy

Primary indication is for causalgia major of the lower extremity. Preoperative lumbar sympathetic blocks may be utilized to evaluate patient for response.

Removal of the L2 and L3 sympathetic ganglion is usually adequate to remove sympathetic tone from the lower extremities (occasionally L1 and sometimes T12 are also removed for causalgia of the thigh).

The most common approach is a retroperitoneal approach through a flank incision. The patient is placed in a lateral oblique position, and the skin incision is made from the anterior superior iliac spine to the tip of the 12th rib. The peritoneum is dissected from the muscular wall and is retracted anteriorly. The kidney and ureter are retracted anteriorly; injury to the ureter being a major risk of the operation. The sympathetic chain is identified on the lateral aspect of the vertebral bodies. The vena cava makes a right-sided approach more difficult as the aorta is easier to deal with on left-sided approaches.

References

99 Pain Procedures

99.1 General information
Medical therapy must be maximized before a patient is a candidate for a pain procedure. Usually this requires escalating the dose of oral narcotic pain medications until the point that the pain is relieved or the side effects (usually somnolence or hallucinations) are intolerable (e.g. up to 300–400 mg/day of MS Contin may sometimes be necessary).

99.2 Choice of pain procedure
Table 99.1 shows some pain procedures that may be used for various indications (the list is not intended to be all inclusive, but is rather to serve as a starting point for organizing pain procedures). In general, nonablative procedures are exhausted before resorting to ablative procedures.

99.3 Types of pain procedures
See pain procedures particular to trigeminal neuralgia (p.482).
Techniques for other conditions include:
1. electrical stimulation
   a) deep brain stimulation (p.1524)¹: targets include thalamus and periaqueductal or periventricular gray matter
   b) spinal cord stimulation (p.1547)
2. direct drug administration into the CNS:
   a) different routes: spinal (p.1545), epidural or intrathecal, intraventricular (p.1547)
   b) different agents: local anesthetics, narcotics (without motor, sensory, or sympathetic impairment seen with local anesthetics) (p.1545)
3. intracranial ablative procedures:
   a) cingulotomy: theoretically reduces the unpleasant affect of pain without eliminating the pain. Must be done bilaterally, recently with MRI. Intolerable pain usually recurs after ≈ 3 mos. 10–30% develop flattened affect
   b) medial thalamotomy: no longer used (presented for historical reasons). Controversial. Was used for some for nociceptive cancer pain. Performed stereotactically
   c) stereotactic mesencephalotomy²: for unilateral head, neck, face and/or UE pain. Use MRI to create lesion 5 mm lateral to sylvian aqueduct at the level of the inferior colliculus. Unlike spinal cordotomy, the lesion is not near any motor tracts. Main complication is diplopia due to interference with vertical eye movement, often transient
4. spinal ablative surgical procedures
   a) cordotomy: see below
      • open
      • percutaneous
   b) cordectomy
   c) commissural myelotomy: for bilateral pain (p.1544)
   d) punctate midline myelotomy: for relief of visceral cancer pain
   e) dorsal root entry zone lesion (p.1550)
   f) dorsal rhizotomy: not useful for large areas of involvement

ᵇ cordotomy (open or percutaneous) if pain is unresponsive to or too high for spinal IT narcotics
99.4 Cordotomy

99.4.1 General information

Interruption of the lateral spinothalamic tract fibers in the spinal cord. Cordotomy is the procedure of choice for unilateral pain below the C5 dermatomal level (≈ nipple; occasionally pain as high as the mandible may be treated), in a terminally ill patient. Better for aching pain, poor for central pain, dysesthesias, causalgia (deafferentation pain) midline visceral pain. May be performed as an open procedure, but is more easily performed percutaneously at the C1–2 interspace (which limits the procedure to the cervical region). If there is any contralateral pain, it will tend to be magnified following the procedure and often leads to dissatisfaction with cordotomy. If there is any bladder dysfunction, it will usually be worse following cordotomy. Bilateral cervical cordotomies carries a risk of the loss of automaticity of breathing (one form of sleep apnea, so-called Ondine’s curse). Therefore, if bilateral cordotomies are desired, the second should be staged after normal respiratory function and CO₂ responsiveness are verified following the first procedure, or the second stage may be done as an open procedure in the thoracic region.

Review the cross sectional spinal cord anatomy for relationships of the critical tracts (spinothalamic and corticospinal) to the dentate ligament, the anterior spinal artery, respiratory (Fig. 1.13), and bladder areas (Fig. 3.1).

99.4.2 Pre-op evaluation

Spirometric measurement of minute volume before and after breathing a mixture of 5% CO₂ and 95% O₂ for 5 minutes. If the MV decreases, these patients are at increased risk of having sleep apnea (usually transient), no increased risk if MV increases or stays the same. Also, patients with <50% of predicted values on PFTs are not candidates.

In patients with pulmonary cancer contralateral to the planned side of cordotomy, check that the contralateral diaphragm is functioning with fluoroscopy, otherwise if the ipsilateral diaphragm is lost due to cordotomy, the patient may be hypopneic.

99.4.3 Percutaneous cordotomy

General information

Indicated for unilateral pain below ≈C4–5 in a terminally ill patient. Radiofrequency current is used to lesion the lateral spinothalamic tract.

Technique

Patient does not need to be NPO. Usual pain medications should be given. The patient must be awake and cooperative (any movement with the needle in the cord may lacerate the cord), however one may give e.g. hydroxyzine (Vistaril®) 50 mg IM on call to procedure for relaxation.

The procedure is performed in the x-ray department with either fluoroscopic or CT guidance. For fluoroscopy, the head is placed in a Rosomoff headholder with the height adjusted to keep the mastoid process in the same horizontal plane as the acromioclavicular joint. Working on the side contralateral to the pain, local anesthetic without epinephrine is infiltrated 1 cm caudal to the mastoid tip. An 18 gauge lumbar puncture needle is inserted perfectly horizontal aiming halfway between...
the posterior margin of the body of C2 and the anterior portion of the C2 spinous process. Stay rostral to the C2 lamina to avoid the nerve (which is painful).

The dura will be penetrated at about the time that the tip of the needle is approximately even with the midline of the odontoid process on AP fluoro. A few ml of CSF are aspirated and shaken in a syringe together with a few ml of Pantopaque®, and several ml of the mixture are injected into the subarachnoid space under lateral fluoro guidance (note: Pantopaque is no longer available, and water soluble agents are less effective). A needle endoscopic technique may be able to localize the spinal cord anterior to the dentate ligaments. Some dye will layer on the anterior cord, some on the dentate ligament, and most in the posterior thecal space. The dye will only stay momentarily on the dentate ligament, thus be ready to immediately advance the needle just barely anterior to this while monitoring the tip impedance which will jump from \( \approx 300–500 \Omega \) (ohms) in the CSF to \( \approx 1200–1500 \Omega \) as the spinal cord is penetrated.

Stimulation at 100 Hz. should produce contralateral tingling at a threshold of \( \leq 1 \) volt. No motor response should be elicited with 100 Hz. in the spinothalamic tract, and if muscle tetany occurs, lesioning must not be performed. If tingling is in the arm, lesioning will usually render from the arm and below analgesic. If tingling is in the lower extremity it will render only that limb analgesic. Stimulation at 2 Hz. should produce ipsilateral twitching of the arm or neck at \( \approx 1–3 \) volts.

Radiofrequency lesioning is performed for 30 seconds while the patient sustains contraction of the ipsilateral hand and the voltage is gradually increased from zero. Any twitching of the hand is indication to back down on the voltage. A second lesion is performed in the same region and is usually less painful. The appropriate body area is then checked for analgesia to pinprick.

If the procedure is performed satisfactorily, an ipsilateral Horner’s syndrome usually occurs.

Complications

For complications, Table 99.2.

Outcome

In experienced hands, 94% will achieve at least significant pain relief at the time of hospital discharge. The level of analgesia falls with time. At 1 year 60% will be pain free, and at 2 years this will be only 40%.

Post-procedure management

CSF leakage will cease spontaneously. Patient is kept supine for 24 hrs to prevent “spinal” (post-LP) headache. Pain medication appropriate to post-operative management is prescribed. If successful, one can rapidly stop the narcotics for the primary pain, withdrawal syndromes occur only rarely.

99.4.4 Open cervical cordotomy (Schwartz technique)

General information

A relatively quick method for open cervical cordotomy. Can theoretically be done under local for patients who cannot tolerate general anesthesia.

Technique

Position: prone; face carefully placed on padded horseshoe headrest, neck slightly flexed to open the interlaminar spaces and to lower the head to prevent accumulation of intracranial air.

Skin incision: midline from occiput to C3. Working only on the side contralateral to the pain, muscles are stripped off the posterior lip of the foramen magnum, and from the lamina of C1 and C2. A Schwartz or Gelpi retractor is engaged between the occiput and C2. To increase exposure, the inferior half of C1 and superior half of C2 lamina are removed with a punch.

Dural incision: the ligamentum flavum is thin between C1–2, and can usually be opened with the dura in a linear incision from the lamina of C1 to C2 placed in the lateral third of the exposure, taking care to avoid bleeding from epidural veins. An angle is cut in the incision at either end to allow increased dural retraction. Tack-up sutures are placed in the dura, the arachnoid is opened, the dentate ligament is located and is gripped with a hemostat and divided between the hemostat and the dura.

Cordotomy: the dentate ligament is used to slightly rotate the spinal cord. A cordotomy knife (or 11 blade) with bone wax placed at 5 mm, is inserted into the cord in an avascular area just anterior to the dentate ligament, sharp side down. The anterolateral quadrant of the cord is cut with the following caveats:

- do not go posterior to the dentate ligament (to avoid corticospinal tract)
- do not cross the midline of the spinal cord
- do not injure the anterior spinal artery
- for patients with lower extremity pain, be sure to start exactly at the dentate ligament (to avoid missing lumbar and sacral fibers).

99.5 Commissural myelotomy

99.5.1 General information

AKA mediolongitudinal myelotomy. Interrupts pain fibers crossing in the anterior commissure on their way to the lateral spinothalamic tract.

99.5.2 Indications

Bilateral or midline pain, primarily below the thoracic levels (including abdomen, pelvis, perineum and lower extremities).

99.5.3 Technique

Laminectomy must extend at least 3 levels above the highest dermatome involved in pain. The dura is opened longitudinally and the operating microscope is then used to identify the midline sulcus (this is usually very difficult to see, and is then estimated as being halfway between where the dorsal roots enter the cord). Veins in the midline are sacrificed for the length of the proposed incision. A number 11 scalpel blade is then placed in a hemostat with 6–7 mm of the tip exposed. The blade is inserted in the midline at the upper end of the desired incision and is then passed caudally for the length of the planned incision (usually 3–4 cm).

99.5.4 Outcome

60% of patients have complete pain relief, 28% have partial, and 8% have none.

99.5.5 Complications

Weakness in the lower extremities occurs in ≈ 8% (usually lower motor neuron, presumably due to injury to anterior horn motor neurons). Dysesthesias occur in almost all patients, but persists >a few days in ≈ 16% (these patients also have impaired joint position sense, all of which are presumably due to posterior column injury). Bladder dysfunction is seen in ≈ 12% Sexual dysfunction may also occur. There is a risk of injury to the anterior spinal artery (rare).
99.6 Punctate midline myelotomy

99.6.1 Indications
Pelvic and visceral pain refractory to other therapies.7

99.6.2 Technique
 Interruption of a midline posterior column pathway.

99.7 CNS narcotic administration

99.7.1 Intraspinal narcotics

General information
Spinal narcotics may be administered epidurally or intrathecally for pain relief. Satisfactory pain control can usually be achieved for pain below the neck, although for pain above the diaphragm/umbilicus some recommend intraventricular morphine (p.1547).8 May also be performed on a “one-time” basis, e.g. injection into epidural space following a lumbar laminectomy. Or, it may be given on a short term continuous basis, via an external epidural or intrathecal catheter. It may also be performed on an intermediate-term basis (<60 days) with the use of a subcutaneous reservoir9 or on a long-term basis with an implantable drug infusion pump10 (e.g. Infusaid® or Medtronic® pump).
Advantages over systemic narcotics include less sedation and/or confusion, less interference with GI motility (constipation), and possibly less N/V. The effectiveness is usually limited to ≈ 1 year and is thus not indicated for chronic benign pain. With time, increased doses are required because of the development of tolerance and/or progression of disease11 with the concomitant development of the usual narcotic side effects.

Agents to use
Must be preservative-free (for either intrathecal or epidural use). This may be prepared by a pharmacist (e.g. add enough preservative free 0.9% saline to 1 or 3 gm morphine sulfate powder to yield a total of 100 ml produces 10 or 30 mg/ml solution respectively, and then filter this through a 0.22 mm filter12). Alternatively, commercially available preparations include Duramorph® (available as 0.5 or 1 mg/ml) and Infumorph® (available in 20 ml ampules of 10 or 25 mg/ml), any of which may be diluted to a lower strength with preservative free diluent (normal saline). Cross tolerance to systemic narcotics does occur, and spinal narcotics are more effective in patients who have not been on continuous high dose IV opiates (patients on high-dose IV narcotics need higher initial intraspinal narcotic doses).

Side effects. Include pruritus (often diffuse, and may be experienced most intensely in the nose), respiratory depression (the respiratory depression with spinal narcotics is usually very gradual, and is often easily detected by monitoring respiratory rate q 1 hr and taking action if the rate decreases), urinary retention, and N/V.

Trial injection
Before implanting a permanent delivery system a test injection should be performed to verify pain relief and tolerance for medication. Administered via percutaneously inserted epidural or intrathecal catheter connected to an external pump. Doses required for intrathecal catheters are usually ≈5–10 times lower than those for epidural catheters.
Sample post-injection orders after a one-time injection:
1. use no other narcotics for ≈24 hrs (with a continuous infusion additional narcotics should be withheld until the effect of the spinal narcotics has been determined)
2. 2 ampules (0.4 mg each) of naloxone (Narcan®) and syringe taped to patients bed (for the first 24 hrs after a single injection; at all times with continuous infusion)
3. head of bed elevated ≥10° for 24 hrs
4. record respiratory rate q 1 hr for 24 hrs; if asleep and respiratory rate <10 breaths/min, awaken patient. If unable to awaken, administer naloxone 0.4 mg IV and notify physician. Repeat naloxone 0.4 mg IV q 2 min PRN
5. optional: pulse oximeter for 24 hrs
6. diphenhydramine (Benadryl®) 25 mg IV q 1 hr PRN itching
7. droperidol (Inapsine®) 0.625 mg (which is 0.25 ml of the 2.5 mg/ml standard concentration available) IV q 30–60 mins PRN nausea
8. PRN supplemental pain medication:
   a) narcotic agonist/antagonist: e.g. nalbuphine (Nubain®) 1–4 mg IV q 3 hrs, OR
   b) ketorolac tromethamine (Toradol®) 15 mg IV or IM or 30 mg IM q 6 hrs (use lower dose for weight <50 kg, age >65 yrs, or reduced renal function)

Implantable drug delivery pumps
Although satisfactory pain control can be achieved with either epidural or intrathecal narcotics (morphine diffuses easily through the dura to the CSF where it gains access to pain receptors), epidural catheters commonly develop problems with scarring and may become less effective sooner than intrathecal catheters. Pumps should only be implanted if patients have successful pain control with test injection of spinal epidural (5–10 mg) or intrathecal (0.5–2 mg) morphine. A life expectancy of >3 months is recommended for implantable pumps (if shorter longevity is anticipated, an external pump may be used).

One such series of commonly used implantable drug delivery pumps is manufactured by Infusaid Inc. The only needle that should be used with their devices are special 22 gauge Huber (non-coring) needles. Delivery rates increase with body temperature 10–13% per °C above 37°C; they decrease by the same amount for every °C below 37°C, and also they become inaccurate at ≤4 ml of reservoir fluid. These pumps should never be allowed to run until empty, as this may permanently affect accuracy and reliability of drug delivery. In addition to the pump reservoir port, most models have one or more side “bolus” ports that delivers injected fluid directly to the outlet tubing. One should not aspirate when accessing either port.

Medtronic produces a programmable pump.

Surgical insertion
Similar to the insertion of a lumbar-peritoneal shunt (p. 1517). The patient is placed in the lateral position, such as on a bean-bag device. The pump is inserted into a subcutaneous pocket, created with a slightly curved 8–10 cm skin incision. The pump may be sutured to the fascia of the abdomen (in obese patients, it may be sutured to the subcutaneous tissue). Excess tubing should be coiled underneath the pump to prevent inadvertent puncture when accessing either reservoir.

The spinal catheter is inserted through a Tuohy needle inserted between lumbar spinous processes either percutaneously or via a small incision 2–3 mm lateral to the spinous processes. Alternatively, it may be inserted directly via a hemilaminectomy. Fluoroscopy may be used intraoperatively to verify rostral placement of the catheter; radiographic visualization of the catheter may be aided by filling it with iodinated contrast, e.g. Omnipaque-300 (p. 219). All bends in the tubing should be very gradual to avoid kinking.

Post-op pain management
Although the pump will be infusing when the patient leaves the operating room, unless they have been on intraspinal narcotics up until the time of surgery, it will usually take several days for the drug to reach equilibrium in the CSF before the level of pain control will be adequate. This can be mitigated by a bolus infusion (3–4 mg morphine for epidural catheters, or 0.2–0.4 mg for intrathecal catheters).

Complications
Meningitis and respiratory failure are rare complications. CSF fistula and spinal H/A may occur. Disconnection or dislodgment of catheter tip may result in failure to control pain, but can usually be surgically corrected.

Outcome
Cancer pain is significantly improved in up to 90% Success rate for neuropathic pain (e.g. postherpetic neuralgia, painful diabetic sensory neuropathy): 25–50%
99.7.2 Intraventricular narcotics

**Indications**
May be used for cancer pain (especially head and neck) unresponsive to other methods in patients with a life expectancy <6 mos.

**Technique**
An intraventricular catheter is connected to a ventricular access device (p. 1518). 0.5–1 mg of intrathecal morphine is injected via the VAD and usually provides ≈ 24 hrs of analgesia.

**Complications**
Side effects. Common ones include dizziness, N/V. The risk of respiratory depression is minimized by using correct dosing. Complications in a series of 52 patients: bacterial colonization of reservoir (4%), dislodged catheter (2%), blocked catheter (6%), postoperative meningitis (2%).

**Outcome**
Pain is successfully controlled in 70% at 2 mos, but thereafter the effectiveness diminishes as a result of tolerance to the narcotics.

99.8 Spinal cord stimulation (SCS)

99.8.1 General information
Originally developed as dorsal column stimulation (DCS), it has since been determined that pain relief also occurs with ventral stimulation (without stimulation induced paresthesias seen with DCS). Pain relief in humans persists beyond the stimulation time, and is not reversed by naloxone. The exact mechanism of action is undetermined, but probably involves some combination of neurohumoral (i.e. endorphin), antidromic stimulation of a spinal pain “gate”, and supraspinal center stimulation. GABA and serotonin levels have been shown to be increased with SCS.

99.8.2 Indications
Possible indications include:
1. pain: postlaminectomy pain syndrome (the most common indication, especially if LE pain > back pain; see below), complex regional pain syndrome (CRPS, formerly “reflex sympathetic dystrophy”) (p. 1548), postthoracotomy pain (intercostal neuralgia), multiple sclerosis, diabetic neuropathy (p. 1549) and sometimes postherpetic neuralgia
2. refractory angina pectoris (p. 1549)
3. painful limb ischemia from inoperable peripheral vascular disease (p. 1549)
4. functional: spastic hemiparesis, dystonia, bladder dysfunction
5. generally not used for cancer pain or for patients with limited life expectant.

99.8.3 Technique
In order for SCS to be effective, it is necessary for the patient to feel the stimulation in the areas of pain. Two techniques are used to place electrodes in the epidural space:
1. plate-like electrodes placed via hemilaminectomy
2. wire-like electrodes placed percutaneously with a Tuohy needle.

Following electrode placement, a trial with an external generator over several days determines if SCS is effective. The electrodes are removed unless clear improvement occurs, in which case an implantable pulse generator is placed subcutaneously.

99.8.4 Complications
With plate electrodes, there is a 3.5% incidence of infection which respond to electrode removal and IV antibiotics. Less common complications: electrode migration (usually seen with first few weeks),
lead breakage (less common with present systems), CSF leak, radicular pain, intermittent interference with cardiac pacemakers, and weakness.

### 99.8.5 Outcome

Success rate in pain control is ≈ 50% improvement in 50% of patients in experienced hands at specialized centers where multidisciplinary approach is available.\(^{15}\) In a retrospective long-term follow-up study (ave = 96 months) of 410 patients that had SCS implantation due to numerous indications, success rate was 74%\(^{16}\)

Prognosticators of a poor response to SCS include: pain resulting from spinal cord injury, from lesions proximal to the ganglion (e.g. root avulsion), failed back syndrome with back pain > LE pain and multiple previous operations (see below), psychological factors such as litigation, workers compensation, familial/marital discord or drug seeking behavior.\(^{17}\)

### 99.8.6 Specific syndromes treated

#### Failed back surgery syndrome

The addition of SCS improves pain control over either PT or medical management alone for failed back surgery syndrome. At 24 months, SCS is as effective as reoperation in treating radicular pain, with no difference in ADLs or work status.

In the PROCESS trial\(^{18}\) (Prospective Randomized Controlled Multicenter Trial of the Effectiveness of Spinal Cord Stimulation), 100 patients with failed back surgery syndrome were randomized to SCS placement plus conventional medical management (52 patients) vs. conventional medical management alone (48 patients). The health-related quality of life, measured using EuroQol-5D questionnaire, was greater in the SCS group despite a higher total health care cost at 6 months.

In long-term follow-up at 24 months, the primary outcome (>50% relief in leg pain) is achieved in 37% of patients that were randomized to SCS plus conventional medical management and 2% of patients that were randomized to conventional medical management only. Patients were allowed to cross-over. After cross-over, the primary outcome is achieved in 47% of patients (34 of 72) who had SCS plus medical management as final treatment versus 7% of patients (1 of 15) in the other group (P=0.02).\(^{19}\)

In another randomized prospective study, patients with persistent or recurrent radicular pain after lumbosacral surgery were randomized to reoperation vs. SCS. On an average of 3-year follow-up, the SCS group required less opiate analgesics. 9 of 19 patients in the SCS group compared to only 3 of 26 patients reoperated had self reported pain relief and satisfaction (P<0.01), and there was no difference in ADLs and work status. Patients in the SCS group were less likely to crossover to undergo reoperation (5 of 24 patients from the SCS group versus 14 of 26 patients in the reoperation group, P=0.02).\(^{20}\) In failed back-surgery syndrome SCSs are better for radicular pain than for low back pain.

#### Complex regional pain syndrome

SCS may be effective for treating CRPS during the first couple of years, however no significant benefit was evident at 5-year follow-up.

CRPS is a chronic pain condition marked by continuous disabling intense aching or burning pain. Type I has no known nerve injury. Type II follows a nerve injury (p. 497). The exact mechanism of the condition leading to intense disproportional pain is unknown and treatment options are limited. In a randomized clinical trial\(^{21}\) patients with CRPS Type I were randomized to receive SCS plus physical therapy (PT) (36 patients) or PT alone (18 patients). 24 of 36 patients had successful SCS trial and
underwent implantation. At 6 months, in the group that received SCS plus PT, pain intensity reduced by 2.4 cm on the visual-analogue scale as opposed to an increase of 0.2 cm in the PT only group (P<0.001). In addition, 39% of patients in the SCS group, had “much improved” globally perceived effect vs. 6% (P=0.01). The health-related quality of life only improved in the SCS group. At 2-year follow-up, pain intensity reduced by 2.1 vs. 0.0 cm in the PT group compared to baseline (P<0.001) and global perceived effect were “much improved” in 43% vs. 6% (P=0.001). However, these benefits were no longer significant in 5 years.23

Peripheral vascular disease

SCS does help with pain due to inoperable limb ischemia. It may or may not improve healing of pressure ulcers.

In a retrospective, non-control study of 38 patients, ≈ 94% experienced pain relief and ≈ 50% experienced healing of ischemic ulcers.24

In a recent review25 of six controlled studies of nearly 450 patients, SCS + medical treatment was compared to medical treatment alone. Although there was no significant difference in ulcer healing, the use of analgesics was less and limb salvage after 12 months was significantly higher in the SCS group (relative risk =0.71).

Angina pectoris

SCS was as effective as CABG in controlling refractory angina and protecting against MIs. SCS improves exercise capacity by an unknown mechanism.

SCS reduces anginal pain and improves exercise capacity by an unknown mechanism, which may be related to decrease in myocardial oxygen consumption26 or altering myocardial blood flow27 rather than just masking symptoms.

In a multicenter, randomized, prospective clinical trial, comparing SCS to CABG in selected patient,28 there was no significant difference in decreasing anginal attack and nitrates consumption between the groups. 5-year follow-up from this trial found that both CABG and SCS offered similar protection from angina pectoris and myocardial infarction.29

In a prospective study of 104 patients who underwent SCS placement for refractory angina pectoris (average follow-up ≈ 13 months), 73% had >50% reduction of weekly anginal episodes compared to baseline.30

Diabetic neuropathy

Available data is limited, but SCS may be a viable modality for refractory pain from diabetic neuropathy. Further study is needed.

No good clinical data are available. A few studies with small numbers of patients suggest SCS can provide significant pain relief in most patients with diabetic neuropathy that failed conservative management.31,32,33

A small prospective, open-label study reported 9 of 11 patients with diabetic neuropathy that failed conservative treatment had significant pain relieved after SCS implantation at 6 months. Pain score on visual analogue scale decreased from 77 to 34. Microcirculatory perfusion did not change significantly from baseline.33
99.9 Deep brain stimulation (DBS)
Deafferentation pain syndromes (anesthesia dolorosa, pain from spinal cord injury, or thalamic pain syndromes) may benefit from stimulation of sensory thalamus (ventral posteromedial (VPM) or ventral posterolateral (VPL)). DBS for chronic neuropathic pain produces a 40–50% reduction in pain in about 25–60% of patients.34

Nociceptive pain syndromes are more likely to benefit from stimulation of periventricular gray matter (PVG) or periaqueductal gray matter (PAG) although PAG stimulation is rarely used because it often produces unpleasant side effects. Still, response rate has been only ≈ 20%35 resulting in failure of the FDA to approve these devices for pain.

Cluster headaches: may respond to hypothalamic stimulation, but larger trials with longer follow-up are needed.34

99.10 Dorsal root entry zone (DREZ) lesions

99.10.1 General information
Although use has been reported for a variety of indications, DREZ lesions appear to be most effective in treating the following:

DREZ lesions appear to be most effective in treating the following:
1. deafferentation pain resulting from nerve root avulsion.36,37,38 This most commonly occurs in motorcycle accidents
2. spinal cord injuries (SCI) with pain around the lowest spared dermatome with caudal extension of pain restricted to a few dermatomes (SCI with diffuse pain involving the entire body and limbs below the injury is less responsive)
3. post herpetic neuralgia (p.493): usually good initial response, but early recurrence in ≤ few months is common, and only 25% have long-term relief of pain
4. postamputation phantom limb pain: there is some support for this in the literature, but others feel this is not a good indication39
5. generally not used for cancer pain

99.10.2 Technique
A laminctomy is performed over the involved segment(s) using radiographic localization. The dura is opened, and the DREZ is identified under microscope magnification using intact posterior rootlets above or below for orientation (contralateral rootlets may also be used to estimate the mirror-image location). Lesions are created ipsilateral to the avulsed nerve roots by radiofrequency current (approximately 50–60 lesions are required for several segments, each lesion is done at 75° for ≈ 15 seconds) or selective incisions extending from the last completely normal rootlet at the rostral end to the first normal rootlet caudally. The lesioning needle or knife blade is angled 30–45° medially and inserted to a depth of 2–3 mm. DREZ lesions may be combined with a cordectomy at the level of anatomic cord disruption in paraplegic patients.39

99.10.3 Post-op management
Bed rest for 3 days may reduce the risk of CSF leakage. Analgesics appropriate for a multilevel laminectomy are administered.

99.10.4 Complications
Ipsilateral weakness (related to corticospinal tract) or loss of proprioception (dorsal columns) occurs in 10% of patients, and is permanent in ≈ half (i.e. 5%).

99.10.5 Outcome
In pain related to brachial plexus avulsion, 80–90% long-term significant improvement can be expected. Paraplegics with pain limited to the region of injury have an 80% rate of improvement, compared to 30% for those with pain involving the entire body below the lesion.
References

100 Seizure Surgery

100.1 General information, indications

20% of patients continue to have seizures despite aggressive medical management with AEDs. Many of these patients may be candidates for surgical procedures to control their seizures.\(^1\)

Seizure disorder must be severe, medically refractory with satisfactory trials of tolerable medication for at least 1 year, and disabling to the patient. Medically refractory is usually considered two attempts of high-dose monotherapy with two distinct AEDs, and one attempt at polytherapy.

The three general categories of patients suitable for seizure surgery have\(^2\):

1. partial seizures
   a) temporal origin: the largest group of surgical candidates (especially mesial temporal lobe epilepsy (MTLE) which is often medically refractory)
   b) extratemporal origin
2. symptomatic generalized seizures: e.g. Lennox-Gastaut
3. unilateral, multifocal epilepsy associated with infantile hemiplegia syndrome

100.2 Pre-surgical evaluation

100.2.1 General information

All patients should undergo high resolution MRI study to rule out neoplasm, AVM, cavernous malformations, mesial temporal sclerosis or hippocampal lesion. Noninvasive techniques allow localization in the majority of cases.

100.2.2 Noninvasive evaluation techniques

Video-EEG monitoring. Pre-operative long-term inpatient video-EEG monitoring (surface electrodes) to correlate the clinically disabling seizure with appropriate electrical abnormalities and possibly to identify the seizure focus is required.

High-resolution MRI. The imaging modality of choice. Extremely good for detecting hippocampal asymmetry of mesial temporal sclerosis (MTS), and neuronal developmental abnormalities (e.g. cortical dysplasia) that may produce complex partial seizures (CPS).\(^3\)

CAT scan. A seizure focus may enhance with IV contrast shortly following a seizure. Subtle enhancement may be present on the side of the focus on interictal CT scan.\(^4\)

PET scan (positron emission tomography). Interictal PET scan using fluorine-18 deoxyglucose (18FDG) shows hypometabolism lateralized to the side of temporal lobe focus in 70% of patients with medically refractory CPS (does not show actual site of origin). Useful when MRI and EEG cannot localize.

SPECT scan (single photon emission tomography). Used to demonstrate increased blood flow during a seizure to help localize site of onset. [99mTc] Technetium (Tc) hexamethyl-propylene-amine-oxide (HMPAO) is usually administered immediately after onset of seizure, and the scan may be obtained within several hours.\(^5\)

MEG (Magnetoencephalography). Functional imaging technique for mapping brain activity by recording magnetic fields created by neuronal activity (electrical current).\(^6\) Synchronized neuronal currents induce a weak magnetic field. Clinical uses include detecting and localizing pathological activity in patients with epilepsy and in localizing eloquent cortex for pre-operative surgical planning. Requires a magnetically shield room.

100.2.3 Mildly invasive techniques

Wada test.\(^7\) AKA intracarotid amytal test. Localizes dominant hemisphere (side of language function) and assesses ability of hemisphere without lesion to maintain memory when isolated. Usually reserved for candidates for large resections.\(^8\) Each cerebral hemisphere is individually anesthetized
via selective carotid catheterization (usually by a neurointerventionalist) and injection of short acting barbiturate.

Start with angiogram to assess cross flow and to R/O persistent trigeminal artery (p. 83). Significant cross-flow is a relative contraindication to anesthetizing the side of dominant supply (patient goes to sleep).

Wada test may be grossly inaccurate with high flow AVM. Also, portions of hippocampus may be supplied by posterior circulation (not anesthetized by ICA injection).

EEG monitoring is usually performed during the test when it is being done for seizure surgery. Patient will show delta waves during deepest level of anesthesia.

Technique
- instruct patient as to what is expected
- catheterize ICA: usually start on side of lesion
- have patient hold contralateral arm in air, and instruct them to hold it there
- inject 100–125 mg sodium amobarbital (Amytal®) rapidly into internal carotid artery (effect starts almost instantaneously, begins to subside after ≈ 8 minutes; (may subside in ≈ 2 minutes with AVM where flow rates are high)
- determine adequacy of injection by assessing motor function in elevated arm (should be ≈ flaccid)
- assess language skills by showing patient pictures of objects and ask them to name each one out loud and remember each one
- assess memory function by asking patient to name as many of the pictures as they can ≈ 15 minutes after test: if they have difficulty, ask them to pick out pictures from a group that contains additional ones not shown to patient
- repeat procedure on other side (use lower Amytal doses with each subsequent injection)

100.2.4 Evaluation techniques requiring surgery

EEG obtained with invasive electrodes. Indications: Lack of lateralizing or localizing electro-physiology in pre-operative evaluation requires invasive electrodes for better definition of seizure focus.

Surgical options:
- Depth electrodes
  o Electrodes are placed stereotactically
  o stereoencephalography (sEEG): popularized in Europe by J. Talairach and J. Bancaud during the 1950s for invasive mapping of refractory focal epilepsy. The techniques requires the placement of multiple depth electrodes in an orthogonal orientation to localize seizure onset, 2-3% risk of intracerebral hemorrhage.8 Risk of infection with depth electrodes8: 2-10%
- Subdural grids or strips
  o Grids are frequently used for extra-operative functional mapping (helpful in children or in the mentally retarded). Subdural grid electrodes are placed with a craniotomy.
  o Surface strip electrodes may be placed through a burr hole
  o useful technique for intra-operative functional mapping

100.3 Surgical techniques

100.3.1 Basic procedures

Three basic types of procedure: resections, disconnections and stimulation.1

1. resections
   a) resection of epileptic focus: higher chance of completely controlling seizures. Performed in noneloquent brain. Seizures must have focal onset (resection not encouraged if multifocal onset). Includes:
      • anterior temporal lobectomy or amygdalo-hippocampectomy for MTLE: see below
      • neocortical resections: especially with neuronal migration abnormalities
   b) resection of lesion in secondary epilepsy (lesional epilepsy e.g. tumor, AVM, cavernous malformation12…). In most cases the seizure focus is in or near the lesion, but some structural lesions are not responsible for the seizures. For seizure foci within the mesial temporal lobe, seizure control is better when lesionectomy is accompanied by amygdalo-hippocampectomy13

2. disconnections: used when eloquent brain is involved, or to separate the electrical activity of the two cerebral hemispheres
   a) section of corpus callosum (callosotomy): when drop attacks are the most disabling seizure type or for multiple bilateral foci (see below)
b) hemispherectomy: for unilateral seizures with widespread hemispheric lesions and profound contralateral neurologic deficit. If any cortex is left, must make sure it is functionally deafferented (disconnected)
  • anatomic hemispherectomy
  • functional hemispherectomy: preservation of the basal ganglia isolates the abnormal side with ≈ 80% seizure control rate (similar to anatomic hemispherectomy, but with lower complication rate).

c) multiple subpial transection\( ^{14} \): for partial seizure originating in eloquent cortical areas. The cortex is transected at 5 mm intervals, thus interrupting the horizontal spread of the seizure while sparing the vertically oriented functional fibers

3. stimulation: usually offered to non-resective candidates (poor localization or surgical failures). It is a reversible and adjustable mode of therapy.

4. Open Loop stimulation: blind stimulation continuously or intermittently
   a) vagus nerve stimulation (p.1558)
   b) deep brain stimulation (DBS)
      • centromedian nucleus of the thalamus\( ^{15} \): better for generalized tonic-clonic seizures
      • bilateral anterior nucleus of the thalamus: for partial seizures\( ^{16} \)
      • hippocampus\( ^{15} \): for partial seizures

5. Closed Loop stimulation: react to a burst of stimulation (detection). Responsive cortical stimulation (RNS)\( ^{17} \) requires a receive and a send electrode for electrical stimulation

Neurostimulation offers between 30-40% seizure reduction for most of the patients implanted. Risks include hardware failure, hemorrhage (not typically seen with VNS), infection and stimulation induced side-effects.

100.3.2 Anesthetic considerations

If intraoperative electrocorticography is to be performed:
  • under local anesthesia: the only anesthetic agents that may be used are narcotics (usually fentanyl) and droperidol
  • under general anesthesia: avoid benzodiazepines and barbiturates

100.3.3 Intraoperative electrocorticography (ECoG)
Subdural strips and/or grids are useful for ECoG and motor/speech mapping.
Methohexital (Brevitol®) may be given to try to provoke a seizure: observe for ↓ fast activity in suspected focus.

100.3.4 Intraoperative cortical mapping
See techniques of cortical mapping (p.1432).

100.4 Surgical procedures
100.4.1 Corpus callosotomy

Indications and contraindications
Partial or total section may be most effective for generalized major motor seizures. Of little benefit for simple or complex seizures. Benefit has been supported for:

1. frequent episodes of atonic seizures (“drop attacks”) where loss of postural tone → falls and injuries\( ^{18} \) (70% reduction with callosotomy), typically seen in Lennox-Gastaut syndrome
2. possibly for generalized seizure disorder with unilateral hemisphere damage (e.g. infantile hemiplegia syndrome); hemispherical resection may be better for this type, whereas callosotomy may promote partial seizures.
   Note: a “functional hemispherectomy” is recommended over “anatomically complete” hemispherectomy to reduce morbidity and mortality\( ^{2} \)
3. some patients with generalized seizures without identifiable, resectable focus
4. Contraindication: major behavioral and/or language deficits may occur even with partial division in patients with speech and dominant handedness located in opposite hemispheres (“crossed dominance”). Thus, Wada test is recommended in all left handed patients
Technical details

Division of the anterior two-thirds of the corpus callosum (CC) (minimizes the risk of disconnection syndrome, see below) may be advantageous over complete callosotomy (controversial). Some advocate sectioning the CC with intraoperative EEG until the typical bisynchronous discharges that are usually seen become asynchronous.19 No need to section anterior commissure. Can usually be performed via a bifrontal craniotomy utilizing a bicoronal skin incision.

May produce post-op ↓ verbalization or akinetic mutism that usually resolves in weeks.

MRI sagittal cuts are ideal for assessing extent of division of the CC.20

Disconnection syndrome

In a patient with a dominant left hemisphere, consists of left tactile anomia, left sided dyspraxia (may resemble hemiparesis), pseudohemianopia, right sided anoma for smell, impaired spatial synthesis of right hand resulting in difficulty copying complex figures, decreased spontaneity of speech, incontinence.

More common with larger surgical sections of the CC. Risk is less if the anterior commissure is spared. Patients usually adapt after 2–3 months, with final function normal for most daily activities (deficits may show up on neuropsychological testing).

100.4.2 Mesial temporal lobe epilepsy (MTLE)

General information

80% of patients with medically intractable temporal seizures have a demonstrable focus in the anterior-mesial temporal lobe. Most patients have neuronal loss and gliosis of mesial temporal structures (mesial temporal sclerosis, MTS). Thus, a standard resection of temporal tip (with amygdalo-hippocampectomy) may be performed. In a randomized trial, anterior temporal lobectomy (ATL) was shown to be superior to medical management for treatment of medically resistant epilepsy. Results at one year show seizure reduction and improved quality of life in those patients who underwent ATL versus medical management alone for intractable epilepsy.21

Limits of resection (without significant neurologic deficit)

Note that these values are generally considered safe, however, variations occur from patient to patient and only intraoperative mapping can reliably determine the location of language centers.22 Most centers spare the superior temporal gyrus.23 The following measurements are made along the middle temporal gyrus:

- dominant temporal lobe: up to 4–5 cm may be removed. Over-resection may injure speech centers, which cannot be reliably localized visually
- non-dominant temporal lobe: 6–7 cm may be resected. Slight over-resection may → partial contralateral upper quadrant homonymous hemianopsia; resection of 8–9 cm → complete quadrantanopsia

Alternatively, intraoperative electrocorticography may be used to guide resection of electrically abnormal areas.

Resection should be performed in subpial plane to prevent injury to vascular branches.

100.4.3 Selective amygdalo-hippocampectomy (SAH)

Surgery for temporal lobe epilepsy was initially treated with anterior temporal lobectomy as described by Penfield and Baldwin. In 1958, Niemeyer described a more selective approach to the hippocampus and amygdala through the middle temporal gyrus.24 It would be almost thirty years until selective amygdalo-hippocampectomy was later modified. The goal of SAH is to remove the epileptogenic focus while minimizing disruption of nearby neurovascular structures and white matter tracts. Image guidance is very helpful for these techniques. More recent studies have compared standard ATL to SAH and found that both techniques have similar outcome with regard to seizure freedom but suggest an improved neuropsychological outcome with SAH versus ATL.25,26

Three basic approaches:

1. transcortical: inferior temporal gyrus (ITG) approach. This technique uses a minimal access approach via a trephine craniotomy for SAH27
2. transsylvian: approach requires a pterional craniotomy. More restrictive and greater risk of injury to M1 portion of MCA within sylvian fissure28
3. subtemporal: uses a temporal fossa approach to access mesial structures29,30
100.5 Risks of seizure surgery
Major risks are related to:
1. removal of essential areas of cortex
2. injury to medullary core underlying cortical resection (projection fibers, association fibers, and/or commissural fibers): the most common deficit after temporal lobectomy is a contralateral (homonymous) superior quadrantanopsia (so-called “pie-in-the-sky” defect, due to an injury to Meyer’s loop wherein the fibers for the superior visual field of the optic radiation take a slight rostral “detour” towards the temporal tip)
3. injury to vessels in area of resection --> ischemic damage to areas supplied: especially sylvian branches during temporal lobectomy, anterior choroidal artery resulting in hemiparesis during mesial temporal lobe resection, or ACA branches with corpus callosotomy
4. injury to nearby cranial nerves: especially third nerve during hippocampectomy where it lies medial to tentorium

100.6 MRI guided laser interstitial thermal therapy (MRGLITT)
Laser-induced thermal therapy uses thermal energy to induce cell death by damaging DNA and causing protein denaturation. The current therapy is performed with simultaneous MRI stereotactic guidance and real time feedback from the ablated lesion. It is considered less invasive than microsurgery. Main advantage is a shorter post-operative recovery period. Technique has been used for lesional and nonlesional epilepsy. Preliminary seizure control ≈60-70% No long-term data is yet available.

100.7 Postoperative management for seizure surgery (epilepsy surgery)
1. ICU for observation (24 hrs)
2. for seizures in the immediate post-op period (“honeymoon seizures”), not necessary to treat only one brief generalized seizure, otherwise load appropriately with IV Keppra or phenytoin
3. 10 mg dexamethasone (Decadron®) IV before surgery followed by q 8 hrs as necessary (longer taper for laser ablation and radiosurgery)
4. anticonvulsants are continued × 1–2 years even if no post-op seizures occur
5. after discharge: neuropsychiatric evaluation 6-12 months after surgery

100.8 Outcome
Modified Engel classification outcome is shown in Table 100.1.

100.8.1 Outcome with resection of seizure focus
The greatest effect of seizure surgery is reduction of seizure frequency, however, any surgical procedure may fail to have a beneficial effect.
Seizure control is usually assessed at 1, 3 & 6 most post-op, and then annually. A post-op MRI is usually obtained at 3 most post-op to assess extent of surgical resection. Most patients take anti-epileptic drugs (AEDs) for 2 years post-op, and then may be discontinued in those free of seizures. Recurrent seizures: although late seizures may occur, 90% of seizures that recur do so within 2 years.

100.8.2 Radiosurgery for epilepsy

Stereotactic radiosurgery has been suggested to be an effective treatment for pharmacoresistant epilepsy with the potential for less morbidity than resection.\textsuperscript{35,36} Seizure free outcomes ≈ 65% for MTLE (delayed response to therapy ≈6-12 months). Potential for long-term complications remains a concern (radionecrosis).\textsuperscript{37}

100.8.3 Vagus nerve stimulation (VNS)

Electrodes wrapped around the vagus nerve in the neck are connected to an implanted programmable generator to stimulate the nerve to reduce seizure frequency. As is also true with many AEDs, the mechanism of action is not well understood.

Indications: Although it has been used (off label) for treatment resistant depression and other psychiatric conditions, the FDA approved indication is for adjunctive therapy for patients >12 years old with partial onset seizures refractory to medical treatment.

Complications: Main risk of surgery is transient or permanent vocal cord paralysis.

Outcome: In a 12 year retrospective review of VNS in 12 patients,\textsuperscript{38} mean seizure frequency decreased by 26% at 1 year, by 30% at 5 years, and by 52% after 12 years.

101 Radiation Therapy (XRT)

101.1 Introduction
Ionizing radiation comprises a portion of the electromagnetic spectrum and includes x-rays and gamma rays (both of which are electromagnetic radiation and transmit their energy via photons) and particulate radiation. The goal of XRT in treating tumors is to cause cell death or to stop cell replication. Photons impart critical energy to achieve this result by the photoelectric effect (at lower energies, <0.05 MeV), by Compton scattering (at higher energies of 0.1–10 MeV, e.g. in linear accelerators and Gamma knives), or by pair-production (at the highest energies).\(^1\) In the Compton effect, the initial collision of the photon with an atom creates a free electron which then ionizes other atoms and breaks chemical bonds. The absorption of radiation by indirect ionization in the presence of water produces free radicals (containing an unpaired electron) which causes cellular injury (usually by damaging DNA) within the tumor. See discussion of radiation dosage and units (p. 223).

101.2 Conventional external beam radiation

101.2.1 Fractionation
The practice in which the total radiation dose is delivered in a series of smaller brief applications. This is one means of increasing the therapeutic ratio (the ratio of the effectiveness of XRT on tumor cells to that of normal cells). Radiation injury is a function of the dose, the exposure time, and the area exposed. Radiation oncologists refer to the four “R’s” of radiobiology:\(^2\):
1. Repair of sublethal damage
2. Reoxygenation of tumor cells that were hypoxic before XRT: oxygenated cells are more sensitive than hypoxic cells because oxygen combines with unpaired electrons to form peroxides which are more stable and lethal than free radicals
3. Repopulation of tumor cells following treatment
4. Redistribution (or reassortment) of cells within the cell cycle: cells in the mitotic phase are the most sensitive

101.2.2 Dosing
The biologically effective dose of fractionated radiation is often modeled by the linear-quadratic equation (LQ-model) shown in Eq (101.1), where \(n\) = the number of doses, \(d\) = dose per fraction, and the factors \(\alpha\) & \(\beta\) are used to describe the cell response to radiation. A high \(\alpha/\beta\) ratio \(\geq 10\) is designated as early-responding tissue such as tumor cells, and a ratio \(\leq 3\) is considered late-responding tissue (mitotically quiescent), such as normal brain and also AVMs.

\[
\text{biologically effective dose (BED)} = \frac{\alpha}{\alpha+\beta} n \times \frac{d \times (\frac{d}{\alpha} + 1)}{\alpha}
\]

101.2.3 Cranial radiation

General information
Following surgery for tumor (craniotomy or spinal surgery), most surgeons wait \(\approx 7\–10\) days before instituting XRT to the surgical site (allows initiation of healing from surgery).

Two CNS tumors that “melt away” with XRT but tend to recur later:
1. lymphoma
2. germ cell tumors

Radiation injury and necrosis

General information
Radiation necrosis (RN) may mimic recurrent (or denovo) tumor both clinically and radiographically. Differences in prognosis and treatment make it important to distinguish between tumor and RN.
Pathophysiology
As radiation is selectively toxic to more rapidly dividing cells, the two normal cell types within the CNS most vulnerable to RN are vascular endothelium (which have a turnover time of $\approx 6$–$10$ mos) and oligodendroglial cells. Vascular injury may be the primary limiting factor to the tolerance of cranial XRT. Injury from XRT occurs at lower doses when given concomitantly with chemotherapy (especially methotrexate).

Etiology of side effects
The mechanism(s) by which XRT causes side effects is not known with certainty, but may be due to:
1. damage to vascular endothelium: effects on cerebral vasculature may differ substantially from effects on systemic vessels
2. glial injury
3. immune system effect

Radiation effects are divided into 3 phases:
1. acute: occur during treatment. Rare. Usually an exacerbation of symptoms already present. Probably secondary to edema. Treat with ↑ steroids
2. early delayed: few weeks to 2–3 mos following completion of XRT. In spinal cord →Hermite’s sign. In brain →post-irradiation lethargy & memory difficulties
3. late delayed: 3 mos-12 yrs (most within 3 years). Due to small artery injury →thrombotic occlusion →white matter atrophy or frank coagulative necrosis

Manifestations of radiation effects:
1. decreased cognition
   a) dementia may develop following XRT in as little as 1 year post-XRT. Incidence was higher when doses of 25–39 Gy were given in fractions $>300$ cGy
   b) children: may attain lower IQ by $\approx 25$ points, especially with $>40$ Gy whole brain XRT. Measurable IQ differences occur in children radiated before age 7, but more subtle deficits occur even in older children
2. radiation necrosis
3. injury to anterior optic pathways
4. injury to hypothalamic-pituitary axis →hypopituitarism →growth retardation in children; see radiation injury to pituitary (p.744)
5. primary hypothyroidism (especially in children)
6. may induce formation of new tumor: tumors most commonly identified as having increased incidence following radiation treatment are gliomas (including glioblastoma), meningiomas, and nerve sheath tumors. Skull base tumors have been reported following EBRT
7. malignant transformation: e.g. after SRS for vestibular schwannomas (p.686)
8. leukoencephalopathy: profound demyelinating/necrotizing reaction 4–12 mos after combined XRT and methotrexate, especially in children with acute lymphoblastic leukemia (ALL) and adults with primary CNS tumors

Evaluation (differentiating RN from recurrent tumor)

Greenberg IMHO
Over the years many methods have been championed to differentiate radiation necrosis from recurrent high-grade glioma. Some are listed below. None have proven adequately reliable, and this may not even be a useful exercise. Tumor cells are frequently found on biopsy. The decision whether to reoperate is usually based on whether there is progressive mass effect (regardless of whether it is necrosis or tumor) taking into consideration the patient’s neurologic condition, projected longevity, patient desires...

CT and MRI
Cannot reliably differentiate some cases of RN from tumor (especially astrocytoma; RN occasionally resembles glioblastoma).
MR spectroscopy (p.233) was reliable in distinguishing pure tumor (elevated choline) from pure RN (low choline), but was less definitive with mixed tumor/necrosis.
DWI: mean ADCs were lower with recurrence (1.18 ± 0.13 X 10⁻³ mm/s) vs. necrosis (1.4 ± 0.17 X 10⁻³ mm/s)¹³ (not all cases biopsy proven).

Nuclear brain scan
Some reports of success with thallium-201 and technetium-99m brain scans.

Computerized radionuclide studies
PET (positron emission tomography) scan: because positron emitting isotopes have short half-lives, PET scanning requires a nearby cyclotron to generate the radiopharmaceuticals at great expense. Utilizing [18F]-fluorodeoxyglucose (FDG), regional glucose metabolism is imaged and is generally increased with recurrent tumor, and is decreased with RN. Specificity for distinguishing RN from tumor recurrence is >90% but sensitivity may be too low to make it reliable.¹⁴ Amino acid tracers such as [11C]methionine and [18F]tyrosine are taken up by most brain tumors, especially gliomas, and may also be used to help differentiate tumor from necrosis. Accuracy may be increased by fusing PET scan with MRL.¹⁶

SPECT (single positron emission computed tomography): “poor man’s PET scan.” Uses radio-labeled amphetamines. Uptake depends on presence of intact neurons and the condition of cerebral blood vessels (including blood brain barrier). Decreased radionuclide uptake indicates necrosis, whereas tumor recurrence has no decreased uptake.

Treatment
Symptoms from any form of radiation toxicity often respond initially to steroids.

Reoperation and excision is appropriate if there is deterioration from mass effect, regardless of whether the mass effect is from recurrent tumor or RN; the decision to reoperate should be based on the patient’s Karnofsky rating (p.1358). Although some benefit has been shown, most reoperation studies are biased because they often select the patients who are doing better.

Other forms of therapy include: hyperbaric oxygen and anticoagulation.

Patients with documented tumor recurrence (as opposed to RN) may also be considered for additional radiation (external beam, interstitial brachytherapy, or stereotactic radiosurgery (SRS)) or chemotherapy.

Prevention
Injury is dependent on total radiation dose, number of treatments or fractions (less damage occurs with more frequent small treatments), and volume treated.

Various studies to determine the tolerance of normal brain to XRT have estimated that 65–75 Gy given over 6.5–8 wks in 5 fractions/week is usually tolerated (radiation necrosis will occur in ≈ 5% after 60 Gy fractionated in 30 treatments over 6 weeks). Other studies have shown tolerance to 45 Gy for 10 fractions, 60 Gy for 35 fractions, and 70 Gy for 60 fractions.⁴

101.2.4 Spinal radiation
General information
Most spine tumors are metastatic cancer. There is no proof that any treatment for spinal metastases will prolong survival. Treatment goals, regardless of the treatment modality, are pain relief and preservation of function.

Radiation therapy (XRT) is the main treatment modality for spinal metastases. Even tumors that are not considered “radio-sensitive” can respond to XRT.

Typical spinal radiation
For most metastatic spine tumors treated with conventional radiation therapy (i.e. not stereotactic radiosurgery), the usual fractionation is 30 Gy administered over 10 fractions.

Emergency spinal radiation
For acute spinal cord paralysis from tumor, if emergency surgery is not a consideration, 8 Gy can be administered in the 1st fraction for lymphoma, multiple myeloma, and (although this is not standard) it could be considered for small-cell (neuroendocrine) carcinoma since it is so radiosensitive.
**Side effects**

1. radiation myelopathy: see below
2. those due to overlap with GI tract: N/V, diarrhea
3. bone marrow suppression
4. growth retardation in children\(^{17}\)
5. risk of developing cavernous malformations of the spinal cord (p. 1247)

**Radiation myelopathy**

Radiation myelopathy (RM) typically occurs in patients with spinal cord included in radiation therapy (XRT) ports used to treat cancer outside the spinal cord, includes breast, lung, thyroid, and epidural mets. Radiation neuropathy may occur with irradiation in the region of the axilla for carcinoma of the breast (p. 544). In the lower extremities, XRT for pelvic or bone tumors (e.g. of the femur) may produce lumbar plexopathy. In addition to permanent changes, radiation therapy may also produce spinal cord edema which may resolve after completion of radiation therapy.

**Epidemiology**

Incidence difficult to estimate due to the fact that the onset is typically delayed together with the poor survival of patients with malignant disease requiring XRT.

Most cases reported involve the cervical cord in spite of the higher frequency with which the thoracic cord is exposed to XRT (perhaps due to higher XRT doses to the head and neck and longer survival than with lung Ca).\(^{18}\) Delay between completion of XRT and onset of symptoms is usually \(\approx 1\) yr (reported range: 1 mos-5 yrs).

Important factors relating to the occurrence of RM include\(^{18}\):

1. rate of application (probably the most important factor)
2. total radiation dose
3. extent of cord shielding
4. individual susceptibility and variability
5. amount of tissue radiated
6. vascular supply to the region radiated
7. source of radiation

**Pathophysiology**

Effects of XRT on the spinal cord that lead to RM are:

1. direct injury to cells (including neurons)
2. vascular changes, including endothelial cell proliferation \(\rightarrow\) thrombosis
3. hyalinization of collagen fibers

**Clinical**

Clinical types of radiation myelopathy

Four clinical types have been described and are shown in Table 101.1.

Onset is usually insidious, but abruptness has also been described; the presentation often mimics epidural mets. First symptoms: usually paresthesias and hypesthesia of LEs, and Hermitte’s sign. Then spastic weakness of LEs with hyperreflexia develops. A Brown-Séquard syndrome is not uncommon.

<table>

</tr>
</tbody>
</table>
Approximately 50% of patients developing RM also have dysphagia from esophageal strictures requiring dilatations (the dysphagia often predates the myelopathy).

Evaluation
Essentially a diagnosis of exclusion. Radiographic imaging (CT, myelography) will be normal. MRI may show spinal cord infarction. The history of previous radiation is key. The differential diagnosis is included in Acute paraplegia or quadriplegia (p.1413).

Prognosis
Prognosis for Type 4 RM is poor. Usually progresses to complete (or near complete) cord lesion. Paraplegia and/or sphincter involvement are poor signs.

Prevention
Maximum recommended cord radiation dose depends on size of port, and varies with investigator. With large field techniques (>10 cm of cord), the risk of RM is negligible with ≤3.3 Gy in 42 days (0.55 Gy/wk), and with small field techniques ≤4.3 Gy in 42 days (0.717 Gy/wk). Larger doses may possibly be given safely if fractionated over longer periods. Recommended upper limit: 0.2 Gy/fraction.

101.3 Stereotactic radiosurgery and radiotherapy
101.3.1 General information

Key concepts
- Stereotactic radiosurgery (SRS): the application of a single large dose of radiation to a stereotactically localized target usually ≤3 cm diameter with minimal radiation delivered to surrounding tissue. May be a single treatment or up to 5 treatment fractions
- Stereotactic radiotherapy (SRT) employs hypofractionated dosing (2-5 treatment fractions) and the target can be larger
- Both SRS and SRT may be performed with properly equipped linear accelerators (LINAC Scalpel, CyberKnife®...), collimated beams from multiple radioactive sources (Gamma Knife®), or less commonly, protons and heavy charged particle beams.

Stereotactic radiosurgery (SRS)
Lars Leksell coined the term “radiosurgery” in 1951. His concept was to replace the use of electrodes or “knives” (scalpels) with multiple intersecting beams of radiation to converge on an intracranial target through an intact skull. The dose of radiation at the point of intersection (the “isocenter”) is higher than outside of the isocenter where the dose falls off sharply such that adjacent tissues receive only minimal radiation from each individual incident beam. When combined with a reliable method for aiming the beams at an intracranial target (e.g., using a stereotactic frame system and three-dimensional imaging) the technique came to be known as stereotactic radiosurgery.

Initially developed to create a necrotic lesion in specific nuclei or pathways for functional disorders, it has subsequently been proven that subnecrotic doses could trigger cellular reactions in tumors and vasculature that would lead to tumor shrinkage or control and obliteration of vascular malformations.

With conventional radiation treatments, the “R’s” of radiobiology (p.1560) are exploited. In contrast, with SRS, precision and accuracy are used to affect the target (e.g. damage tumor or thrombose AVM) and spare normal tissue.

Stereotactic radiotherapy (SRT)
Methods of immobilization and point-of-delivery imaging technologies have since made it practical to deliver stereotactic radiation spread out over several individual treatment sessions (known as fractions) when desirable. Many authors refer to this as stereotactic radiation therapy (SRT). The precise definition of SRT has evolved over time, with some publications describing it as using a
conventional fractionation scheme (1.8-2 Gy / fraction). However the majority of authors refer to SRT in terms of a hypofractionated approach, generally limited to five treatment fractions (see below).

Fractionation capitalizes on the differential response of normal tissue from tumors to radiation insult; see the Four “R’s” of radiobiology (p.1560). The value of fractionation is more apparent for tissues with high rates of proliferation and less capability to repair sublethal DNA damage (high α/β ratio in Eq (101.1)). However these models apply more directly in conventional fractionation schemes; their use in single- or hypofractionated schemes is a subject of current research.

Treatment over multiple fractions renders impractical the traditional stereotactic frame. SRT therefore employs various techniques for patient immobilization including thermoplastic masks, dental-implantation-based bite-blocks, and other relocatable frame systems. Displacement errors can be as high as 2-8 mm with mask systems, however these uncertainties can be reduced with in-room imaging systems such as cone-beam CT (CBCT) which can assist in patient localization, as well as intra-fraction motion monitoring techniques such as orthogonal kilovoltage x-rays, surface tracking systems, and infrared marker tracking systems.

Blurred lines between SRS and SRT

Although some purists insist that SRS is performed in a single session, the current definition was expanded by AANS/CNS/ASTRO in 2007 to include radiosurgical procedures “using a rigidly attached stereotactic guiding device, other immobilization device and/or a stereotactic image-guidance system … performed in a limited number of sessions, up to a maximum of five.”

To further muddy the waters, for billing purposes in the U.S., the cpt codes used by Medicare for SRS (for brain and spine) describe treatment in one session, whereas SBRT (stereotactic body radiation therapy) allows treatment delivery not to exceed 5 fractions within the body. For 5 or more fractions, Medicare considers it to be intensity modulated radiation therapy (IMRT).

Comparison of SRS technologies

Various methods for delivering SRS/SRT are clinically available. Three main categories (based on sources of radiation) are Gamma Knife, linear accelerator based, and heavy charged particle radiosurgery. Fundamentally, there is no difference between a photon created by radioactive decay (gamma ray) from a photon created using electrical energy in a linear accelerator (x-ray).

Gamma knife radiosurgery. In the original Gamma Knife (GK), the source of radiation is gamma decay of 201 cobalt-60 sources that align with an inner collimator to direct the resulting photon beams. A treatment couch includes a mount for an external collimation “helmet”, each of which has either a 4-, 8-, 14-, or 18-mm diameter beam aperture for each source. The stereotactic frame affixed to the patient’s head is positioned within the collimator helmet so the area to be treated is at the focus point of treatment unit. Several dwell positions (also called “shots” or “isocenters”) may be defined to match dose distributions to irregularly shaped targets.

In the newer GK model Perfexion®, 192 cobalt-60 sources are distributed on 8 sectors attached to sector drive motors to move the sources along a fully internalized tungsten collimator. This allows each sector to move from “home”, 4-, 8-, 16-mm collimators or shielded positions. The design makes possible composite use of different beam diameters to help optimize dose distribution. The Gamma Knife is specifically designed for cranial and upper cervical lesions, and is best suited for smaller lesions (<3 cm diameter).

As the gamma sources age, output declines, and treatment times necessarily become longer. Eventually, the sources must be replaced, which is a time consuming and expensive process.

Linear accelerator-based radiosurgery. Linear accelerators (linacs) generate x-rays by accelerating electrons and directing them to strike a target of a substance with high atomic number. The x-ray source and beam collimation is mounted on a rotating gantry, creating a fixed isocenter in space. Beam convergence is achieved via rotating arcs with the isocenter fixed on the target. The target is aligned to the isocenter using a treatment table that is adjustable in up to 6 degrees of freedom (6 dof, 3 translations, 3 rotations). Beams are collimated using either narrow-aperture cones (SRS cones) or multileaf collimators (MLCs), the latter of which use banks of computerized leaves to shape the treatment field and may be modulated to achieve specific dose distributions. Linacs are more versatile than GK in that they can treat cranial and extracranial targets, often have built-in CBCT imaging to assist with patient setup and target localization, and can have a higher dose rate (and thus potentially faster treatment). However they are generally technically more complicated than GK and require substantially more quality assurance to maintain technical confidence. The
Cyberknife is an SRS-specific linac that uses a robotic arm rather than an isocentrically-mounted linac to achieve 6 dof targeting.

Heavy charged particle radiosurgery. Heavy charged particles (protons or helium ions) from a cyclotron can be used for radiosurgery. Unlike high-energy photons (gamma and x-rays), which deposit the majority of their energy upon entrance into tissue and continue to deposit decreasing amount of energy as they travel through the body, heavy charged particle beams have a shorter, bounded range of penetration wherein particles sharply increase energy deposition near the terminal depth of penetration (Bragg peak effect). Particle radiosurgery achieves a well-localized volume of high dose radiation by taking advantage of cross firing of a number of beams as well as the Bragg peak. Due to the expense and increased complexity of heavy charged particle SRS, this therapy is only available in a few centers in the world.

101.3.2 Indications

In general, SRS is useful for well-circumscribed lesions less than approximately 3 cm diameter. For larger lesions, the radiation dose must be reduced because of anatomic and radiobiological constraints.

Published uses of SRS include:

- **Vascular lesions**
  - AVMs (including dural arteriovenous fistulas)
  - Cavernous malformations
- **Tumors**
  - Metastases
  - Vestibular schwannomas
  - Meningiomas
  - Pituitary adenomas
  - Gliomas
  - Others: craniopharyngioma, pineal tumors, etc.
- **Functional disorders**
  - Trigeminal neuralgia
  - Intractable chronic pain: thalamotomy
  - Movement disorders: pallidotomy for Parkinson’s disease or thalamotomy for tremor (Usually not a technique of choice because of inability to perform physiologic stimulation prior to lesioning. May be a consideration for the rare patients who cannot undergo placement of a stimulator/lesioning needle)
  - Psychiatric diseases (e.g. obsessive compulsive disorder)
  - Epilepsies

101.3.3 Contraindications

Compressive tumors of the spinal cord, brainstem or optic structures: even with the sharp falloff of radiation dose, there remains radiation delivered within a few millimeters of the margins of the isocenter. This, together with post-radiation swelling, might create significant risk of neurologic injury. Surgical removal should be considered in these situations especially for benign lesions in young individuals.

101.3.4 Treatment procedure

The treatment procedure includes placement of stereotactic frame (in framed-based SRS), obtaining stereotactic images, target definition, treatment planning and execution of treatment.

Target localization

MRI is the predominant imaging modality for SRS procedures given its superior soft tissue and tumor contrast. Typical MRI protocols include T1-weighted pre- and post-contrast images using 3D pulse sequences. If visualization of structures in surrounding CSF (trigeminal nerves, CPA tumors) is required, special sequences such as constructive interference in steady state (CISS) is useful. Fat-saturation sequences are used in cases with previously resected skull base tumors. NB: there is a 1-2 mm shift due to spatial distortion artifact from the MRI magnet. This effect is more prominent in high field strength MRI.
CT accuracy is never better than 0.6 mm, which is the pixel size. Usually is used when MRI is contraindicated or in cases where distortion in MRI may be a concern (dental brace, shunt). CT does not suffer susceptibility distortion as MRI and one can use a stereotactic CT to merge with nonstereotactic MRI for treatment planning.

Stereotactic angiography remains the best method to define the AVM nidus and their arterial supply and venous drainage. Given that angiograms provide only two sets of orthogonal images (usually AP and lateral images), CTA and/or MRI/MRA can be used as an adjunct to provide vascular anatomy on axial plane.

**Treatment planning**

Treatment planning is the process by which a dose distribution is created with the goal of adequately treating the target areas while largely sparing normal surrounding structures. In GK treatment, a dose distribution is created by defining one or more isocenters (shots). Each isocenter can make use of full complement beams of various diameters, however, in certain cases one or more of beams can be blocked to shape the dose distribution for irregular targets and protect adjacent critical structures. For linac-based SRS, treatment planning is accomplished using computer simulation programs to help select the number of arcs or beams with certain orientation. Also, static and dynamic collimators have been developed. Intensity modulation is also a means of delivering the desired dose to a target while decreasing the dose given to surrounding structures.

Lesions that are not round or ellipsoid in shape are not a problem when using linac, but with older GKs, multiple isocenters must be used to conform to an irregular surface. This results in multiple “hotspots.” This problem is eliminated with the GK Perfexion, which can create a single isocenter using different beam diameters. In the case of multiple metastases, it can generate individually shaped isocenters for each tumor and thus avoid having to change the helmet or add isocenters during a treatment.

Normal tissue tolerance. Cranial nerves: Damage to small nutrient vessels and Schwann cells or oligodendroglia are the possible mechanisms of radiation injury to cranial nerves. Special sensory nerves (optic, vestibulocochlear) are the most radiosensitive. The precise dose tolerance of cranial nerve is unclear; the optic nerve can probably tolerate doses lower than 8-10 Gy. Nerves in the parasellar region, the facial nerve and lower cranial nerves tend to tolerate higher doses.

SRS treatment may also have a deleterious effect in structures sensitive to swelling, such as brainstem. However, the structures at highest risk are those within the higher isodose lines immediately adjacent to the lesion.

Table 101.2 shows maximum recommended doses of various organs for a single fraction. In the brain, critical radiation sensitive structures include: optic vitreous, nerve, and chiasm, brain stem, pituitary gland, and cochlea.

Dose. Dose is usually prescribed as a particular dose (in units of Gray) to the periphery of target. The periphery of the target is usually defined as the isodose curve, which covers the substantial (usually 95-100%) of the target. The isodose curve is the curve of equal dose usually defined as a percentage of the maximum dose point. Traditionally, treatment planning for GK uses the 50% isodose line because for a single isocenter this is the location of steepest dose gradient. Linac-based SRS used higher isodose line (70-90%) to increase homogeneity of dose distribution.

Dose-volume relation: The dose of radiation that can be tolerated is highly dependent on the volume being treated (larger treatment volumes require lower doses to avoid radiation injury). Dose selection is made based on known information or is estimated from dose-volume relationship. If uncertain, err on the side of a lower dose or slightly underdose the margin of tumor. Previous radiotherapy must also be taken into account by the treatment team, as local structures are more sensitive.

101.3.5 Lesion-specific issues

Arteriovenous malformations and other vascular lesions

SRS is best accepted for the treatment of small to moderate-sized (<3 cm) AVMs that are deep or border on eloquent brain and have a “compact” (i.e., sharply demarcated) nidus. The radiation induces endothelial cell damage, smooth muscle cell proliferation, thickening of the vascular wall, and ultimately obliteration of the lumen over a period of 2-3 years (latency period).31

Lesions other than AVMs: Dural arteriovenous fistulas (AVFs) have also shown promising response to SRS.32 However, dural AVFs with cortical drainage should not be treated with SRS as these AVFs pose high risk of hemorrhage. SRS is of no benefit for venous angiomas.33 SRS for cavernous malformations remains controversial, as the lesions could not be precisely evaluated with MRI or angiography. However, published retrospective studies have demonstrated reduction of hemorrhage rates following SRS.34,35

Dose. Early study from Karlsson et al. demonstrated increased obliteration rate with increased margin dose.36 The effect reached the plateau at 25 Gy and a higher dose produced more complications without extra benefits. The optimal dose for AVMs generally ranges between 23-25 Gy. The dose might be reduced for nidi at critical locations or with a large volume. At McGill with linac SRS, they use 25-50 Gy delivered to the 90% isodose curve at the edge of the nidus. With Bragg-peak, complications occurred less frequently with doses <19.2 Gy compared to doses above that (this may reduce the obliteration rate or increase the latency period).37

Results. SRS has an overall obliteration rate of 70-80% across all cases of AVMs treated.38 At 1 year, 46-61% of AVMs were completely obliterated on angiography, and at 2 years 86% were obliterated. There was no reduction in size in <2% of cases. Smaller lesions have higher obliteration rates (with Bragg-peak in AVMs <2 cm diameter, 94% thrombosed at 2 years, and 100% at 3 years).37 AVMs >25 mm in diameter have only ≈50% chance of obliteration with 1 SRS treatment.

Grading system. A few SRS-based grading systems have been developed to predict patient outcomes since scales developed for surgical resection (e.g., the Spetzler-Martin scale) have not proven applicable for AVM radiosurgery. Long-term outcomes of 1012 patients treated with GK at UVA were analyzed to create the Virginia Radiosurgery AVM Scale (Table 101.3 and Table 101.4).38 Multivariate analysis showed that AVM volume, non-eloquent location, and no history of hemorrhage, were independent predictors of AVM obliteration without hemorrhage or permanent neurologic deficits.

The radiosurgery-based grading system by Pollock and Flickinger39 has been validated in both GK and linac treatment centers. This AVM score is calculated using the following formula:

\[
\text{Score} = \frac{\text{AVM volume} \times (2 - \text{Age})}{100^{\text{Eloquent location}}} 
\]

Embolization. Controversy exists as to whether embolization is helpful or harmful prior to SRS. Some experts find that target definition after embolization is extraordinarily difficult because of multiple small residual nidi. Experimental studies have shown attenuation of radiation effect by embolic material.40 However, for large AVMs, embolization remains an effective adjunct to reduce

Table 101.3 Virginia Radiosurgery AVM Scale38: variables and points
the size of nidi to make AVMs amenable to SRS. Additionally, pre-SRS embolization should be considered for high flow fistulas, which are more radioresistant, and intranidal/perinidal aneurysms, which are at risk for rupture.

Large AVMs. Large AVMs (>10 cm³) remain a significant challenge to treat with any modality. Single stage SRS has resulted in low obliteration and high complication rates. To maximize the dose/volume response, SRS can be performed in a volume-staged fashion. The Pittsburgh group reported overall rates of total obliteration of 18% 45% and 56% at 5, 7, and 10 years, respectively in a group of 47 patients with large AVMs. Ten patients had hemorrhage after SRS, and 5 of these patients died.

Residual lesions after SRS. Factors associated with treatment failures include: incomplete angiographic definition of the nidus (the most frequent factor, responsible for 57% of cases), recanalization of the nidus (7%), masking of nidus by hematoma, and a theorized “radiobiological resistance.” In some, no discernible reason for failure could be identified. In this series the complete obliteration rate was ≈ 64% If AVMs persist, retreatment with SRS 2-3 years later is an option.

The ultimate goal of radiosurgery for AVMs is elimination of risk of hemorrhage. An imperfect surrogate marker for this goal has been total obliteration of the nidus on imaging. Reduced, unchanged, or increased hemorrhagic rates during the latency period have been reported. Proton beam treatment of AVMs affords no protection against hemorrhage in the first 12-14 months following treatment; this is similar to the 12-24 month latency for photon radiation. Hemorrhages may occur during the latency period even in AVMs that had never bled before, and the question has been raised whether a partially thrombosed AVM is more likely to bleed because of increased outflow resistance. Yen et al. reviewed a large group of AVM patients undergoing radiosurgery and reported that the hemorrhagic rates reduced from 6.6% before SRS to 2.5% after SRS. The protective effect is more significant in those AVMs that had a prior hemorrhage (10.4% to 2.8%).

Metastases

The gold standard and level 1 recommendation for a single brain metastasis amenable to surgical resection is surgery followed by WBRT. This does not apply to extremely radiosensitive tumors such as lymphoma, small cell lung cancer, germ cell tumors, and multiple myeloma. There has not been a randomized study to compare surgery alone to SRS alone. A prospective randomized study by Muacevic et al. showed comparable survival and local tumor control between SRS vs. surgery plus WBRT in patients with a single brain metastasis but a higher incidence of distant recurrence in the SRS arm. When tissue is required for diagnosis, surgery should be considered. Tumors with significant mass effect should also be resected if the patients are fit for surgery. In patients with ≤3 mets, single dose SRS provides superior survival advantage as compared to WBRT (level III recommendation). Radiographic local control rate of ≈ 88% (reported range: 82-100%) has been cited.

No significant difference has been found with SRS between tumors considered “radiosensitive” and those that are “radioresistant” as defined by standards developed for EBRT (see Table 52.7; however, histology may affect the rate of response). The lack of significance of “radioresistance” may be due in part to the fact that the sharp dose drop-off with SRS allows higher doses to be delivered to tumors than would be used with EBRT.

General guidelines for when to consider SRS for brain metastases are:
- total tumor number ≤ 10
- total tumor volume ≤ 15 cm³
- single tumor volume is < 10 cm³, and
- no leptomeningeal disease present.

Recent studies on SRS for brain metastases have shown that total tumor volume is a better predictor of overall survival, local control, and even distant failure than tumor number.49,50,51

Dose. RTOG 90-05 study recommended 24 Gy as the maximum tolerated doses of single fraction SRS for tumors ≤20 mm in maximum diameter; 18 Gy for 21-30 mm; and 15 Gy for 31-40 mm.52

Vestibular schwannomas (VS)
Possible indications of SRS for VS are: poor surgical candidates (due to poor medical condition and/or advanced age, some use >65 or 70 years as a cutoff), patient refusing surgery, bilateral VS, postoperative treatment of incompletely removed VS that continue to grow on serial imaging, or recurrences following surgical removal. See the Management algorithm under Vestibular schwannomas for strategies that take into account the natural history.

A few nonrandomized prospective studies comparing GK SRS to microsurgery in small to middle sized VS have demonstrated superiority of SRS treatment.53,54 The largest series of 2336 VS with at least 3 years follow-up from Marseille showed a tumor control rate of up to 97.5% trigeminal nerve injury 0.5% facial palsy 0.5% and hearing preservation at 65%.54 However long-term follow-up is needed. SRS following deliberate subtotal resection of large Koos stage IV VS reduced the risk of facial weakness compared with GTR.55 Dose range for SRS of VS is usually 11-12 Gy. SRS tolerable dose to cochlea seems to be around 4.2 Gy, but also depends on age and pre-SRS hearing class.56

Temporary increase of tumor size following SRS is a common finding and can be managed conservatively.

SRT or multisession SRS has been used to treat VS. Selch et al. reported a local control rate of 100% with a median follow-up of 36 months.57 Their group showed the hearing preservation rate has been high (93%) and incidence of facial nerve injury has been low (2.2%new facial palsy, 2.2%facial numbness). SRT has not been compared head-to-head with SRS, but preliminary results suggest the results of both modalities might be similar.

Dose. Sample SRT protocol: 6-MV linac with a micromultileaf collimator used to deliver 54 Gy in 30 fractions of 1.8 Gy prescribed to the 90% isodose line via 7-22 noncoplanar static fields or 4-6 noncoplanar dynamic arcs to a target defined as the tumor volume plus a margin of 1-3 mm. Multi-session SRS has been used to treat large VS. In a study of 33 patients with VS greater than 8 cm³ treated with Cyberknife, radiological growth control was 94%at a median follow-up of 48 months.58 Hearing was retained in 7 of 8 patients with serviceable baseline hearing. Only 1 patient each had cranial nerve deficits including vertigo, tongue paresthesia and trigeminal neuralgia.

Meningiomas
In a large series of meningiomas treated with SRS by the Pittsburgh group,59 among 942 patients with 1045 tumors treated, the control rate for patients with surgically verified WHO grade I meningiomas was 93% Control rate for presumed meningiomas based on imaging (no prior histological confirmation) was 97% The control rates for WHO grades II and III tumors were 50% and 17% respectively.

Dose. The authors used a mean dose of 14 Gy to the tumor margin.59

Pituitary adenomas
Surgery is the mainstay of management for pituitary tumors especially for nonsecretory tumors with mass effect and secretory tumors that fail medical treatment. For residual/recurrent secretory or nonsecretory tumors, SRS is an appropriate tool to arrest tumor growth and/or normalize hormonal function. In a large series of 418 patients with pituitary adenomas residual/recurrence treated with GK at UVA, the overall tumor control rate was 90%in patients with imaging follow-up available. The endocrine remission rates are 53% for acromegaly, 54% for Cushing's disease, and 26% for prolactinomas.

Dose. The usual dose for nonsecretory tumors is ≈ 16-18 Gy, and a higher dose is required for secretory tumor ≈ 25 Gy.

Results. Early studies of SRS showed limited numbers of hypopituitarism and cranial nerve injuries. Available long-term follow-up studies now demonstrate a 20-30%rate of new endocrinopathy after SRS and a low but not negligible risk of cranial nerve damage.60
Infiltrating tumors

SRS is generally not indicated as a primary treatment for infiltrating tumors, e.g. gliomas, due to the lack of a definable capsule and very close relationship between target volume and tolerated radiation dose. SRS has been used for recurrent lesions following standard treatment (surgical excision and adjuvant EBRT 60 Gy and Temozolomide). One of the arguments for SRS in these tumors is the fact that 90% of recurrences are within the original radiographic solid tumor volume. However, support for SRS boost declined after a 2004 RTOG trial showing no survival benefit in newly diagnosed GBM patients with upfront use of SRS followed by EBRT and BCNU chemotherapy. SRS can be used as a salvage treatment for small (<10 cm³), recurrent GBM after standard treatment. Kong et al. showed SRS salvage treatment in these cases prolonged OS to 23 from 12 months.

101.3.6 Treatment morbidity and mortality

Immediate morbidity and mortality

Immediate mortality from the actual treatments themselves is probably zero. Morbidity: all but ≈ 2.5% of patients were discharged home within 24 hours. Many centers do not admit patients overnight. Some immediate adverse reactions include:

- 16% of patients require analgesics for post-procedural headaches and antiemetics for nausea/vomiting
- at least 10% of patients with subcortical AVMs had focal or generalized seizures within 24 hrs of treatment (only one was on subtherapeutic AEDs. All were controllable with additional AEDs.)

Premedication

The Pittsburgh Gamma Knife group gives methylprednisolone 40 mg IV and phenobarbital 90 mg IV immediately after the radiation dose to patients with tumors or AVMs to reduce these adverse effects. For small lesions and patients without prior history of seizures, premedication with steroids or antiepileptics are probably not necessary.

Delayed morbidity

Long-term morbidity directly related to the radiation may occur, and just as with conventional XRT, is more frequent with larger doses and treatment volumes. Radiation complications include:

- radiation-induced changes, high intensity on MRI T2WI or low density on CT: usually occur ≈ 13 months after SRS for AVMs. The incidence is 34% with 8.6% having imaging changes associated with neurological symptoms (focal deficits, seizures, or headache) and 1.8% developing radiation necrosis and permanent deficits. The possible mechanisms of this side effect include glial cell damage, breakdown of blood brain barrier or early venous thrombosis. Premature venous thrombosis or occlusion before obliteration of AVM nidus can produce venous hyperemia or intracranial hemorrhage.
- vasculopathy: diagnosed by narrowed seen on angiography or by ischemic changes on imaging in ≈ 5% of cases
- cranial nerve deficits: occur in ≈ 1% of all cases. Incidence is higher with tumors of CPA or skull base
- radiation induced tumors: only a few case reports of newly formed malignant tumors (glioblastomas) or malignant transformation of a benign tumor (vestibular Schwannoma). Loeffler reported 6 cases over 80,000 radiosurgical procedures for benign diseases. Radiation-induced meningioma is a well-known complication of radiation therapy. In a large series of AVM patients treated with SRS, the incidence of radiation-induced meningioma was estimated to be 0.7%

101.4 Interstitial brachytherapy

101.4.1 General information

Technique whereby radioactive implants are used to deliver locally high doses of radiation directly to tumors while exposing nearby normal brain to less toxic doses. At present, the numbers are too small and the follow-up too short to determine the efficacy of interstitial brachytherapy. Interstitial brachytherapy (IB) may reduce the rate of tumor growth, but it rarely produces clinical improvement. Patients are generally not considered for IB unless their Karnofsky score is ≥ 70.
101.4.2 Techniques

Techniques include:

1. insertion of high activity iodine-125 pellets which remain in place (either by conventional open surgery or by stereotactic technique)
2. insertion of catheters (so-called afterloading catheters) containing radioactive source (such as gold or I125) by stereotactic technique, which are then removed at a predetermined time (usually 1–7 days)
3. instillation of radioactive liquids (e.g. phosphorous isotope) into a cyst cavity

I125 has several characteristics that favor its use: it emits low-energy gamma rays which are absorbed by surrounding tissues minimizing radiation exposure of the normal brain, medical personnel and visitors. It is available as low-activity (<5 mCi) or high-activity (5–40 mCi) seeds.

Treatment planning is devised to deliver 60 Gy to the edge of a volume that extends 1 cm beyond the contrast-enhancing tumor, with variations included to spare radiosensitive structures (e.g. optic chiasm). Usual delivery rates are 40–50 cGy/hr to the tumor margin (30 cGy/hr is the critical dose for cessation of human tumor growth) requiring that the seeds stay in the afterloading catheter ≈ 6 days.

101.4.3 Radiation necrosis

Symptomatic radiation necrosis (RN) occurs in ≈ 40% of cases, and may occur as early as several months after IB. It may be impossible to differentiate from recurrent tumor in many cases. Symptomatic treatment is often achieved with increased corticosteroid dosages. Continued neurologic deterioration may require craniotomy.

101.4.4 Outcome

IB is often used as a “last ditch” effort in a patient with a recurrent malignant tumor who has received maximal external beam irradiation and who is not a candidate for reoperation (as expected, the results in patients with such poor prognoses are not good). However, patients eligible for IB are usually better than those who are not candidates, and this may bias the results towards a better outcome. Some studies with early (primary treatment) use have shown possible benefit.

References

102 Endovascular Neurosurgery

102.1 General information

102.1.1 Introduction

Endovascular Neurosurgery, AKA Neuroendovascular surgery, endovascular and surgical Neuroradiology (ESNR), or interventional neuroradiology (INR), combines catheter based techniques and imaging for the diagnosis and treatment of specific cerebral and spine conditions.

102.1.2 Indications/Conditions treated

Endovascular neurosurgery include diagnosis as well as the following treatment of:

- Aneurysms: coiling (± stent or balloon assistance), flow diverting stents e.g., Pipeline, parent vessel sacrifice
- Arteriovenous malformations (AVMs): embolization (pre-operative or curative)
- Dural arteriovenous fistula (DAVF): curative or palliative embolization
- Spinal AVMs: embolization
- Arteriovenous fistulas: e.g. Carotid Cavernous fistulas (CCF)
- Acute embolic stroke: intra-arterial clot thrombolysis or mechanical thrombectomy
- Cranial sinus thrombosis (CST): Thrombolysis or mechanical thrombectomy
- Cerebrovascular arterial dissections: stenting or parent artery sacrifice
- Cervical internal carotid artery stenosis: angioplasty/stenting
- Tumors: embolization. Primarily used before surgery as an adjunct to decrease vascularity e.g., with some meningiomas and hemangioblastomas
- Intracranial atherosclerosis
- Vasospasm
- Transverse sinus stenosis: stenting as in pseudotumor cerebri
- Inferior Petrosal sinus sampling for localizing pituitary macroadenomas
- Iatrogenic vascular injuries: stenting or embolization to achieve hemostasis
- Refractory epistaxis: embolization to achieve hemostasis
- Wada testing: evaluation for language and memory localization (e.g. epilepsy patients being considered for surgery)
- Intraarterial chemotherapy: e.g. retinoblastoma
- Intraoperative angiography: typically used in aneurysm surgery to confirm exclusion of the aneurysm and patency of parent vessels, and during AVM surgery to confirm elimination of nidus

102.1.3 Contraindications

- Uncorrected bleeding disorders
- Poor renal function (due to iodine dye load)
- Relative contraindication: connective tissue disorder that predisposes to vessel dissection
- For spinal angiography: thoracic aortic aneurysm (relative)

102.1.4 Risks of cerebral angiography

Risk varies with the nature of the pathology being investigated and with the experience of the angiography team. Overall risk of a complication resulting in a permanent neurologic deficit: 0.1%. In ACAS, there was a 1.2% complication rate (p. 1276).

102.1.5 Miscellaneous angiography

Tumors. While angiography is no longer used diagnostically for tumors, there are a few general principles worth knowing. Typically, non-vascular deep lesions cause changes in venous structures, whereas superficial lesions affect arterial structures. Malignant neoplasm (e.g. glioblastoma): the classic feature on angiography is an early draining vein. Meningiomas: the stain (contrast) “arrives early, stays late” (appears early in arterial phase, blush persists beyond venous phase); see also other angiographic findings with meningiomas (p. 695).
102.2 Pharmacologic agents

102.2.1 General information

This section presents drugs as they are used in neuroendovascular procedures. The indications cited are specific to endovascular intervention.

102.2.2 Abciximab (ReoPro)

General information

The Fab fragment of an antibody. Prevents binding of fibrinogen to platelet GP IIb/IIIa receptors. Platelet inhibition lasts up to 48 hours.

Indications and case selection

- Acute endoarterial thrombus during endovascular intervention
- Dissection with thrombus adherent to intimal flap
- Prophylaxis for intracranial or extracranial stent implantation

Dosing

: bolus with 0.25 mg/kg IV over 10–60 minutes (shorter duration for the acute complications during intervention) followed by infusion of 0.125 mcg/kg/min (max. 10mcg/min) for 12 hours.

Reversal

Discontinue abciximab infusion. Allow 10–30 minutes for clearance of the drug from plasma, followed by platelet transfusion. Surgical intervention should be delayed for 12 – 24 hours after discontinuation.

102.2.3 Aspirin

General information

Irreversibly inactivates cyclo-oxygenase, resulting in platelet inhibition by preventing formation of prostaglandins from arachidonic acid.

Indications and case selection

- Intra (short-term) and post-procedural (short + long-term) prophylaxis of thromboembolic events e.g., during
  - diagnostic cerebral angiography
  - coil embolization of aneurysms
  - stent implantation (typically with a second antiplatelet agent)
  - balloon test occlusions
  - therapeutic occlusion of large arteries
- Subacute management of procedural complications e.g.,
  - parent artery coil herniations
  - thrombus or clot on coil phenomena
  - in-stent thrombus (alone or in combination with a second agent)

Dosing

: 325–1300 mg orally, daily

Uncoated Aspirin (ASA) achieves peak plasma concentrations within 30 – 40 minutes. Entericoated ASA achieves peak plasma concentrations in up to 6 hours. 60% of population is resistant to the antiplatelet effect of low dose (81 mg) ASA, while up to 30% are resistant to 325 mg/day. However, the assessment of ASA resistance is highly assay dependent. A dose related effect i.e., improved
response to increasing the dose, indicates that ASA also exert antiplatelet effects through non-cyclo-oxygenase pathways.\textsuperscript{5}

Reversal
Reversal is achieved by platelet transfusion. ASA causes an irreversible inactivation of the platelet cyclo-oxygenase that persists through the lifespan of the exposed platelets.

102.2.4 Clopidogrel (Plavix\textsuperscript{TM})
General information
A platelet ADP receptor antagonist.

Indications and case selection
• Prevention of intra-procedural and short-term post-procedural (4–12 weeks) thromboembolic events related to endovascular procedures including
  ◦ Coil embolization of wide-neck cerebral aneurysms where stent will be used
  ◦ Stent implantation (with a second antiplatelet agent)
  ◦ Therapeutic occlusion of large arteries (often with a second antiplatelet agent)
• Subacute management of procedural complications (alone or in combination with a second agent)
  ◦ Parent artery coil herniations
  ◦ Thrombus or clot on coil phenomena
  ◦ In-stent thrombus (may be more effective than other agents)

Dosing
: 75 mg PO daily. Start 5 days prior to the actual procedure because there is a 3–7 days latency period to full therapeutic effect
LD: 300 mg PO, if there was no time to achieve therapeutic effect over a course of days. A therapeutic effect can usually be achieved within 2 to 3 hours of LD.

Reversal
Platelet transfusion.

102.2.5 Eptifibatide (Integrilin\textsuperscript{®})
General information
A reversible inhibitor of platelet aggregation by preventing the binding of fibrinogen, von Willebrand factor, and other adhesive ligands to GP IIb/IIIa. Platelet aggregation inhibition appears dose and concentration dependent and is reversible following discontinuation of eptifibatide. It causes a 5-fold increase in bleeding time and has no measurable effect on PT or aPTT.

Indications and case selection
These are the same as for abciximab (see above).

Dosing
: bolus 180 mcg/kg IV (max 22.6 mg) over 1–2 minutes followed by infusion of 2 mcg/kg/min.

Reversal
• Discontinue drug. Significant reduction of anti-platelet effects occurs in 2–4 hours.\textsuperscript{10}
• For clinical signs or imaging evidence of hemorrhage:
  ◦ For ICH, hemodynamic compromise, or decrease in Hb > 5 g/dl or decrease in HCT > 15% give platelet transfusion
  ◦ For a decrease in Hb < 5 g/dl or decrease in HCT < 15% give desmopressin : 0.3 mcg/kg × 1.
102.2.6 Heparin

General information

A glycosaminoglycan that indirectly inhibits thrombin by modulating antithrombin III (AT III) activity. It also indirectly inactivates factors IXa, Xa, Xla and Xllla and restores electronegativity to endothelial surfaces. It prevents thrombin-platelet aggregation and inhibits von Willebrand factor. The anticoagulant effects are immediate. The half-life of IV heparin is approximately 1.5 hours.11,12

Indications and case selection

- Prophylaxis during diagnostic angiography (used in flush solutions only)3,13
- Neuroendovascular procedures including,
  - coil embolization of intracranial aneurysms,
  - therapeutic occlusion of carotid, vertebral, or other large cerebral artery
  - Transarterial embolization of brain AVM or dural AVF
  - Percutaneous transluminal angioplasty
  - Intra- or extracranial stent implantation
  - Balloon test occlusion of carotid, vertebral, or other large cerebral artery

Dosing

- Flush systems: 6000 i.u. per liter of 0.9% normal saline (6 i.u. per cc) for flush systems used in neuroendovascular procedures. During intraoperative angiography: 2500 i.u. per liter of 0.9% normal saline (2.5 i.u. per cc). The lower dosage during surgery is a precaution against excessive bleeding from operative sites e.g., during craniotomy.

  Endovascular interventions:
  - Coil embolization for unruptured aneurysm: 5000 units bolus. Check the activated clotting (ACT, Table 102.1) 20–30 minutes after bolus and then hourly. Administer heparin 0–5000 units hourly prn to maintain ACT between 250–300.
  - Coil embolization for ruptured aneurysm: Place the framing coil prior to heparin bolus.
  - Angioplasty with/without stenting: 5000 units bolus. Perform ACT 20–30 minutes after bolus and then hourly. Administer heparin up to 5000 units hourly prn to maintain ACT between 300–350.

  Post procedure heparinization: For aneurysm embolization, the following regimens are recommended:
  - Heparin dosing for post coiling neurosurgery patients
    - University of Cincinnati Protocol14: devised to administer a safe dose of heparin that does not require repeat blood draws and titration to ACT or aPTT
      - Weight-based dosing
        - Weight ≤ 75 kg: 900 units/hour, no bolus doses, for 12 hrs
        - Weight > 75 kg: 1300 units/hour, no bolus doses, for 12 hrs
      - Labs: no ACT or other laboratory draws required.
    - Alternative: The most commonly used heparin weight based protocol (NB: this differs from dosing e.g. for coronary indications or treatment of DVT or PE15): bolus dose of 60–70 units/kg followed by a maintenance IV infusion rate of 18 units/kg/hour. Titrate to ACT as shown in Table 102.1.

Reversal

IV protamine sulfate at 1 mg per 100 units of circulating heparin (not to exceed 50 mg total).

A preloaded syringe of 50 mg should be available at all times. Normally protamine is administered as an IV infusion over 10 – 30 minutes, to prevent idiosyncratic hypotension and anaphylactoid

symptoms. In an emergency e.g., vessel or intracranial aneurysm perforation, anticoagulation must be immediately reversed by rapid IV bolus of 10 mg protamine over 1–3 minutes.

102.2.7 Nitroglycerine

**General information**

Produces strong and immediate vasodilatation by stimulation of cGMP, which results in vascular smooth muscle relaxation.

**Indications and case selection**

Vessel spasm during catheterization.

**Dosing**

: 100 – 300mcg through the catheter.

102.2.8 Papaverine

**General information**

A benzylisoquinoline alkaloid that vasodilates by inhibition of cAMP and cGMP phosphodiesterases in smooth muscle, leading to increased intracellular levels of cAMP and cGMP. It may also inhibit the release of calcium from the intracellular space by blocking calcium ion channels in the cell membrane. Papaverine is short acting, with half-life of less than 1 hour.

**Indications and case selection**

Pre-treatment for angioplasty. The resulting vasodilatation will assist with balloon catheter placement. Due to its short duration of action necessitating repeated administration, other agents e.g., verapamil, are generally preferred.

**Dosing**

: 300 mg of 3% papaverine (30 mg/ml) at pH 3.3, is diluted in 100 ml of normal saline to obtain a 0.3% concentration. It is administered intra-arterially through the microcatheter, which is positioned just proximal to the affected vascular segment at a rate of 3 ml/minute.

Do not mix Papaverine with contrast agents or heparin, which may result in precipitation of crystals.

102.2.9 Sodium Amytal

**General information**

A barbiturate derivative that activates GABA<sub>A</sub> receptors. When it is administered into cerebral vasculature during Wada test, it temporarily anesthetizes the perfused region, resulting in isolation of the contralateral hemisphere permitting assessment of cortical functions including language and memory. It blocks neuronal activity and in conjunction with lidocaine, which blocks axonal activity, it is administered as a test injection in procedures such as spinal AVM embolization, or embolization of spinal tumors, prior to the injection of the embolic agent.16

**Indications and case selection**

Wada Test

Test injection prior to embolization of feeder vessel of AVM. In order to suppress both neuronal and axonal activity, amytal injection is followed by xylocaine injection.

**Dosing**

: 50–100 mg per test injection via catheter.

For administration, dilute 500 mg sodium amytal in 20 cc 0.9% NS to yield a concentration of 25 mg/cc of sodium amytal.
For Wada test, after catheterization of vessel of interest, 100 mg of Sodium Amytal (4 cc of the preparation described above) are injected through the catheter. Additional boluses of 25 mg (1 cc) or modification of the original bolus may be required, per the neurologist’s request.

102.2.10 Tissue Plasminogen Activator (tPA)

General information
A fibrin specific thrombolytic protease that converts plasminogen to plasmin.

Indications and contraindications

Indications:
- Cranial sinus thrombosis (CST)
- Patients with acute ischemic stroke who are 18 years of age, or older; have clinical diagnosis of ischemic stroke with measurable neurologic deficit
  - symptom onset ≤ 4.5 hours prior to initiation of treatment: given IV
  - up to 6 hours after symptom onset: given by intra-arterial administration. May be up to 24 hours after onset for posterior circulation (where there is less likelihood of hemorrhagic conversion of infarct).

Absolute Exclusion criteria:
- Brain CT scan demonstrating ICH prior to treatment.
- Only minor or, rapidly improving symptoms of stroke.
- Clinical presentation suggestive of SAH, even with a normal CT.
- CT demonstrating ICH or SAH.
- Active internal bleeding.
- Known bleeding diathesis including platelet count < 100 X10^3/mm^3.
- Heparin within 48 hours with an elevated aPTT.
- Current oral anticoagulation use e.g., warfarin, or recent use with an elevated PT (> 15 sec) or INR (> 1.7).
- Current use of direct thrombin inhibitors (desirudin, bivalirudin, argatroban) or direct factor Xa inhibitors (Rivaroxaban, Edoxaban, Betrixaban) with elevated aPTT, INR, platelet count, Ecarin Clotting Time (ECT), TT, or factor Xa activity assays.
- Intracranial or intraspinal surgery, severe TBI, or previous stroke within 3 months.
- Suspected aortic dissection associated with stroke.
- Suspected subacute bacterial endocarditis or vasculitis.
- Recent (within past 7 days) arterial puncture at a non-compressible site.
- Lumbar puncture within 7 days.
- History of ICH.
- Known AVM or aneurysm.
- Persistent SBP > 185 mm Hg or DBP > 110 mm Hg at time of treatment, or patient requires aggressive treatment to reduce BP within these limits.

Relative Exclusion criteria:
- Witnessed seizure at the same time as onset of symptoms of stroke
- NIHSS > 22 (severe deficit) or < 4 (mild deficit)
- Baseline CT demonstrating extensive ischemic changes e.g., sulcal effacement, mass effect, or edema, hypodensity in more than 1/3 of MCA territory distribution
- Major surgery or serious trauma within 14 days
- History of GI or urinary tract hemorrhage within 21 days
- Recent acute MI (past 3 months)
- Post myocardial infarction pericarditis
- Blood Glucose < 50 mg/dl (2.7 mmol/l) or > 400 mg/dl
- Age > 80 years
- Pregnancy
- History of ischemic stroke AND diabetes
- History of terminal cancer or other medical condition with limited life expectancy
- History of advanced dementia
Dosing

: Intravenous: 0.9 mg/kg (max. 90 mg). The first 10% of the calculated dose is administered as an IV bolus over 1 minute and the remainder is infused over an hour, within the 4.5 hour window.

: Intraarterial: The maximum intra-arterial dose is 22 mg. It is independent of any previously administered intravenous dose.

1–2 mg tPA is administered manually distal to the clot, then administer an infusion of 0.5 mg/ml at 20 ml/hr (10 mg/hr). The infusion is prepared by mixing 10 mg of tPA in 20 ml in normal saline, resulting in a concentration of 1 mg tPA per 2 ml saline (or 0.5 mg/ml). An infusion pump may be used for more precise administration.

Angiography is performed every 15 minutes (following infusion of 2.5 mg tPA) as the catheter is gradually drawn back through the clot. The lesion is re-crossed after each angiogram. If the artery is still occluded, inject 1–2 mg tPA manually and resume the tPA infusion.

Discontinue tPA if
- adequate recanalization is achieved
- extravasation of contrast material is noted on angiography
- The maximum dose has been administered, or the administered dose approaches the maximum dose without clinical or angiographic improvement.

In CST, usually 2–5 mg are administered through the thrombus and then an infusion started at a rate of 1 mg/hr, usually for 12 hours. If a clot burden is still present on angiography, a longer duration of administration until the clot resolves is a consideration.

For CST, the infusion is prepared in a concentration of 1 mg/10 ml (0.1 mg/ml), for a rate of 10 ml/hr.

Reversal

FFP transfusion.

102.2.11 Verapamil

General information

A nondihydropyridine calcium channel blocker that reduces the influx of calcium through L-type calcium channels in smooth-muscle cells, enabling vasodilation. Half-life is about 3–7 hours.

Indications and case selection

- Before balloon angioplasty: chemical vasodilatation prior to mechanical vasodilatation may enable a smoother and safer angioplasty.
- Mild vasospasm, that does not warrant angioplasty.
- Moderate vasospasm, that cannot be safely treated with angioplasty.

Dosing

: 5–10 mg IA. It is slowly infiltrated (over 2–10 minutes) into the vasospastic vessel via a microcatheter into the intracranial vessel, and/or via diagnostic or guide catheter into larger vessels e.g., ICA or, VA.

Reversal

For clinically significant hypotension or high degree AV block: treat with vasopressors and cardiac pacing e.g., epinephrine, norepinephrine and vasopressin infusions. Calcium chloride infusion is given in large doses e.g., 1 gm/hr for more than 24 hours. 20% intralipid infusion (100 ml bolus followed by continuous infusion at 0.5 ml/kg/hr) may also be useful. Atropine may be administered for bradycardia. Hemodialysis is ineffective.

102.2.12 Xylocaine

General information

Blocks the fast voltage gated Na+ Channels in neuronal cell membranes. There may be inhibition of postsynaptic neurons and consequently, action potentials.
Indications and case selection
As a local anesthetic prior to arteriotomy. Preparations with or without epinephrine may be used.
Cardiac xylocaine is used to test axonal function. It may be used alone or in conjunction with amobarbital.
Used for functional testing in case of spinal vascular disorders.
Provocative functional testing in cerebral AVMs.

Dosing
- for local anesthesia: Approximately 5 ml of 2% lidocaine (max. 4 mg/ml to 280 mg; 14 ml)
- for neurophysiological testing (Wada test): 10–40 mg i.a. of cardiac lidocaine.

Reversal
Lidocaine overdose: intravenous bolus of 20% lipid emulsion 1.5 ml/kg over 1 min and start IV infusion at 15 ml/kg/hr. The bolus may be repeated twice at 5 min intervals, if cardiovascular stability is not restored. Additionally, the infusion may be doubled to 30 ml/kg/hr if instability persists after 5 minutes. Lipid emulsion is continued until cardiovascular stability is restored or maximum dose administered. Do not exceed the maximum cumulative dose of 12 ml/kg.

Concurrent supportive care includes following ACLS protocols e.g., securing airway, hemodynamic support etc.
Propofol is not a substitute for lipid emulsion in such cases. It has only 10% lipids which is too low to be of benefit, and the cardio-depressant properties of propofol may be counterproductive in such situations.

102.3 Neuroendovascular Procedure Basics
102.3.1 Vascular access
General information
Most commonly, vascular access is obtained through femoral artery. If femoral access is not possible then the radial artery, brachial artery or carotid artery (least common) may be used.

Femoral artery access
After prepping and draping the groin, place the left little finger on anterior superior iliac spine and span with thumb to the pubic symphysis. This approximately demarcates the ilioinguinal ligament. Bisect this line with the other hand and palpate the femoral pulse. The site of access is 3 finger-breadths below the point of bisection, to ensure the vessel puncture site is below the ilioinguinal ligament and therefore, compressible. A marker (e.g. hemostat) can be placed over the pulse and a fluoro shot taken to confirm that the planned access site is situated over the middle of the femoral head.
A small, superficial stab incision in the skin is made at the selected point, after infiltration of local anesthesia. In an elective case, a micropuncture set with a 7 cm 21 or 23 gauge needle may be used for vessel puncture. In an emergency (e.g., stroke) a larger 18G single wall needle is used. The artery is palpated and immobilized between the index and middle finger of one hand, while the needle is introduced through the stab at 45°. Once the artery is accessed, blood will emanate through the needle hub. An exchange over wires is made using modified Seldinger technique to place the sheath of desired size. The sheath is connected to continuously running flush of heparinized saline and secured with adhesive or suture to prevent dislodgement.

Radial artery access
First perform Allen’s test with pulse oximetry to ensure the hand has satisfactory vascular supply, in case the procedure results in radial artery occlusion.
Allen’s Test: Palpate the radial and ulnar arteries and place a pulse oximeter on the thumb or index finger. Make the patient flex and extend their fingers repeatedly. With digital pressure, compress both the radial and ulnar arteries during finger extension and maintain the compression until the oximetry pulse is lost. The wrist is maintained in approximately 20° flexion, in order to avoid false positive test when the wrist is in hyperextension. Release the pressure on the ulnar artery. Measure the time taken to achieve visual capillary refill in finger pads and at least 92% oxygen saturation. Normal capillary refill time is <5 sec, refill times of 5–15 secs are considered equivocal. A refill time longer than 15 sec is abnormal. Allen’s test can also be performed using ultrasonography.
Reverse Allen’s Test: It should be performed when the radial artery is being subjected to a repeat procedure. Compress both the radial and ulnar arteries with digital pressure during finger extension and maintain the compression. Release the pressure on the radial artery. Measure the time taken to achieve visual capillary refill in finger pads and at least 92% oxygen saturation, as indicated above.

During access, the following modifications are made from the technique described above. A shorter needle 21 G (e.g., 3 cm, instead of 7 cm) is used. Avoid entering the artery at a steep angle, as this may cause difficulties in threading the wire through the artery.

Advance a 0.018” wire through the needle hub into the radial artery and remove the needle. Make a nick in the skin over the wire, to aid in smoother insertion of larger sheaths. A 4 Fr micropuncture sheath (with dilator) over the wire is advanced over the wire and then the wire and dilator are removed. A cocktail of heparin (5000 IU/ml), verapamil (2.5 mg), 2% lidocaine (1.0 ml), and nitroglycerin (0.1 mg) are administered through the introducer sheath to relieve and/or prevent vasospasm. The patient should be forewarned about a transient but uncomfortable sensation of severe burning, as the cocktail is injected into the artery. The standard 0.035” wire is advanced through the sheath. The desired sheath size is then placed.

Note: After completion of the procedure, a closure device is not used for radial artery. Only manual compression for 15–20 minutes is applied.

102.3.2 Sheath Management

Once placed, the sheath is connected to a continuously running heparinized saline solution at a rate of 30 ml/hr. The flush consists of 6000 units of heparin in 1000 ml of 0.9% saline bag (6 units/ml).

The saline bag is placed in a pressure infuser which is inflated to 300 mmHg. It is important that the sheath be continuously irrigated and the saline bag be under a pressure greater than the patient’s own arterial pressure. The patient’s leg on the side of the sheath is kept straight to prevent kinking of the sheath. If the intention is to maintain the sheath for several hours or a few days, it should be secured by suturing to the patient’s skin.

102.3.3 Arteriotomy closure

After completion of the procedure, if vascular access will not be required within next few days, the sheath is removed. To do this, the following options are available:

- Pressure
  - Manual Pressure: Palpate the artery proximal to site of arteriotomy, remove sheath and apply manual pressure for 15–30 minutes and gradually decreasing pressure every 5 minutes.
  - Femostop™: Prior to application, ensure ACT is <150 and BP is under control. The inner circle of the Femostop dome should be positioned 1 cm superior and 1 cm medial to the actual puncture site and over the femoral artery. Inflate the Femostop to 20–30 mm Hg above the patient’s systolic pressure. If this does not result in hemostasis, inflate to higher pressures until distal pulses are occluded. Maintain distal pulse occlusion for 5–7 minutes, then readjust the manometer pressure until good pedal pulse and good color of extremities is achieved. Continue to progressively decrease the applied pressure over the course of several hours, until the device can be discontinued entirely. Usually, a Femostop is maintained for 6–12 hours.

- Percutaneous closure devices
  - Angioseal™: effects closure by deposition of fibrin plug in the vessel which is then pulled back into the arteriotomy defect of the vessel wall. Angioseal is available in 6 and 8 Fr sizes. Deployed by exchanging it with the sheath over a wire. After deployment, the patient remains supine for 2 hours (with pillow under the head) with the leg on the side of Angioseal kept straight. Patient is mobilized thereafter.
  - Mynx™: a bio-absorbable sealant that is deposited in the arteriotomy defect. Available in 5, 6, 7 Fr sizes. Tends to be the least painful.
  - Starclose™: Also exchanged with the sheath over a wire. Deployment results in stitch closure of the arteriotomy defect. Tends to be more painful.

102.4 Diagnostic angiography for cerebral subarachnoid hemorrhage

102.4.1 General information

Objective: diagnose source of hemorrhage, assess supplying blood vessels and collateral vessels (may require additional provocative maneuvers), assess vessels for possible bypass, assess for vasospasm.
The most common cause of nontraumatic SAH is ruptured cerebral aneurysms. Other causes include AVM (cerebral or spinal), vasculitis, pre-truncal nonaneurysmal subarachnoid hemorrhage, arterial dissection, dural sinus thrombosis, pituitary apoplexy, bleeding dyscrasias, sickle cell disease and cocaine abuse. In 14–22% a cause for SAH is not found on angiography.\textsuperscript{21}

102.4.2 Setup
A sheath is placed in the femoral artery, connected to a continuously running flush of heparinized saline. A diagnostic catheter is attached to a continuously running flush of heparinized saline. It is introduced into the vasculature, via the sheath and advanced over the guidewire through the aorta to the target vessel. The catheter is advanced with the guidewire leading and pulled back with the guide wire completely retracted into the catheter. Once the catheter is in desired position, the guidewire is withdrawn completely and angiography performed, by using manual injections or the auto-injector.

102.4.3 Planning
Pre-planning the procedure will save time, amount of contrast administered and radiation exposure. Standard views (half Towne’s and lateral for anterior circulation; Towne’s and lateral for posterior circulation) are obtained. Additionally, the images in appropriate projections are obtained, keeping in mind the patient’s pathology. As needed, rotational angiography is performed and the 3D reconstruction manipulated for further examination, as well as, selection of further projections for angiography.

102.4.4 Additional views
In case of aneurysms, based on their location, the projections as shown in Table 102.2 may prove useful.

102.5 Disease-specific intervention

102.5.1 Aneurysms

General information
The coil vs. clip debate is a moving target, especially given the fact that as long-term data about endovascular treatment is becoming available, the technology continues to evolve which renders the data obsolete. While there will always be a role for surgical clipping, endovascular therapy has emerged as a first line therapy for most aneurysms (particularly ruptured aneurysms or in poor surgical candidates). Surgery still remains a strong option for MCA aneurysms and many believe for most PICA aneurysms.

Indications
The selection of aneurysm for treatment depends upon the following considerations:

Ruptured vs. unruptured. A ruptured aneurysm needs to be treated urgently, as the risk or re-rupture is 2–3%/day in first few days and 20% in 2 weeks. The risk of morbidity and mortality of an untreated ruptured aneurysm is 45-50%\textsuperscript{22,23}

Symptoms other than rupture. Aneurysms that present with symptoms e.g., cranial nerve palsy, loss of vision or ischemia, may be at a higher risk of rupture than asymptomatic aneurysms (some symptoms may be due to acute expansion)\textsuperscript{24,25,26,27,28,29}

Size. Large aneurysms (\textgt;7–10 mm) are more likely to rupture than small (<7 mm) aneurysms\textsuperscript{29,30}

Shape. An irregularly shaped aneurysm may be at a greater risk of rupture then a spherical saccular aneurysm. Irregular shape includes morphological characteristics such as daughter blebs, or irregular borders\textsuperscript{31}
Aspect ratio. In addition to size, the aspect ratio (aneurysm depth/neck width) may predict the aneurysms at risk of rupture. An aspect ratio greater than 1.6 may create low flow conditions in the dome of the aneurysm that lead to stasis, thrombosis and a fibrinolytic cascade that results in breakdown of the intima.

A retrospective evaluation of 75 ruptured and 107 unruptured aneurysms, demonstrated the mean aspect ratio to be 2.7 for ruptured and 1.8 for unruptured aneurysms (p < 0.001). The mean depth of aneurysm was also greater in ruptured aneurysms (7.7 ± 4.9 mm vs 5.1 ± 4.5 mm). 75% of the ruptured aneurysms were <10 mm, and 62% of these had aspect ratio >1.6.

Location. The ISUIA studies demonstrated posterior circulation aneurysms had a higher risk of rupture compared to anterior circulation. Conversely, cavernous segment aneurysms had a 0% risk of rupture until they reached a size of 13–24 mm, when the 5 year cumulative risk became 3%.

Choice of treatment. The choice of treatment should take all of above in addition to individual patient considerations e.g., age, and overall health.

---

</tbody>
</table>
Wide necked aneurysms were previously thought better suited for clipping, but the availability of stents that may act as scaffolding for coils e.g., Enterprise™ stent or act as vascular reconstruction devices e.g., Pipeline, has greatly increased the spectrum of aneurysms amenable to endovascular treatment. Additionally, small aneurysms (<4 mm) in size may be less favorable for coiling.

**Endovascular Options**

Coiling. This is the treatment of first choice for most narrow-necked aneurysms. The first coil (framing coil) used is equal to the size of aneurysm, or slightly oversized (especially in unruptured aneurysm). The coils are progressively downsized as embolization progresses. The goal is to maximally pack the aneurysm such that no contrast is seen entering it and without causing any loop to herniate into the vessel lumen. Even after maximal packing, the actual packing is about 20–30%.

Coiling with stenting. For wide-necked aneurysms, a stent may be used to prevent the coils from herniating out of the aneurysm into the blood vessel. When a stent is used, the patient is required to be on ASA (indefinitely) and Plavix (for at least 1 month). Therefore, stent assisted coiling is generally avoided in ruptured aneurysms, in part due to the fact that if an EVD is needed it cannot be safely placed with the patient on Plavix. Therefore, stent assisted coiling is generally avoided in ruptured aneurysms. However, it has also been undertaken successfully in ruptured cases, with 93% technical success, clinically significant ICH in 8% (including 10% known to have EVDs), and significant thromboembolic events in 6%.

Balloon-assisted coiling. This technique may be used for wide necked aneurysms where stenting is deemed less desirable e.g., ruptured aneurysm, since it bypasses the need for dual anti-platelet therapy. A balloon catheter is selected based on the diameter of the artery and the width of the aneurysm neck. The balloon segment of the catheter (indicated by radiopaque markers) is positioned across the neck and kept inflated during coil deposition into the aneurysm. It is deflated prior to coil detachment and the stability of the deposited coil assessed. If the coil appears stable, it is detached. This inflation-deflation technique is continued as required, until the aneurysm has been completely coiled.

Dual catheter technique. In this case two microcatheters are placed in the aneurysm. Coil loops are deposited alternatively from each.

**Coil types.** Bare platinum coils: Guglielmi detachable coils are bare platinum coils that come in various diameters (mm) and lengths (cm). They come as standard, soft and ultra soft, as well as 360˚ and helical configurations.

More recently, the same manufacturer has introduced Target coils. The advantage over GDC is “less kickback” when being deposited in the aneurysm especially during final stages when coiling is near completion.

Other bare platinum coils include Trufill/Orbit coils, Micrus, and Target.

Hydrocoils. Platinum coils coated with hydrogel which expands upon contact with blood filling the residual space between loops.

Liquid embolic agents. A less commonly used technique where a DMSO compatible catheter is placed into the aneurysm and a balloon catheter inflated across its neck, while a liquid embolic agent (e.g. Onyx 500) is injected into the aneurysm. Onyx may be used in sidewall aneurysms that have a wide neck (≥4 mm) or with dome-to-neck ratio <2, that are not amenable to surgical clipping. It may also be used in patients who are allergic to metal (e.g., cobalt, chromium, platinum or tungsten). It is important to keep the balloon catheter inflated until the Onyx solidifies, as otherwise embolization into the normal vessel may produce a stroke.

**Pipeline Embolization Device (PED).** The woven design of this particular stent makes it low porosity which attenuates blood entry into the aneurysm and therefore encourages stasis. If needed, two or more of these may be deployed within each other across the neck of the aneurysm, to cause adequate flow stasis in the aneurysm. Angiography immediately post deployment, demonstrates contrast stasis in the aneurysm. Six month follow up angiography usually demonstrates complete obliteration of the aneurysm, such that it is no longer visualized. Once an aneurysm is successfully treated with PED, there is a 0% recurrence rate. The most recent iteration of the device known as Pipeline Flex™ is a 48 braid device that is somewhat easier to deploy than the earlier version. It is available in diameters from 2.5 – 5 mm. Sometimes, coil deployment in the aneurysm may also be required to encourage aneurysm thrombosis.
A strategy used in case of ruptured aneurysms is to “undercoil” the aneurysm to address the risk of re-rupture and then complete treatment with PED when it becomes safe to use dual antiplatelet therapy.

In case of ruptured blister aneurysms, Pipeline device has been used with success by administering an abciximab bolus (0.125 mcg/kg) IV, approx. 10 minutes prior to device deployment.

Indications:
- Large or giant wide-necked ICA aneurysms, from petrous to the superior hypophyseal segments.
- Presently, patients must be 22 years of age or older.
- PED has been used in cases outside the established indications e.g. in MCA, vertebral and basilar arteries.

Contraindications:
- Ruptured aneurysm (due to requirement of pre-embolization dual anti-platelet therapy). However, it has been used in ruptured blister aneurysms.
- Patients in whom dual anti-platelet therapy is contraindicated.
- Patients who have not received dual anti-platelet therapy (ASA and clopidogrel) prior to procedure.
- Active bacterial infection.
- Metal allergy to cobalt, chromium, platinum or tungsten.
- Patients with pre-existing stent in the parent artery at the target aneurysm location (relative contraindication).

**Treatment of aneurysmal rupture during coiling**
- notify anesthesia: for assistance with critical care management and in case you need to go to the O.R.
- immediately lower the blood pressure
- inflate balloon if balloon-assisted coiling
- immediately reverse anticoagulation. Give 50 mg of protamine (protamine should always be available during the procedure)
- do not remove the coil that caused the perforation, continue deploying it and follow with additional coils in rapid succession
- insert an extraventricular drain (EVD)

### 102.5.2 Endovascular management of vasospasm

#### General information

A ruptured aneurysm needs to be secured by coiling or clipping prior to hyperdynamic therapy or endovascular intervention for vasospasm.

#### Indications

Failure of resolution, or worsening of symptoms of vasospasm with hyperdynamic therapy for 12 - 24 hours.

Patients with conditions such as congestive heart failure, cardiac ischemia or pulmonary edema, that limit the institution of hyperdynamic therapy.

#### Treatment options

In addition to pharmacological (hyperdynamic or triple-H) therapy, endovascular options for management of vasospasm include intra-arterial chemical spasmolysis, utilizing selective catheterization of the involved segment and, mechanical spasmolysis using angioplasty.

Chemical spasmolysis. Verapamil: Drug of first choice for spasmolysis in many centers. Its advantage is a relatively long half-life (6–12 hours).

Indications:
- Mild to moderate vasospasm that does not warrant angioplasty. Or, when angioplasty cannot be used safely.
- Vasospasm consequent to manipulation during endovascular intervention.
- Prior to performing angioplasty, so that the dilatation is performed on the relaxed dilated artery, rather than a relatively rigid vasoconstricted one.
Dose: 5-10 mg injected gradually (over 2–10 minutes) via microcatheter, as the microcatheter is withdrawn through the spasmotic segment. Up to 20 mg may be given into each arterial tree. It is injected gradually to prevent a significant drop in BP or bradycardia.

Other drugs used for chemical spasmolysis include nicardipine, papaverine and nitroglycerine. Similar to verapamil, nicardipine has a relatively long half-life (9 hours). Papaverine (<1 hour) and nitroglycerine (minutes) are comparatively short acting.

Angioplasty. A balloon mounted catheter is positioned across the arterial segment in spasm. The balloon is gradually inflated under fluoroscopic visualization to the desired width (equal to or less than the caliber of the adjacent non-spastic segment. The rate of balloon inflation is at a rate ≤1 atm/15 sec (to “stretch” not “crack” the vessel)

A combination of chemical and mechanical spasmolysis may also be used such that initially the spastic segment is dilated using verapamil infiltration, followed by balloon angioplasty.

Balloon dilatation produces durable results. However, even verapamil induced spasmolysis has been noted to persist on angiographies performed 48–72 hours post treatment.

Angioplasty is performed under direct fluoroscopic visualization. To this effect, contrast media is admixed with normal saline (50:50 to 2/3 -1/3 ratio) that is used to inflate the balloon

Precautions during angioplasty:
- Avoid inflating the balloon beyond the normal caliber of the vessel.
- Inflate gradually at a rate ≤1 atm/15 sec (to “stretch” not “crack” the vessel)
- Do not inflate the balloon beyond its indicated “burst pressure.” This can also be avoided by selecting a balloon catheter of appropriate width of the particular vessel and length of the segment in spasm.

Complications and management. Vessel rupture. This can be avoided by not inflating the balloon beyond the normal caliber of the vessel. Following rupture, reverse therapeutic heparinization by administration of protamine 1 mg. per 100 units of heparin (max. 50 mg). In such an emergency, rapid IV bolus of protamine (10 mg over 1–3 minutes) is delivered rather than over 10 – 30 minutes, which is usually done to prevent idiosyncratic hypotension and anaphylactoid symptoms.

Maintain wire (0.014") access across the injured vessel. Exchange for a balloon catheter 1 mm smaller in size and inflate it for about 20 minutes. Then deflate and perform angiography to see if bleeding has been controlled. Where feasible, use a covered stent to address the perforation. If necessary, sacrifice the involved vessel using coils. With this approach e.g., in the M2 segment of MCA, the complication of stroke is accepted with the aim of saving the patient’s life. Additionally, decompressive craniotomy and evacuation of the clot may be required.

Dissection. If it is minor, non-flow limiting and without a raised intimal flap, no intervention may be necessary. The dissection may be re-examined after an interval to verify resolution. If managed conservatively, place the patient on aspirin, with or without Plavix.

In case of a significant dissection, place a stent across the affected segment and start patient on ASA and plavix. Plavix 75 mg PO daily is usually administered for a month while ASA is continued indefinitely.

Thromboembolic complications. A thrombus consequent to hardware, vessel injury blood stagnation or inadequate heparinization is apparent as a filling defect on control angiography. This can usually be readily addressed by administration of abciximab bolus of 0.25 mg/kg IV over 10–15 minutes, followed by infusion of 0.125 mcg/kg/min (max. 10mcg/min) for 12 hours. Repeat angiography 15 minutes following the initiation of ameiximab. If the thrombus persists, an angioplasty may be performed to flatten the thrombus against the wall of the vessel. Once blood flow is restored, its lytic properties, as well as the abciximab may resolve the thrombus. Another consideration is to deploy a stent to restore lumen and blood flow.

ICH. This may happen due to causes including vessel injury, bleeding into a previous area of infarct, hyperperfusion in a previously compromised area, or hypertension. When detected, discontinue and reverse the heparinization using protamine. Monitor patient closely. A decompressive craniotomy or craniectomy may be required if the hemorrhage is significant.

Surveillance and follow-up. In addition to diligent monitoring in NICU, the progress or resolution of vasospasm can also be assessed by performing serial TCDs. Depending upon extent of availability, these can be daily, every other day or at least bi-weekly (e.g., q Monday and Thursday). The TCDs may be discontinued when resolution of vasospasm is apparent clinically and radiologically.

Angiography may be repeated approximately 3 days following initial intervention, or when there is significant change indicating worsening vasospasm. It need not be repeated, if the patient is
obviously improving. Alternatively, CTA may be used for surveillance. At the time of surveillance angiography, additional treatments with chemical spasmolysis and/or balloon angioplasty may be considered. Therefore, start off with a larger sheath (usu. 6 Fr) to enable intervention.

Usually, the patient will remain in the NICU for approximately 10–14 days considering that vasospasm is maximal by 7–8 days and usually resolves by 14 days,43,44,45,46

102.5.3 Arteriovenous malformation

Indications for endovascular intervention

- The most common form of endovascular intervention for AVM is preoperative embolization to facilitate surgical AVM resection.
- Presence of associated lesions e.g., aneurysm or pseudoaneurysm on the feeding pedicle or nidus, venous thrombosis, venous outflow restriction, venous pouches or dilatations.
- A small surgically inaccessible AVM, or where surgery carries a high risk of morbidity and mortality. Curative AVM embolization is rare and limited to small lesions with simple angioarchitecture. The small surgically inaccessible AVM can also be treated with radiosurgery, which has a better track record than curative AVM embolization attempts.
- As a palliative treatment in an AVM that is not completely treatable by any approach or their combination, due to location and/or diffuse morphology, but is symptomatic. Use with caution: data suggests that partial embolization of complex AVMs may increase rupture rate and worsen outcome.

AVM embolization

This can be performed using numerous agents (or their combination).

The agents include coils, onyx, NBCA and PVA.

Coils. These may be used to close down a vessel supplying the AVM, an AVM pouch or aneurysms on the arteries associated with AVM. However, it cannot be relied upon to completely obliterate the AVM nidus, or effect a cure.

Onyx™. A “lava-like” liquid embolic agent – Ethylene vinyl alcohol (EVOH) copolymer; ethylene and vinyl alcohol dissolved in dimethyl sulfoxide (DMSO) with micronize tantalum (for radioopacity) – that solidifies through the process of precipitation which is initiated when it comes into contact with an aqueous solution (e.g. blood, body fluids, normal saline, water) to form a cast. Not an adhesive. Amongst all agents currently available, it has the best and most controlled penetration of the AVM nidus. Therefore, Onyx has the greatest likelihood of achieving complete cure. Complete cure rates with onyx alone are possible in 20 – 51% of highly selected patients.47,48,49 Supplied in premixed ready-to-use vials of Onyx-18, Onyx-34 and Onyx-500 in which the number (e.g. 18 for Onyx-18) corresponds to the nominal viscosity (as measured in centistokes) which the manufacturer controls by altering the EVOH concentration. Prior to use, the product must be shaken on a mixer for at least 20 minutes. Higher numbers indicate greater viscosity. Onyx 18 is most commonly used, Onyx 34 is used for very high flow AVMs, while 500 is used for aneurysm embolization.

Onyx is used with DMSO compatible microcatheters (marathon, echelon, rebar, ultra flow) that have been primed with approximately 0.3 to 0.8 ml of DMSO injected slowly through the microcatheter (depending on the deadspace of the microcatheter) prior to injecting Onyx itself. This is done to eliminate any contrast, saline or blood within the microcatheter that will cause the onyx to solidify in the catheter. The microcatheter tip is wedged in an arterial branch supplying the AVM, as close to the nidus as possible. It is ensured that the branch is exclusively supplying the AVM, by performing angiography through the microcatheter. The microcatheter is then primed with DMSO and Onyx embolization commenced under fluoroscopy. The onyx is visible due to admixed tantalum powder. It is injected slowly and continuously avoiding too much force, as this could cause the Onyx to reflux instead of flowing forward and prematurely close off access to the nidus. No more than 1 cm of Onyx reflux on the microcatheter should usually be allowed, as it may make the removal of catheter difficult later and may well cause disastrous complications. If reflux is noted, wait for 1–2 minutes and then continue with the injection. The already deposited Onyx will form a plug around the microcatheter causing the new deposit of Onyx to flow forward. The injection is stopped once Onyx is noted only to reflux and not flow into the nidus. Care is taken not to allow the Onyx to flow into the major draining vein or sinus, especially before the entire arterial supply is interrupted. The concept is the same as in surgical removal of AVMs, where major draining veins are occluded only after eliminating the arterial supply of AVM. Otherwise, the result is the same with ensuing venous
hypertension resulting in AVM rupture and catastrophic ICH. In case of a large AVM, it is sometimes best to stage the procedure, addressing one major arterial tree at a time.

Intravenous or combined IV, and IA embolization of AVM has been performed in a select group of small, deep seated AVMs, with single deep drainage.\(^5^0\)

NBCA. N-butyl cyanoacrylate is an embolic agent that is a glue which rapidly solidifies when it comes in contact with blood. Since the introduction of Onyx, its use has declined considerably due to the drawbacks of very short working time, greater risk of embolization into venous sinuses and, adhesion to catheters rendering their extraction following embolization difficult. Such adhesion may cause inadvertent catheter fractures with retained foreign body, or intracranial bleeds.

PVA. Polyvinyl alcohol (PVA) particles are available in sizes ranging from 50 to 1000 \(\mu\)m. While it may be useful in temporarily devascularizing the AVM e.g., in preparation of craniotomy and surgical resection of AVM, the endovascular treatment with PVA alone is not durable.

Postoperative Management

Post-op orders:
- Admit the patient to NSICU.
- Keep leg on side used for procedure straight \(X\) 2 hrs (in case of angioseal closure) or 6–8 hours (in case manual compression was applied), with HOB elevated 15\(^\circ\).
- Post procedure heparinization is not required with AVMs because most ischemic events occur during the procedure and are related to the passage of embolic materials into normal blood vessels.\(^1^1\)
- Check groins, DP’s, vitals and neuro checks q 15 min X 4, q 30 min X 4, then q hr.
- Maintain mild hypotension for 12–72 hours especially in case of larger AVMs and monitor the patient for perfusion pressure break through bleeding, seizures and other possible complications.
- Review/Resume preprocedure medications (Hold metformin for 48 hours after intervention; hold all oral hypoglycemics, until good PO intake established).\(^5^1\)

Follow-up:
- Outpatient appointment in 4 weeks.
- Follow-up angiography at 3 months. In case of staged AVM embolization, the interval between sessions is at the discretion of the endovascular neurosurgeon e.g., 1–4 weeks apart.

102.5.4 Dural arteriovenous fistulae (DAVF)

General information

These are abnormal direct arteriovenous shunts within the leaflets of dura.

Classification

There are numerous DAVF classifications. Borden (p. 1252) and Cognard (p.1252) are amongst the more widely used.

Indications for endovascular intervention

- DAVF with “aggressive” features (Table 102.3) are always considered for treatment. Due to the high annual mortality rate (10.4%) and annual hemorrhage rate (8.1%), the treatment should be expeditious.\(^5^2\)

</table>
• DAVF with angiographic findings including:
  ○ Selective contrast injection into ICA or VA demonstrating delayed cerebral circulation time. The
    is indicative of venous congestive encephalopathy.
  ○ Pseudophlebitic pattern: Brain surface demonstrating tortuous, dilated collateral veins in the
    venous phase of the angiogram. This finding is associated with a greater risk of hemorrhage, or
    non-hemorrhagic neurological deficit.
  ○ Cortical venous reflux (CVR). To ensure that this is not missed, always perform selective (rather
    than global, non-selective) angiography when assessing for DAVF. Venous stenosis or obstruct-
    tion is commonly found in patients with CVR.

If a DAVF is detected, look for additional fistulae, as they are multiple in up to 8%

Those with “benign” features (see Table 102.3), may be considered for treatment if the symp-
toms are causing considerable discomfort to the patient, or are angiographically progressive. In
many cases the treatment is palliative i.e., the symptoms are reduced but the fistula is not com-
pletely obliterated. The benign type of DAVF should continue to be followed, even when treatment is
not indicated because of the risk of conversion to a more aggressive form with CVR. The follow-up
may be clinical, with radiological assessment for any change in symptoms. A suggested protocol is to
perform MRA with gadolinium annually, with follow-up conventional catheter angiography at 3
years. If there is any change in the patient’s clinical condition, whether it is worsening, improvement
or resolution of the symptoms, perform standard angiography to assess for CVR.

Asymptomatic DAVF can usually be followed.

Contraindications to endovascular intervention

Most contraindications are relative, and a risk benefit assessment is performed on a case by case
basis:
- Provocative tests demonstrating intolerance to occlusion
- Recent major surgery
- Pregnancy
- Contraindication to anticoagulants and/or thrombolytics.
- NBCA should not be used in those with allergy to cyanoacrylates, ethiodol or iodine. Premedica-
tion in those with iodine allergies is a consideration.
- PVA should not be used as a therapeutic option (other than in cases of epistaxis). It is usually indi-
cated for pre-surgical devascularization of lesion.

DAVF embolization

The approach can be transarterial, transvenous or a combination. When feasible, a transvenous
approach is preferred, as the probability of fistula obliteration is greater via the venous route. Very
infrequently, it is possible to access the venous side from the arterial route because of a large connec-
tion between the dural artery and adjacent vein e.g., in traumatic DAVF. This is usually not possible
in spontaneous DAVF, as the feeding artery is too small.

For transvenous route, consider the potential outcome of venous occlusion e.g., venous infarct, if
the sinus being occluded is also the main source of drainage for normal veins. In such a situation, consider highly selective occlusion that will spare the normal drainage. Alternatively, instead of per-
forming a complete occlusion, consider partial treatment only such that CVR is eliminated, conver-
ting the fistula into the benign Borden type I.

When using the venous route, ascertain that the venous channel is not tenuous (e.g. acute DAVF)
rendering it prone to rupture during manipulation. The venous walls become sturdier when the fis-
tula has been present for a while.

Coils. Measure the maximum width of the fistulous site to be occluded and select the appropriate
sized coils. Deposit as many coils as necessary to occlude the fistula.

Sometimes a “combined” strategy may be used, where initially coils are deposited to slow the
rapid blood flow through the fistula, followed by occlusion using a liquid embolic agent. If this strat-

egy is used, start off with or exchange for a microcatheter compatible with the liquid embolic agent.

Onyx. During transarterial embolization with liquid embolic agents, wedge the catheter as close
as possible to the fistula. The technique of deposition is the same as for AVM (see above). It is impor-
tant to disrupt the fistulous connection to achieve cure. Therefore, Onyx must penetrate into the
venous aspect of the DAVF.
NBCA. It is used less frequently since the availability of Onyx, for reasons described above.

PVA. It really has no significant role in the treatment of DAVF.

102.5.5 Carotid cavernous fistulae (CCF)

General information
CCF categorized as direct and indirect. The direct type are usually posttraumatic and are a high-flow single shunt between the ICA and the cavernous sinus. Indirect are low flow from meningeal branches. The section below describes management of direct type.

Indications for endovascular intervention
Direct fistulae usually require treatment as they frequently do not resolve spontaneously. Other indications: corneal exposure, diplopia, proptosis, intolerable bruits or headaches.

Timing of treatment
If the patient is stable, treatment may usually be performed within a couple of days of the diagnosis (i.e., treatment does not have to be emergent).

Indications for urgent treatment: ICH, epistaxis, increased IOP, decreased visual acuity, rapidly progressive proptosis, cerebral ischemia and enlargement of traumatic aneurysm beyond the cavernous sinus.

CCF embolization
The treatment goal is to eliminate the fistula.

Angiography is performed to identify the exact location and size of the fistula and its venous drainage. To address the high flow, consider angiography at 7.5 fps, instead of the usual 2–4 fps. In addition to the CCF, also look for other vascular injuries/anomalies.

Selective catheterization of both ECAs and ICAs are performed, to assess their contribution to the CCF. Angiography is also performed after manual compression of the CCA on the side of fistula, to better assess cross flow from the contralateral side. The digital compression will attenuate the high blood flow to the fistula, enabling its visualization. Do not compress both carotids simultaneously.

Rotational angiography with 3D reformatting, may be performed to study the fistula and select appropriate working views for intervention. It is important to be cognizant of the venous involvement including, cavernous sinuses, superior and inferior ophthalmic veins, sphenoparietal sinus, superior and inferior petrosal sinuses and the pterygoid plexi.

The following routes may be utilized for treating CCF: Transarterial; transvenous; and, via superior ophthalmic vein (if conventional routes are not available). Other indications: corneal exposure, diplopia, proptosis, intolerable bruits or headaches.

Coils. Currently, the method of choice is transarterial coil embolization of the CCF.

Using roadmapping, the microcatheter is advanced over microwire into cavernous sinus via the fistula. This may take some effort. Coils are then deployed and detached, as previously described for aneurysms. Periodic angiography is performed and further coils placed, until the cavernous sinus (CS) is completely occluded. Complete occlusion is indicated by no further contrast entering the CS.

Onyx. Refer to AVM section (p. 1589) for details regarding usage. In case of a high flow fistula, prior to Onyx deposition, it may be advisable to initially deposit coils into the CS to slow the blood flow. This will prevent the inadvertent embolization of Onyx into the draining veins and sinuses. A balloon can be inflated within the parent ICA in order to protect it as Onyx is being injected into the cavernous sinus.

NBCA. NBCA should be used with great caution, preferably after having slowed the flow through the CCF in order to prevent untoward deposition in the venous sinuses.

There is also potential for reflux into the carotid artery, which could cause a stroke. This may particularly occur when the CCF closure is near completion and the pressure gradient between the carotid artery and the CS is lowered. As with Onyx, a balloon can be inflated in the parent artery to protect it.
Detachable balloons. Balloons were initially utilized with success for endovascular CCF treatment and remain available outside of the US; however, these balloons are no longer available in the US due to technical concerns relating to premature detachment and deflation over time.

Coil occlusion of the ICA. The desirable treatment for CCF is the occlusion of the fistula itself, essentially resulting in ICA reconstruction. This is frequently not possible. If the CCF is not amenable to treatment by any other route, sacrifice of the involved ICA is an option, especially if satisfactory supply has been confirmed from the contralateral ICA via anterior communicating and/or supply via the posterior communicating arteries.

Post-operative management and follow up
Post-op orders:
- Admit the patient to NSICU for overnight observation. Further ICU stay will depend upon the patient’s clinical condition.
- Consult or arrange follow up with ophthalmic surgery.
- 0.9%NS+20 meq KCl @ 150 cc/hr X 2 hrs, then decrease to 100 cc/hr if patient is NPO overnight, then advance diet as tolerated.
- Keep the leg that was used for procedure straight for 2 hrs in case of Angioseal closure, or 6–8 hours when manual compression was applied. May elevate 15° HOB e.g., a pillow under the head.
- Check groin, DPs, vitals and neuro checks q 15 min X 4, q 30 min X 4, then q hr
- Review/Resume preprocedure medications (Hold metformin for 48 hours after intervention; hold all oral hypoglycemics, until good PO intake established).

Follow-up:
- D/C next morning after mobilizing, if there are no complications/other ongoing medical concerns requiring hospitalization.
- F/u on outpatient basis in 4 weeks.
- F/u angiography at 3 months.

102.5.6 Vertebrojugular fistulae (VJF)

Etiologies
- Iatrogenic e.g., during spine surgery or angiography, chiropractic manipulation, nerve block injection or radiation therapy
- Trauma e.g., penetrating injury, or GSW
- Vasculitis

Endovascular management of VJF

Stenting. A polytetrafluoroethylene (PTFE) covered stent, e.g., Jostent, may be used to cover the ostia of the fistula.

Coil occlusion. In the presence of adequate blood flow through contralateral healthy vertebral artery, the fistulous artery may be occluded with coils. Verify that the arterial wall with the fistulous connection is part of the occluded segment.

NBCA occlusion. Rarely, NBCA occlusion has been performed when stenting or coils occlusion were not possible. Onyx may also be used similarly.

102.5.7 Carotid dissection

General information
See general information (p. 1324).

Angiographic features
Luminal stenosis (65%), occlusion (28%), pseudoaneurysm (28%), luminal irregularity (13%), embolic distal branch occlusion (13%), intimal flap (12%) and slow ICA-MCA flow (11%).
Management
The initial management in the absence of ICH is intravenous heparin for 7 days followed by warfarin. The goal aPTT with heparin is 1.5 – 2.0 times the control value (50–80 sec). Warfarin is continued for 3–6 months with target INR range of 2.0 – 3.0. If anticoagulation is contraindicated, anti-platelet therapy is a consideration. In pregnant individuals, obtain obstetric consultation prior to initiating anticoagulation or anti-platelet therapy.

Indications for endovascular intervention

- Persistent ischemic symptoms despite anticoagulation therapy.
- Flow-limiting lesion with hemodynamic compromise

Contraindication to anticoagulation and/or anti-platelet therapy

- Impending risk of stroke
- Expanding pseudoaneurysm formation
- Iatrogenic dissection during endovascular procedure where flow compromise is apparent

Stenting with/without coiling

The endovascular treatment for carotid dissection is stenting. In case of intimal flap, the stent will appose the flap back to the arterial wall. Pseudoaneurysms have also been successfully occluded with stenting. Both uncovered and covered stents have been used successfully. JoStent is a PTFE covered stent that is available in US. A vein covered stent has also been used.

In case of a pseudoaneurysm that continues to show significant residual filling after stenting, coiling of the pseudoaneurysm will cause occlusion.

After stenting, the patient remains on dual antiplatelet therapy (ASA + Plavix) for at least a month and ASA alone indefinitely.

Follow-up

Follow-up should be arranged for patients on warfarin (e.g., “Coumadin clinic”). Follow-up study in 3–6 months, which could be CTA, Doppler ultrasonography or catheter angiogram.

102.5.8 Subclavian artery stenosis

General information

Radiologically demonstrable stenosis of the subclavian or innominate artery is present in approximately 17%. Of these, 2.5% have angiographic flow reversal in vertebral artery. Only 5.3% of those with angiographic steal have neurologic symptoms.

Symptoms. The 5 D’s of VBI i.e., diplopia, dysarthria, defective vision, dizziness and drop attacks. Other symptoms include headache, nystagmus, hearing loss and focal seizures.

The arterial stenosis is proximal to the origin of VA. Symptoms are induced by exercise or exertion using the arm ipsilateral to the stenosis. The increased flow demand due to the exertion results in retrograde blood flow through the VA. The neurological symptoms may be because of continuous brainstem ischemia or more commonly, ischemia due to ipsilateral arm exercise or exertion.

Indications for endovascular intervention

Symptomatic subclavian artery stenosis i.e., stenosis resulting in subclavian steal syndrome.

Endovascular intervention

This includes angioplasty and stenting. A balloon mounted stent e.g., Express LD may be used, as the stent is deployed concurrently with angioplasty. However, if the stenosis is particularly severe (e.g., <2 mm), pre-dilatation may be performed by a smaller balloon to achieve a caliber of 4 mm at site of stenosis. Normal antegrade blood flow is restored following successful angioplasty and stenting.
Postoperative management
The patient is monitored at least overnight in NSICU.
After stenting, the patient remains on dual antiplatelet therapy (ASA + Plavix) for at least 1 month, and ASA alone indefinitely.
Follow-up study in 3–6 months, which could be CTA, Doppler ultrasonography or catheter angiogram.

Complications of angioplasty and stenting
The frequency of complications is 17.8% (of 73 procedures) for innominate and VA angioplasty and stenting. These include access-site bleeding and distal embolization.\(^{67}\)

102.5.9 Ischemic Stroke

IV tPA
The target time for IV tPA administration (“door to needle time”) is within 60 minutes from time of arrival to hospital. However, IV tPA can be administered up to 4.5 hours after the onset of symptoms if the patient does not have any contraindications.\(^{68}\)
Dose: 0.9 mg/kg (max 90 mg) with 10% of the dose administered as a bolus over 1 minute and the rest infused over 60 minutes.

Endovascular intervention

General information
Recent studies have established the effectiveness and relative safety of endovascular intervention. These trials favor rapid endovascular intervention in acute ischemic stroke with proximal vessel occlusion, small infarct core and moderate to good collateral circulation.\(^{69,70,71,72}\)

Indications and case selection for endovascular intervention
Intra-arterial tPA may be indicated for the following situations:
- Persistent symptoms of stroke despite IV tPA and adequate medical management
- Where angiography may be performed and treatment administered within 3 and 6 hours after symptom onset with an NIHSS score greater than 4, or those with an NIHSS score of greater than 20 and the ability to be treated within 6 hours
- Posterior circulation strokes may be treated endovascularly for up to 24 hrs (due to a lesser likelihood of hemorrhagic conversion of infarct)
- CTA or MRA demonstrating a diffusion-perfusion mismatch. In face of significant penumbra, it may be worthwhile to perform endovascular intervention even outside the therapeutic window. Conversely, intervention may be abandoned even within the therapeutic window, if the stroke is complete. Centers are relying more and more on neuroimaging rather than the therapeutic window
- When IV tPA is contraindicated e.g., recent surgery

Contraindications to intervention
Most contraindications are relative and have to be weighed against the risk of not intervening. These contraindications include:
- Hemorrhagic infarct or, ICH
- CT demonstrating hypodensity or mass effect consistent with evolving infarct of more than one-third of middle cerebral artery territory
- Recent major surgery
- Pregnancy
- When considering stenting, contraindication to anticoagulants and/or thrombolytics

Preprocedural management
This may be under the supervision of a stroke neurologist, or the neurosurgeon. Ensure the following:
- Rapid transfer of patient to a stroke center/facility with endovascular capabilities.
- ABC’s take precedence.
• Ensure patient has two intravenous lines, preferably 18G or larger. Start monitoring BP, pulse oximetry, ECG, O₂ saturation, cardiac rate and rhythm, respiratory rate. Insert a Foley catheter.
• Verify laboratory values including Platelet count, BUN, CR, APTT, PT/INR. β-HCG for females of reproductive age group.
• Maintain MAP ≥ 90 mm Hg.
• CT scan head: To rule out ICH.
• CTA: To assess location of the clot (hyperdense artery sign (p.1281)) and vascular tortuosity.
• MRI head (select cases).
• If available and can be done without delay, then perfusion studies e.g., CTP or MRP. These perfusion studies will demonstrate viable brain (penumbra) vs completed stroke.
• In centers where available, CT, CTA and CTP all are performed during the same session on CT scanner.
• Be cognizant of renal insufficiency, diabetes, congestive heart failure etc., in which case consider diluted non-ionic contrast agent and carefully pre-plan, to maintain contrast load to minimum.
• If the patient is not responding to IV tPA or if it is contraindicated, then endovascular intervention is considered.
• The goal of intervention is to re-establish circulation, as soon as possible.

Techniques

Stent retrievers. Due to higher success rate, stent retrievers have become the method of first choice for clot removal in embolic stroke. The recanalization rate is 88.8% – 100%73,74,75,76 The two devices currently available in USA are Solitaire and Trevo. A 7 or 8 Fr sheath is placed in the femoral artery, through which a 6 Fr balloon guide catheter is positioned in the ICA (in case of anterior circulation strokes). Angiography is performed to identify site of occlusion. Using fluoroscopy and road mapping, a microcatheter is advanced over a microwire, across the site of occlusion. The microwire is removed and the stent retriever is advanced through the microcatheter such that it extends proximal and distal to the clot. The stent retriever is unsheathed by retracting the microcatheter as the retriever is maintained stationary. The stent retriever expands to its actual size and this results in restoration of flow in the occluded artery. After five minutes, the balloon on the guide catheter is inflated to arrest blood flow. Maintaining gentle aspiration on the guide catheter, the stent retriever and microcatheter are retracted simultaneously. Once both the microcatheter and retriever are within the guide catheter, vigorous aspiration is applied as the two devices are concurrently retracted and removed from the patient. Angiography is performed to confirm reconstitution of circulation.

Some surgeons administer a small amount of i.a. tPA as ‘mop up’ after mechanical thrombolysis, to address potential distal debris.

Vessel perforation during stent retriever withdrawal has been reported.77

Penumbra aspiration. Until the introduction of stent retrievers, the penumbra device boasted the highest recanalization rate. A recanalization rate of >80% is quoted in literature.78,79 This device includes a microcatheter that is advanced over a microwire, through the positioned guide catheter. The tip of the microcatheter is positioned adjacent to the proximal aspect of the clot. A separator is advanced through the microcatheter that is advanced back and forth through the clot to disrupt it. The proximal end of the microcatheter is connected to an aspiration pump that is turned on to aspirate the clot fragments.

Unlike stent retrievers that affect recanalization within minutes, Penumbra aspiration device takes longer, with median time of 49 min.80 Its use is confined to the straight arterial segments because of risk of vessel perforation by the separator action.

Intra-arterial tPA. This may be the simplest endovascular technique to undertake, when compared to above. However, on its own, while the recanalization rates may be better than IV tPA, they are inferior to the above-mentioned mechanical techniques.81,82 Currently, i.a. tPA is used in conjunction with other techniques in ischemic stroke.

In addition to above, other techniques to extract thrombus have also been employed with mixed results including, aspiration with a simple syringe attached to a microcatheter, usage of snares, angioplasty at site of thrombus, stenting etc.

102.5.10 Cranial sinus thrombosis

General information

Also see Cerebrovascular venous thrombosis (p.1308).

Hydration with IV fluids and IV anticoagulation are part of the initial treatment for cranial sinus thrombosis (CST). Prior to initiation of treatment, blood for hypercoagulopathy tests is drawn.
Indications for endovascular intervention

- Persistent ischemic symptoms despite anticoagulation therapy.
- Contraindication to anticoagulation and/or anti-platelet therapy including hemorrhagic infarct.
- Impending risk of stroke.

Endovascular treatment

Chemical Thrombolysis: A catheter may be advanced to the involved sinus or close to it, through the femoral vein. The advantage of local administration is that, a larger amount of tPA actually reaches the clot vs systemic administration through a peripheral vein. Usually, 2–5 mg are administered through the thrombus and then an infusion started at a rate of 1 mg/hr, usually for 12 hours. If clot burden is still there on angiography, the infusion may be continued for longer, until the clot resolves.

For CST, the infusion may be prepared in a concentration of 1 mg/10 ml (0.1 mg/ml), for a rate of 10 ml/hr.

Mechanical Thrombolysis: Similar to arterial embolic stroke, devices such as Stentriever or Penumbra may be used for clot extraction. Additionally, devices intended for other sites e.g., clot extraction from dialysis fistula, have also been used in cranial sinuses. The challenge during endovascular intervention is negotiating the sigmoid-transverse sinus junction especially when using bulkier catheters e.g., AngioJet.

102.5.11 Tumor embolization

Indications

Preoperative devascularization of vascular tumors including
- meningiomas: embolization for meningiomas is location specific, size dependent, institution dependent, and potentially controversial. May be best reserved for large hypervascular convexity meningiomas. Usually performed 24 hours to 1 week preoperatively. The devascularization causes attenuation in intraoperative blood loss and the resultant necrosis frequently renders the tumor softer and easier to remove. However, tumor swelling may occur and occasionally an emergency craniotomy may be required.
- hemangiopericytomas
- juvenile nasopharyngeal angiofibromas
- glomus jugulare tumors
- hemangioblastomas
- vascular metastases

Technique

A sheath is placed in the femoral artery and a guide catheter is positioned as close as possible to the vessels of interest e.g., in case of a meningioma the guide catheter tip is positioned in the proximal ECA. Angiography and roadmapping are performed through the guide catheter. Using fluoroscopy and road mapping, a microcatheter is advanced over wire into the branches supplying the tumor. Angiography is performed through the microcatheter to ascertain the branch supplies the tumor and no concerning collaterals with intracranial circulation exist. A blank road map is obtained and embolization commenced. PVA particles or Onyx may be used for embolization. In case of Onyx, a DMSO compatible catheter must be used. PVA may be cheaper and quicker to use for tumor embolization. However, the devascularization is not durable and the occluded vessels may recanalize; therefore, with PVA the surgery should be performed within a few days of the embolization.

102.5.12 Intraoperative angiography

Typically used in aneurysm surgery to confirm exclusion of the aneurysm from the circulation and to verify patency of critical adjacent vessels, and during AVM surgery to confirm total elimination of the nidus.

1. using traditional iodinated contrast and fluoroscopy. Requires use of radiolucent headholder.

2. indocyanine green (ICG): can be visualized under normal light, or sometimes to better advantage when illuminated with near-infrared light. Use is restricted to surface vessels. May be less reliable with giant or wide-neck aneurysms or with thickwalled atherosclerotic
102.5.13 Refractory epistaxis

Indications
Epistaxis that has not responded to treatment including manual compression, nasal packing, local vasoconstrictors, endoscopic cautery or surgical ligation of sphenopalatine arteries

Preoperative management
Verify lab values including Platelet count, BUN, CR, APTT, PT/INR, and ß-HCG for females of reproductive age group. In renal insufficiency, diabetes, CHF etc., use diluted non-ionic contrast agent and pre-plan carefully to maintain contrast load to minimum.

 Liquids only on morning of procedure. NPO (for ∼6 hours) when procedure performed under general anesthesia.

 Obtain informed consent for angiography and embolization of ECA branches

 Ensure two I.V. lines inserted. Insert Foley. The patient will be more comfortable and cooperative with an empty bladder, if the procedure becomes prolonged.

 Technique. Position patient on the neuroangiography table. Attach pulse oximetry and ECG leads for monitoring O₂ saturation, HR, cardiac rhythm respiratory rate and BP.

 A sheath is placed in the femoral artery. A guide catheter is positioned in the proximal ECA on the side of bleeding or pathology. Angiography and roadmapping are performed through the guide catheter. Using fluoroscopy and road mapping, a microcatheter is advanced over the wire into the sphenopalatine branches. Angiography is performed through the microcatheter to ascertain appropriate positioning and to ensure no concerning collaterals with intracranial circulation exist. Contrast extravasation, tumor blush or pseudoaneurysms may be detected. A blank road map is obtained and embolization of the offending vessel commenced. PVA particles (250–300 mcg/m) or Onyx (18 or 34) may be used. In case of Onyx, a DMSO compatible catheter is used. PVA may be cheaper and quicker to use.

Postoperative management
Post-op orders:
- Admit to ICU for overnight observation. Typically, nasal packing is left intact overnight and removed for inspection for bleeding the next day
- IV: 0.9% NS + 20 meq KCl @ 150 cc/hr X 2 hrs, then decrease to 100 cc/hr, if patient is NPO
- Activity: Keep right/left leg (whichever side was used for procedure) straight for 2 hrs (in case of Angioseal closure), or 6–8 hours (in case manual compression was applied), with HOB elevated 15°. This is achieved by placing a pillow under the patient’s head. There should be no flexion in the femoral region. If more head elevation is required, place bed in reverse-Trendelenberg position.
- Check groins, DP’s, vitals and neuro checks q 15 min X 4, q 30 min X 4, then q hr.
- Advance diet as tolerated. Review/resume preprocedure medications (except oral hypoglycemics, until good PO intake established).

Table 103.17: Measures to treat an acute ICP crisis (Table 56.6), see text for details (p. 869)

Check airway, neck position... For resistant or sudden IC-HTN, consider STAT unenhanced head CT

Be sure patient is sedated and paralyzed

Drain 3–5 ml CSF if IVC present

Osmotic therapy: mannitol 1 gm/kg IV bolus or 10–20 ml of 23.4% saline

Hyperventilate: to PaCO$_2$ 30-35 mm Hg

Pentobarbital 100 mg slow IV or thiopental 2.5 mg/kg IV over 10 minutes

Table 103.18: Summary of initial steps for status epilepticus: adults and children >13 kg (Table 27.5), see text for details (p. 469)

- Turn patient on their side. Check VS. Neuro exam
- Monitor/labs: Pulse oximetry. EKG/telemetry. Fingerstick glucose. Blood tests (do not wait for results to begin): electrolytes, CBC, ABG, AED levels, LFTs, Mg$^{++}$, Ca$^{++}$, head CT
- thiamine 100 mg IV and/or 50 ml of 50% dextrose (if needed)

First-line AED:
- lorazepam (Ativan®) 4 mg IV for adults, 2 mg IV for children >13 kg @<2 mg/min
  Repeat dose if necessary

Second-line AED: given with failure of (or simultaneously with administration of) repeat dose of benzodiazepine
- fosphenytoin: 15-20 mg PE/kg IV @ 150 mg PE/min (preferred drug: faster infusion rate, less irritation)
  OR
- phenytoin: 15-20 mg/kg IV @ 50 mg/min (less expensive) If no response to loading dose, an additional 10 mg/kg IV may be given after 20 min.
  NB: following infusion rate guidelines is imperative

  phenytoin level ≈ 10 min after PHT loading dose; repeat 10 min later additional dose if required

Alternative second-line AEDs:
- sodium valproate: 20-30 mg/kg IV bolus (max rate: 100 mg/min)
  OR
- phenobarbital: 20 mg/kg IV (start infusing @ 50-100 mg/min). A repeat dose of 25-30 mg/kg can be given 10 min after first dose.
  OR
- Levetiracetam (Keppra®): 20 mg/kg IV bolus of over 15 minutes – evidence less clear

If seizures continue >30 mins and are refractory to 1st and 2nd line AEDs: intubate in ICU and begin continuous infusion therapy (CIT) of:
- Midazolam: 0.2 mg/kg IV loading dose followed by 0.2-0.6 mg/kg/hr
  OR
- Propofol: 2 mg/kg IV loading dose followed by 2-5 mg/kg/hr

* option for failures with NIHSS>8-10
** from 6-8 hrs, check perfusion before mechanical embolectomy

Fig. 103.3 Spinal nerve root sensory dermatomes (Fig. 1.14), see text for details (p.73) (Redrawn from “Introduction to Basic Neurology”, by Harry D. Patton, John W. Sundsten, Wayne E. Crill and Phillip D. Swanson, © 1976, pp 173, W. B. Saunders Co., Philadelphia, PA, with permission)
Index

5
5-aminolevulinic-acid (5-ALA) guided resection of gliomas 621

2
21-aminosteroids, for severe TBI 875

24 month rule (for peripheral nerve repair) 510

A
abciiximab, for endovascular neurosurgery 1576
abdominal cutaneous reflex 951
— in multiple sclerosis 180
abdominal pseudocyst, see pseudocyst - abdominal
abducens nerve 87
— palsy of 567
— as false localizing sign 567
— due to brainstem compression 1303
— due to clival fracture 885
— due to elevated ICP 567
— due to elevated ICP from tumor 592
— following lumbar puncture 1507
— in Gradengo’s syndrome 570
— in pseudotumor cerebri 768
— in trauma 829
abduction relief sign 1070
abductor sign 1049
ablative surgery, for Parkinson’s disease 1526
abscess
— cerebral 320
— from gunshot wound 908
— MR spectroscopy findings 234
— Nocardia 335
— toxoplasmosis 332
— treatment 324
— spinal epidural 349
absence seizure
— absence status epilepticus 473
— definition 440-441
acalculia 98
ACAS, see either asymptomatic carotid stenosis, or Asymptomatic Carotid Atherosclerosis Study
ACDF, see anterior cervical disectomy
acetaminophen 137
acetazolamide
— challenge, with CTP 228, 1265
— for CSF fistula 388
— for hydrocephalus 414
— for Meniere’s disease 575
— for pseudotumor cerebri 772
— for seizures 455
— IV 455
— side effects 455
acetazolamide challenge, with SPECT for NPH 405
achondroplastic dwarf 1096
— and macrocephaly 1404
— and myelopathy 1407, 1413
acid inhibitors 129
acid pump inhibitors 130
ACNU 595
acoustic neuroma, see vestibular schwannoma
acrocephaly 253
acro-egy 725
— and hyperostosis frontalis interna 780
— biochemical cure criteria 753
— evaluation 736
— growth hormone endocrinology 151
— management 741
— outcome following treatment 753
— reversibility of abnormalities 726
— treatment
— medical treatment 741
— radiation therapy for 745
ACST, see Asymptomatic Carotid Surgery Trial
activity modifications for low back problems 1034
acupuncture 1036
acute cerebellar ataxia 1398
acute confusional state 174
acute intermittent porphyria 111, 547
acute intermittent porphyria varicella-zoster leukoencephalitis 366
— encephalopathy 330
— from cadaveric bone graft 1073
— management of intracerebral lesions 332
— neurologic manifestations 329
— neuropathy 347
— in pseudotumor cerebri 768
— toxoplasmosis abscess treatment 333
AIN, see anterior interosseous nerve
— neuropsych pathy
— air embolism 1445
— akinetic mutism 1406
— alar ligaments 70
— ALL 224
albendazole
— for echinococcosis (hydatid cyst) 375
— for neurocysticercosis 374
— albumin
— for hyperdynamic therapy 1185
— albuminocytologic dissociation 185
— alcohol (ethyl), see ethanol
— alcohol withdrawal seizures, see ethanol - withdrawal seizures
— alendronate, for osteoporosis 1010
— alexia without agraphia 98
— Alexia without alexia 98
— algie 18
— ankylosing spondylitis 185
— amyotrophic lateral sclerosis
— admission criteria
— adrenal crisis (adrenal insufficiency) 147
— Addisonian crisis 147
— and macrocephaly 1404
— and meningitis (Waterhouse-Friderichsen) 318
— precipitated by ketoconazole 743
— precipitated by steroid withdrawal 144
— precipitated by stress 146
— precipitated by thyroid replacement 144
— adrenal crisis (adrenal insufficiency) 147
— adrenal tissue transplantation, for parkinsonism 1525
— adenectomy
— and Nelson’s syndrome 743
— for Cushing’s disease 743
— adenocorticotropic hormone, see corticotropin
— adult Chiari malformation 277
— adult degenerative scoliosis 1111
— adult deformity 1111
— AED, see antiepileptic drugs
— affrent papillary defect 561-562
— Affix™ interpositional fusion plate 1106
— AFO, see ankle-foot-orthosis
— afterloading catheters 1572
— agenesis of the corpus callosum 257, 259, 285
— Aggrenox® (dipyridamole/aspirin)
— 1275
— agraffesthesia 98
— agryria 287
— Ahumada-del Castillo syndrome 722
— Aicardi syndrome 260
— AIDS 329
— AIDS related myelopathy 1410
— and CNS lymphoma 331-332,
— transudtion 155
— and infectious aneurysms 1228
— and neurophilis 331
— and varicella-zoster leukoencephalitis 366
— from gunshot wound 908
— and medico-tumor cerebri 772
— in meningitis (Waterhouse-Friderichsen) 318
— in pseudotumor cerebri 768
— in trauma 829
— abduction relief sign 1070
— abductor sign 1049

— dorsally exophytic 634
— tectal glioma 634
brainstem nodules (in hydranencephaly) 288
brainstem syndromes 99
breakthrough bleeding
— following AVN surgery 1245
— following carotid endarterectomy 1292
breach 651
brevicollis 272
bridge therapy 164
bright spot in pituitary gland 737
bridged-base disc herniation 1025
Broca’s (motor) aphasia 98
Broca’s area 58, 1466
Brodmann’s areas 58
Index 1621

bromocriptine
- for acromegaly 742
- for prolactinoma 740
- with extremely high prolactin levels 740
brachyogenic cancer
- metastatic to brain 802
- non-small-cell 803
- small-cell 802
brachyoscopy, from contrast media reaction 223
brown tumor of hyperparathyroidism 1373
Brown-Séquard syndrome 947
- from cervical disc herniation 1414
- from spinal cord herniation 1150, 1408
- in cervical spondylosis 1086
- in radiation myelopathy 1563
- with spinal cord tumor 790
Brudzinski sign 318, 1158
bruit
- carotid
- asymptomatic 1271
- with carotid dissection 1325
- cranial
- with AVM 1239
- with carotid-cavernous malformation 1257
- with dural AVM 1252
- spinal, with spinal AVM 1141
Brun syndrome 373
Burns-Garland syndrome 545
BSEER, see brainstem auditory evoked responses
buffalo hump (in Cushing's syndrome) 724
bulbar-cerebellar dissociation 944, 963
bulbocavernous reflex 943
bullet velocity, see ballistics
bundles of Probst 260
buprenorphine 142
burner (football injury) 936
burning hands syndrome 937
- differential diagnosis 1421
burst holes
- for chronic subdural 900
- for trauma (emergency) 836
Frazier 1450, 1452, 1513
burst fractures
- cervical 998
- CI 971
- subaxial 989
- thoracicolumbar 1003
- treatment 1006
burst suppression
- and pontobulbaral levels 876
- definition 238
- during aneurysm surgery 1203
- with eutomade 1203
butyrophanol 142
butterfly glioma 618
butterfly vertebra 216
- in lipomyelomeningocele 269
- transarticular facet screws 1479–1480
Cl-2 puncture 1511
C1-palsy, post-op 1092
C7 lateral mass screw 1486
C7 transfacet screw 1486
cablegeline
- dosing forms 740
- for prolactinoma 740
eachexa, pitiuary 719
caecum, as pain medication adjuvant 143
calcidiol 1010
calcifediol 1010
calcification
- basal ganglia 1381
- choroid plexus 1380
- in stroke 1281
- intracranial (diagnostic) 1380
- subarachnoid hemorrhata 914
- pineal 1380
calcitonin
- for fibrous dysplasia 781
- for odontoid fracture 979
- for osteoporosis 1010
- for Paget's disease 1122
calcitriol 1010
calcium, for osteoporosis 1010
calcium channel blockers, for vasospasm 1165
callosotomy 1464
calories, see ocalulostibal reflex
Calve-Kummen-Verneuil disease 1392
Camylobacter jejuni in Guillain-Barré 185
Canavan's disease 1404
candelabra effect 311
candalal meningitis, treatment 320
 candidiasis
- infections in CNS 1376
- shunt infections 339
- candle guttering
- on myelography in arachnoiditis 1041
- with tuberculous sclerosis 607
capillary telangiectasia 1246
capping (on myelography) 818
capsaicin
- for diabetic neuropathy 496
- for diabetic diabetic neuropathy 545
- for postherpetic neuralgia 496
- for trigeminal neuralgia 482
carcinomatous meningitis 811
carriers of McConnell 79
capsule (disc space), definition 1024
caput medusae 1245
- carbachol 449
- as cause of myelomeningocele 290
- as cause of SIADH 111
- dosing forms 450
- for deafferentation pain 137
- for trigeminal neuralgia 481–482
Carbamazepine 449
carbon dioxide
- and cerebrovascualar vasodilatation 872
- and hyperventilation for ICP control 872
- and laparoscopic surgery 427
carbon monoxide
- and basal ganglion abnormalities 1386
- and leukoencephalopathy 1371
- and secondary parkinsonism 177
- encephalopathy 208
- toxicity 208
carbonic anhydrase inhibitors, see acetazolamide
carinoembryonic antigen 601
carcinoid syndrome 654
carbogeline
- during angiography 1275
- for a-com a. 1161
- for angiography 1257
- Mehringer-Hieshman maneuver 1257
- to treat dural AVMs 1253
carotid dissection, see internal carotid artery - dissection
carotid endarterectomy 1290–1291
- and intracerebral hemorrhage 1296, 1332
- complications 1292
- emergency 1295
- indications 1290
- post-op check 1292
- technique 1294
- vs.angioplasty/stenting 1297
- carotid ring 1214
- carotid sinus syncope 1396
cardiac stenting (for stenosis), see angioplasty - stenting
- carotid stenting (for stenosis), see angioplasty - stenting
- carotid tubercle 1521
- carotid-cavernous fistula 979
- with carotid stenosis 1271
- with extreme high prolactin levels 601
carcinoid syndrome 654
cardiogenic brain embolism 1304
- risk on withholding anticoagulation 1341
carnitine, see BUN 1257
carotid angioplasty/stenting 1297
- carotid artery, see internal carotid artery
- aneurysms, see aneurysm - carotid
- bruit
- with carotid dissection 1325
- with carotid stenosis 1271
- injury, grading 850
- plaque morphology 1271
- stenosis
- angiographic criteria 1272
- asymptomatic 1275
- carotid body tumor 653
- carotid cavernous fistula, endovascular treatment 1592
- carotid compression
- Alcock test 1216
- during angiography
- for a-com a. 1161
- for angiography 1257
- Mehringer-Hieshman maneuver 1257
- to treat dural AVMs 1253
carotid dissection, see internal carotid artery - dissection
carotid endarterectomy 1290–1291
- and intracerebral hemorrhage 1296, 1332
- complications 1292
- emergency 1295
- indications 1290
- post-op check 1292
- technique 1294
- vs. angioplasty/stenting 1297
- carotid ring 1214
- carotid sinus syncope 1396
- carotid stenosis (for stenosis), see angioplasty - stenting
- carotid tubercle 1521
- carotid-cavernous fistula 1256, 1258
- following percutaneous trigeminal rhizotomy 485
- from ruptured cavernous carotid aneurysm 1226
- carotid-vertebrobasilar anastomoses 83
- carotidynia 201, 1324
carpal tunnel, release 524
carpal tunnel syndrome, management of 523
carpal tunnel syndrome 519
- acute 520
- electrodiagnostic findings 521
- surgery for 524
- CASANOVA study 1277, 1290
- CAT scan 227
- cisternography for CSF fistula 387
- definitions 227
- following myelogram 236
- following pituitary tumor removal 753
- following tumor removal 596
- for head trauma
- findings 832
- follow-up 833
